The general healthfulness of Southern California has been alluded to in the account of Los Angeles (vol. iv.), and a table printed on pages 10 and 11 of Dr. Orme's pamphlet, which shows the prevalence at each of twenty-four towns of the diseases occurring throughout this region in the year 1884–85, reveals the fact that San Diego compared very favorably with any of the other points specified. For phthisical invalids it is probably not quite so suitable a winter residence as are Pasadena and other inland points. *Huntington Richards.*

SAN FRANCISCO. The chart on next page, obtained from the Chief Signal Office, at Washington, represents the climatic conditions prevailing at the city of San Francisco, Cal. (For a detailed explanation of the chart and suggestions as to the best method of using it, see article Climate, vol. ii., pp. 189–191.)

Whatever may be the advantages of the winter climate at San Francisco when compared with that found at places of corresponding latitude in the eastern and central portions of the United States, it is very much less mild than that found at points lying further south in the same State, and particularly at such as lie to the south of the Tehachipi and Santa Ynez mountain ranges, in what is known as Southern California. As for the summer climate, it is by very common consent pronounced to be exceptionally disagreeable; and is by no means suited to the benefit of invalids affected with any form of pulmonary disease.

The situation of San Francisco, at the mouth of a gap through which the cool air lying over the surface of the Pacific is sucked up to supply the place of the heated air radiated from the great inland basin comprising the Sacramento and San Joaquin Valleys, is the cause of its peculiar, and to most persons very disagreeable, summer climate. The hotter it is at this season in the interior, the colder and more windy will it be in San Francisco, a fact which is well corroborated by the data in the accompanying chart. The windiness of the summer season, as compared with other parts of the year, is plainly to be seen in the data of Column S. The direction of the prevailing wind at this season, the high relative humidity of July, August, and September, the low absolute and average daily maxima, and the small mean daily range of July and August as compared with those of June and

Climate of San Francisco, Cal.—Latitude 37° 48′, *Longitude* 122° 26′.—*Period of Observations, March* 8, 1871, *to December* 31, 1883.—*Elevation of Place of Observation above the Sea-level,* 13 *feet.*

September, all point in the same direction, and receive their full explanation in the following passages, which are taken from Blodget's "Climatology of the United States," and are quoted by the author of that work from the writings of Dr. Gibbons, of San Francisco. The first of these passages discusses the increase in the force and frequency of the sea-winds during the summer season.

"Whatever may be the direction of the wind in the forenoon in the spring, summer, and autumn months, it almost invariably works around to the west in the afternoon. So constant is this phenomenon that in the seven months from April to October, inclusive, there were but three days on which it failed to do so, and these were rainy. The sea-winds are moderate until May, when they begin to give trouble. In June they increase in force, reaching their greatest violence at the beginning of July. In August they decline in force, but not in constancy; in September they continue steady, though moderate; and in October they lose their annoying qualities, and become gentle and agreeable."

What these "annoying qualities" are will appear from the second passage quoted from Dr. Gibbons, wherein he describes the course of a summer day at San Francisco:

"The sun shines forth with genial warmth, the mercury rising generally from 50° at sunrise, to 60° or 65° at noon; but when the sun has reached the zenith the wind rapidly increases, coming down in gusts from the hills which separate the city from the ocean,* and often bringing with it clouds of mist. But the dampness is never sufficient to prevent the elevation of clouds of sand and dust which sport through the streets in the most lively manner. The mercury falls suddenly, and long before sunset fixes itself within a few degrees of 50°, where it remains pertinaciously till next morning, often not moving a hair's breadth for twelve hours. . The mist often increases toward evening, and when the wind falls remains all night in the shape of a heavy fog. Sometimes, when the sun has been shining brightly, the mist comes in from the ocean in one great wave and suddenly submerges the landscape. In short, there is no conceivable admixture of wind, dust,† cloud, fog, and sunshine that is not constantly on hand during the summer at San Francisco."

This fog, we are told by Mr. Blodget, does not blow in from the sea, but is formed on the spot by contact of the cold sea-air with the naturally warmer land-air. The sea-breeze in summer is a more or less cold breeze, he tells us, all the way down the coast as far as the extremity of the peninsula of Lower California, at Cape St. Lucas; but at San Francisco its coldness is most marked, because the indraught of air at that point is vastly stronger than elsewhere, for reasons which will be found fully explained in his work, and which have been already briefly referred to in this article.

San Rafael, a town of some three thousand inhabitants (population in 1880, 2,276) lying twelve miles north of San Francisco, about three miles from the shore of San Pablo Bay (a subdivision of the great gulf comprising San Francisco, San Pablo, and Suisun Bays, which is entered through the Golden Gate), is a place much better sheltered from the direct influence of the sea-winds than is San Francisco, and on this account possesses a much more agreeable climate. "The scenery about San Rafael and in the approaches to it is extremely fine . . and the air is pure and bracing, and, though hardly warm enough for consumptives in advanced stages of the disease, is admirably adapted for

* Blodget's Climatology was published in 1857. Dr. Gibbons's meteorological observations at San Francisco covered the period of sixteen months, from December, 1850, through March, 1852.

† The dust is less troublesome now than at the time when this account was written, more than thirty years ago, the streets of the city being kept carefully watered.

such as are in the preliminary stages, and only need a dry and tonic climate inviting to an out-door life" (Appleton's "Handbook of Winter Resorts," 1886-87). The hills which lie close about San Rafael on its western aspect, that is, on the side toward the ocean, are quite high (1,500 feet according to a writer in the New York *Daily Graphic* of January 22, 1885), and, moreover, the distance in a direct line to the sea-coast is, in a southwesterly direction ten miles, in a westerly direction twenty miles. I have no data to illustrate the superiority of San Rafael over San Francisco in point of climate. Monterey, a small town lying directly upon the Pacific coast, at the southern extremity of the Bay of Monterey, and at a distance of about one hundred miles from San Francisco in a SSE. direction, has acquired some reputation during late years as a pleasure and health-resort, and a large hotel has been built there by the Southern Pacific Railway. Through the kindness of Dr. C. B. Currier, of San Francisco, I received, some two years ago, a printed table showing the absolute monthly maximum and minimum temperatures, the mean daily temperature, and the total rainfall for each of the fifty-four months, July, 1880, to December, 1884, inclusive. The observations of which these data are the record were taken at the hotel just mentioned; the hours of observation I do not know.

* Observations of five years. For the other months the observations covered only four years.

From this table, sent by Dr. Currier, I have deduced by calculation the data standing in columns AA, T, V, and O of the chart herewith presented; the figures in the remaining columns (B, E, and F) are copied directly from the table, but are differently arranged. The columns of this chart may be compared with corresponding columns of the San Francisco chart (and of other Signal Office charts), but in doing so the reader should bear in mind that the period of observations at Monterey was a very short one, the hours of observation perhaps different from those adopted by the Signal Service, and the method of taking maximum and minimum observations unknown to me. A careful study of the chart not only shows that Monterey possesses a mild winter and a cool summer climate, but also reveals facts which bear out the observations made by Mr. Blodget, to the effect that the peculiarity already noticed in the summer climate of San Francisco exists also at other points upon the coast, but that it is very much less marked at places lying to the south of San Francisco than it is at San Francisco itself. Columns T and V by no means correspond to columns C and D of the Signal Office charts; the former give the average of *monthly*, the latter of *daily*, maxima and minima.

Huntington Richards.

SANICLE, Codex Med., *Sanicula europæa* Linn., order *Umbelliferæ.* A small European perennial with palmate or reniform, five-lobed leaves, unisexual flowers, and ovoid spiny fruits. It contains tannin, bitter extractive, and resin. Sanicle is a household herb of Europe, and used both internally and externally in numerous conditions. It probably has no value. *W. P. Bolles.*

SANITARY INSPECTION, PRINCIPLES OF. This is a comprehensive subject, as it relates to inquiries into all influences affecting or tending to affect injuriously the health of a locality. It involves a knowledge of the importance of perfect purity and cleanliness of air, water, food, and soil as the fundamental and paramount conditions of health, and seeks to discover and guard against or counteract those influences which are liable to render impure these essentials to the maintenance of healthy life. It is through this important public service that the local health authority is kept informed of those conditions which tend to endanger the health of the inhabitants, and that knowledge is obtained with regard to the sanitary state of the people, and the preventable causes of sickness and death, which forms the basis of all intelligent and efficient sanitary legislation and administration.

Sanitary inspection is not restricted in its objects simply to the collection of information which is indispensable to the application of the provisions of the public health laws; it also includes the execution of the provisions of such laws whenever the circumstances of the case may justify and require it. An executive service is the natural and necessary complement of an inspection service, inasmuch as the purpose of the latter, in detecting all such influences as are injurious to the public health, is to suggest and make possible the proper steps for their removal.

The causes of disease with which public hygiene is concerned, such as affect the mode of life of masses of population, operate through a great variety of channels, and their discovery and removal require the exercise of knowledge affecting the various conditions under which people live, whether in the city, town, or hamlet. Such knowledge relates to the natural and acquired features of the locality, its meteorological peculiarities, and the social and sanitary state of its population; the character of the soil, ground-water, wells, and springs; the water-supply; plans of drainage and sewerage; the distribution of buildings and of open spaces, whether paved or unpaved; the sanitary arrangements of houses, especially those of the poorer classes; the management of burial-grounds and the arrangements for the burial of the dead; the nature of manufacturing and other industrial establishments; the housing of the poor, and the facilities afforded for bathing, washing, etc.; the conduct of slaughter-houses and all establishments where food-supplies are prepared; the examination of foods with respect to their wholesomeness; the sanitary inspection of schools and school children; the regulations for cleansing the public ways and markets, and for the removal and disposal of domestic and trade refuse; the examination of persons and houses with the object of restricting or suppressing contagious or infectious diseases of local origin, and of vessels and passenger-trains in order to prevent the introduction of such diseases from without.

While the intelligent exercise of the functions of the sanitary inspector requires a familiarity with these various subjects, a high degree of efficiency is more surely attained by a division of labor according to special branches of inquiry, a plan which yields the advantages of more matured experience and greater precision of knowledge. Besides the ordinary nuisance inspectors and inspectors of quarantine, it is becoming more and more customary to appoint officers fitted for particular lines of work by special education and training. In order to prevent the sale of adulterated and unwholesome foods and drugs, it is necessary to have officers who, in addition to other qualifications, shall possess a knowledge of chemical analysis and microscopical examination. The sanitary inspection of school buildings and the supervision of the health of the children are wisely entrusted to men who have had a medical training. The sanitary supervision of house-drainage and plumbing required under the laws recently established in many American cities, imposes upon the local health boards the duty of employing experts skilled in the technics of this art. The examination of immigrants and travellers, with the object of preventing the introduction and spread of dangerous communicable diseases, is another special branch of sanitary inspection which none but a medical officer is qualified to conduct.

Qualifications of Sanitary Inspectors.—Efficient sanitary inspection depends primarily upon an adequate knowledge of the various subjects relating to hygiene and public health, and the officers employed in it should be fitted for the work by special and sufficient education. As many of these subjects relate to diseases, their causes, mode of propagation, and the means of their suppression, a medical knowledge becomes an essential qualification of at least a portion of the force employed as sanitary inspectors by a board of health. Under the English health laws the officer of health, whose duties are largely those of an inspecting officer, must be qualified by law to practise medicine or surgery, though such qualification is not made necessary in the case of inspectors of nuisances.

Intelligent sanitary inspection rests upon a knowledge of the following subjects:

1. The principles of chemistry, particularly with regard to the methods of analysis (including microscopical investigation). Such knowledge is indispensable in forming accurate judgment as to impurities of air and water, injurious impregnations of the soil, harmful admixtures in food, and also in the proper use of disinfectants. An acquaintance with chemical physics, including the chief phenomena of light, heat, and electricity, is also advantageous.

2. Natural philosophy, which should embrace a thorough knowledge of the principles of pneumatics, hydrostatics, and hydraulics, with special reference to ventilation, water-supply, drainage, construction of dwellings, and sanitary engineering in general. The laws of natural philosophy will be of great aid in tracing nuisances, in determining questions of ventilation and of overcrowding, and in studying atmospheric changes; and, in conjunction with chemistry, will be of the greatest service in the investigation of industries and trades alleged to be prejudicial to health, and in devising measures for the abatement of the evils associated with them.

3. A knowledge of the laws relating to public health.

4. The sanitary construction and arrangements of dwellings, including soil, structure, materials, internal decoration, lighting, ventilation and warming, water-supply, house and soil drainage, and disposal of refuse.

5. A knowledge of the effects of overcrowding, vitiated air, impure water, bad or insufficient food, unhealthy occupations, and of the diseases they produce; the character of nuisances injurious to health, the disposal of sewage, and the effects of soil, season, and climate upon the health of localities.

6. A knowledge of the causes, propagation, and prevention of contagious and infectious diseases. In addition to a familiarity with the above subjects, there should be the further qualifications of methodical and industrious habits, competent powers of observation, sound judgment, and conscientiousness in the investigation and statement of facts.

It may be objected that the qualifications outlined above are too comprehensive, and that the knowledge deemed essential for the performance of the duties of sanitary inspector is such as should only be required of a professional expert. But it should be remembered that sanitary inspection is pre-eminently the service by which information is obtained of the numerous and various conditions which operate against the health of a locality, and constitutes a large and important part of the work of sanitary government. In order to recognize and intelligently investigate these conditions, and advise as to the means of their amelioration or removal, a comprehensive knowledge of the principles and laws of science involved in their consideration is indispensable. Efficient sanitary inspection requires skilled or expert labor, which can only be secured by special knowledge and experience.

Sanitary Survey.—A systematic sanitary survey of a locality is the true basis of measures for its sanitary improvement. Such a survey embraces an investigation of the natural and artificial or acquired conditions affecting the health of the inhabitants in the district.

The natural conditions affecting the health of a district comprise the geological and topographical characteristics of the locality, the climate, water-supply, etc. The causes of many of the most common diseases arise from conditions connected with the earth's surface and underlying structure, as well as with the soil polluted by the act of man. The influence exerted upon human health by the drainage of a locality, by the moisture in the soil, the ground-water, and telluric emanations, has long been recognized, but the exact effects of these conditions cannot be rightly understood without a knowledge of the physical characteristics of the soil, studied in their relations to the records of diseases in their geographical distribution and local history. These two series of facts, studied side by side, lead to the interpretation of the laws governing the relations of the earth's features to health and disease. Detailed and exact records of the configuration of the earth's surface and its underlying structure, illustrated so far as possible by means of maps and diagrams, form the basis of correct knowledge of sanitary geography and local hygienic history. It is only by the aid of these facts that the health of a town or district and the records of prevalent diseases can receive their proper explanation.

The influences of climatic conditions upon health are also to be investigated in connection with the natural local conditions. The daily temperature and rainfall, the force and direction of the wind, the barometric pressure, degree of humidity, etc., should be subjects of careful observation and record. In many places these data can now be obtained from the Signal Service Bureau of the Government. In districts where such observations are not recorded, arrangements should be made for obtaining the necessary information. The meteorological fluctuations exert a powerful influence on health and disease, and though they are beyond the control of man, a knowledge of their effects will be most useful in the investigation of other local conditions more amenable to human effort, and in assigning to them their proper share of hurtful influence.

The quantity and quality of the water-supply of a district depend mainly on its geographical and topographical characteristics, which must be studied in their relations to this important fact. The quality of water is necessarily affected by the character of the soil through which it flows and by the surface upon which it is collected. A water may become so thoroughly impregnated with mineral or vegetable matters contained in the soil, or with organic matter upon its surface, as to be unfit for domestic use. A wholesome water may become polluted by the transmission of impurities through the porous structure of the ground. In locating wells the physical characteristics of the soil should be taken into consideration with reference to the risks of pollution of the supply.

Soil moisture and the state of the ground-water play an important rôle in the causation of disease. These natural characteristics of the soil depend on certain combinations of geological and topographical structure, which must be investigated in every locality before improvements necessary to secure healthfulness can be intelligently undertaken. Before drying and aerating the soil one must have a knowledge of its natural drainage and physical conditions. No plans of artificial drainage or of sewerage can be satisfactorily accomplished without a thorough comprehension of the natural drainage system of the district.

The acquired conditions affecting health relate to the habitations of the population, the water-supply, the drainage and sewerage, removal of refuse matters, public ways and places, gas and lighting, slaughter-houses and abattoirs, markets, food-supplies, manufactures and trades, public school buildings, hospitals and public charities, police and prisons, fire establishments, cemeteries and burial, the arrest of contagious and infectious diseases, etc. A series of questions upon these and other subjects relating to municipal sanitation have been framed by the National Board of Health to serve as a guide in making a systematic sanitary survey of a district, and their practical use is exemplified by surveys taken of several cities and detailed in the reports of that Board for the year 1879, to which reference should be made. The annual volumes of the American Public Health Association also contain valuable information upon the same subject.

Sanitary Inspection of Habitations.—The health authority should, so far as practicable, have a full knowledge of the general sanitary condition of every house in the district which it controls. The acquisition of such information is of necessity a laborious undertaking, requiring painstaking and systematic search, and a considerable outlay of money; but when the record of facts is once completed its benefits will be continuous. A brief description of every house, showing the structure of the building, the facilities for ventilation, the drainage arrangements, its connection with the sewer, the nature of the water-supply, the conditions of the soil, health of occupants, number and causes of deaths that have occurred in it, and other pertinent information, should form a permanent record, and this record should be kept up by recording any changes noted upon subsequent examination. The complete sanitary history of every locality thus obtained will be useful for reference, and will serve as a guide to the discovery of unhealthy premises and the causes of their insanitary conditions, and lead to the employment of measures of improvement. By reference to the records the condition of each house at once becomes known, and the effort to determine the exciting cause of any disease therein existing will be greatly facilitated.

It is the right of everyone proposing to buy or rent a house to have a knowledge of its sanitary history. Such information is generally obtained with the greatest difficulty, because no sanitary survey has ever been made. With this as a basis the local sanitary authority ought to be able, for a small fee, to furnish to anyone proposing to occupy a house a copy of the health history of the house, certified from the records.

The tabulated forms to be used for a sanitary inspection of houses will vary slightly according as the district is urban or rural. The form presented below is a modification of the schedule of questions proposed and used by the National Board of Health, and differs in several respects from that given in the next article. The headings should be printed in tabular form, on paper of convenient size and shape, arranged in the style of a tablet.

Sanitary Inspection of Houses and Premises.

3. Area of lot......; of house......; of out-houses......
4. Site of house, wet or dry......
5. Age of house......; material......; number of stories......
6. Number of living-rooms......; of sleeping-rooms......
7. Cellars and basement.....
8. Sinks, drains, and cesspools......
9. Privies or water-closets, location and condition......
10. Yards......
11. Hogs or other animals......; fowls......; number......; where kept......
12. Public nuisances on or near premises......
13. Number of families in house......; names of heads of families ......; number of persons in each family, specifying number of whites and blacks......; total number of occupants......
14. Sickness now in house......; what diseases......
15. Sickness during past year......; what diseases......; number of cases .....
16. Deaths during past year..... ; what diseases......
17. Persons vaccinated......; persons not vaccinated......
18. Water-supply, whence derived, sources of contamination......
19. Sanitary needs and estimated cost......
20. Additional observations......

.... Certified as correct,

........................,
Inspector.

Upon the other side of the blank may be printed directions for the guidance of the inspector.

Directions: 1 and 2. Give the exact and full name of the owner and occupier of the premises. Give the street and number, and describe the location so that it cannot be mistaken.
3. Give dimensions of sheds, privies, stables, etc., with their relations to living-rooms.
4. State whether site is above, below, or upon same level as adjoining land. Conditions of the soil, whether damp, wet, or dry or "made-ground."
6. Note how ventilation is secured.
7. Examine cellars very carefully, and describe their condition, particularly with regard to dampness, amount and kind of filth, ventilation, drains, etc. State whether used for living purposes.
8. Is there any offensive smell from the sinks? Are the drains water-tight, clogged, or uncovered? Are there any traps to prevent drain-air from coming into the rooms? Are there sewer-connections, intercepting-trap, soil-pipe ventilation? Are the cesspools tightly covered, clean, and ventilated? Do the cesspools leak into the cellar or into the well?
9. Privies and vaults. Describe their condition particularly. Are they full, foul, leaky, or overflowing? Are they shallow or deep, water-tight or leaking, connected with the sewer, trapped, ventilated, etc.?
10. Describe the kind and amount of all heaps of filth about the premises, and the general condition of the yard, area, etc.
12. Public nuisances, as sewers, badly paved and drained streets, gutters, etc., stables, manufactories.
13. Note overcrowding and social condition of the inmates.
14, 15, 16, and 17. Inquire particularly.
18. State whether, in addition to the supply from the public water mains, water is used from a well or cistern; whether it is called good or bad; whether any filth probably drains into the well.
19. State what is necessary to be done to remove nuisances, and improve the sanitary condition of the premises, and the approximate cost of such improvements.

The duty of collecting information upon the subjects embraced in a sanitary inspection should be performed with great discretion, so that, while nothing necessary to be known shall escape observation, the service shall not excite opposition by its obtrusiveness and unnecessarily inquisitorial character. It must be remembered that in most cases these examinations can only be carried out by the sufferance of the people; but by tact and politeness it is possible in nearly all instances to obtain all the information desired.

Upon the completion of a general house-to-house inspection, the returns—containing a record of sanitary facts—should be tabulated, paged, indexed, and grouped by wards or districts in such a manner as to make instant reference to the original inspection of every house and locality possible. From these data sanitary ward-maps may be compiled, indicating by color the special insanitary features of a district; as, for example, insufficient or defective drainage, polluted or suspicious water-supply, unhealthy habitations, public nuisances, centres of excessive mortality, prevalence of epidemic disease, etc., these subjects being so arranged that ready reference can be made to the original records of inspection for a full description and sanitary history of any house or locality.

The frequency with which a systematic inspection of a district should be made must necessarily vary according to the extent and character of the district and other circumstances. It would be a useless task and a waste of time and money to inspect localities containing the best residences and a population of the better class, as frequently as streets and houses in poor neighborhoods, particularly such districts as are notoriously unhealthy. The latter, of course, will require most vigilant watching. At the same time, no part of a town, however favorable its sanitary reputation, should be exempt from

periodical visits, as it is only by universal and rigid scrutiny that a full record of facts favorable or otherwise to the public health can be satisfactorily obtained. Whenever made, these inspections should be thorough and systematic, so that the data secured shall represent the actual state of every part of the district.

Sanitary Inspection of the Water-supply.—An abundant supply of wholesome water is an essential to the health and comfort of man. An insufficient quantity leads to impurities of all kinds, and an impure quality is a frequent cause of disease. Experience has taught us that a community will be unhealthy in proportion as the supply of water is scanty and the quality bad, other things, of course, being equal. In providing a supply, it is to be presumed that the water commissioners have given due consideration to the quality of the water, the quantity required, and the risks of pollution, both as regards the source of supply and the mode of distribution. But this fact does not relieve the health authorities from the duty of vigilant inspection of the source, storage, and distribution of the water used for domestic purposes, in order to discover any permanent, temporary, or accidental cause of contamination. It is pertinent to such an inquiry to ascertain all facts connected with the source from which the supply is derived. If from a river or stream, whether the drainage from towns, villages, and factories, or other polluting matters flow into it above the point at which the water is taken; whether the gathering grounds are cultivated lands, enriched with night-soil or other excrement, and whether the territory from which the water is drained is sufficiently populated to seriously affect the quality of the latter; whether the supply is ample for general and domestic purposes, and is distributed to every house; whether impurities of storage are carefully guarded against, and the processes of filtration and purification are successfully conducted; whether the channels of distribution are protected from all risk of pollution, and whether the supply is always constant and the pressure in the mains sufficiently strong to insure delivery at the top of the house, if necessary, and also to prevent regurgitation.

These and other questions relating to the character of the supply should not be overlooked, but the services of the sanitary inspector will be more constantly required in searching for the sources of pollution to which water may be exposed after it has been brought into the town and into the houses. It will be necessary to inquire into the situation, construction, and condition of cisterns and tanks, the means of separation of cisterns used for domestic supply from those supplying water for the closets, the situation of the overflow-pipes, and the relation between the service-pipes and the water-closets, the object being the prevention of any influx of foul air or foul matter into the service-pipes, and the consequent contamination of the supply.

The color, taste, and smell of water will generally indicate the presence of impurity, but if this evidence is not satisfactory, more exact information should be obtained by chemical analysis. The inspector should not be required to make such an analysis, but he can carefully procure samples of the water to be submitted to a chemist who is expert in this branch of investigation.

In rural districts and in towns where the supply is collected or obtained on the premises, it is important that the state of every well and other source of water used by the inhabitants should be fully known. Rain-water stored in cisterns and well-water are liable to contamination from many sources. If the collecting surface is defiled, impurities will be washed into the cistern by the first fall of rain. Rain-water collected in the neighborhood of inhabited places is liable to contain gaseous and solid impurities washed from the air. Inspection should be made, from time to time, of the interior of cisterns, in order to see that impurities are not collecting, that no leaks exist, and that the overflow-pipes are properly arranged. A leaky condition of a cistern may lead to contamination of the water by influx of deleterious matter from the soil, aided by a favorable state of the surface of the ground. Rain-water may take up lead from the lining of the cistern and from lead pipes, and zinc from zinc roofs.

The situation and construction of wells, with reference to their liability to contamination from surface washings, oozings from drains or cesspools, and other sources of filth, will require the most careful investigation. Whenever cesspools or drains, whether open or closed, or accumulations of filth, are near a well and the soil about it is wet and filth-sodden, there will be a presumption of contamination. When suspicions arise, samples of the water should be taken for examination. Under certain circumstances, however, the evidence may be such as to warrant the closing, cleansing, or repairing of wells without resort to proof of impurity by chemical examination. When well-water is used it is advisable to inquire into the condition of the soil, which more or less influences the quality of the ground-water from which shallow wells are supplied. In districts where the soil is made use of as a reservoir for excremental matters deposited in cesspools and privy-vaults, or is exposed to defilement by leakage from disjointed or broken drains, badly constructed sewers, or leaky gas mains, or where filth is stored upon the surface of the ground, the entire water-bearing stratum in time becomes polluted, and the water of wells is rendered impure. On this account surface and shallow-well waters in thickly populated places are always to be regarded with the greatest suspicion. Shallow wells, even in rural districts, are often horribly polluted by sewage, and by animal matters of the most disgusting origin.

Public drinking-fountains should not escape notice, as they are sometimes improperly arranged, as, for example, in connection with drinking-troughs for horses. Cisterns for the public supply of ice-water may be permitted to become unclean by the accumulation of deposits, or the water may be rendered unwholesome by the injudicious use of impure ice.

Public baths should be kept under strict sanitary supervision. Not only should the supply of water be maintained in a fresh condition, but the regulations prescribing the proper use of the baths should be rigorously enforced.

Sanitary Inspection of Drainage and Sewerage.—The drainage and sewerage of a town bear important relations to the public health, and therefore properly come under the notice of the sanitary inspector. Nuisances arising from insufficient surface drainage, from dampness of the sites of habitations, and from badly planned and managed sewerage-works, frequently engage the attention of the health officials. It may not devolve upon these officers to suggest special schemes for the construction and improvement of public works, but it is a part of their duties to notice gross defects so far as they tend to exert an injurious influence upon the public health, and to urge the adoption of means for their remedy.

It may be necessary in some localities to have a system of deep drainage to facilitate the movement of the ground-water, and thus make both air and ground drier. A moist soil exerts an injurious influence upon health, it having been shown upon reliable evidence to be favorable to the production of lung diseases, rheumatic and catarrhal affections, and to be connected in some way with the development of typhoid fever and cholera. The drainage of swamps, areas of made-land, and places saturated with water, near or in inhabited districts, will be followed by the best results to the public health.

Surface drainage should be free and unobstructed, so as to promptly carry off the greatest amount of rainfall, and prevent the overflow of cellars or the intrusion of soil-water.

Nuisances are often caused by the disposal of slop-waters upon the surface of the ground or by wayside channels. Slop-waters or house-waters are in fact a condensed form of sewage, as they contain not only the cooking-water and water used for washing the person, clothing, and house, but almost invariably some portion of urine. Such matter is not fit to be discharged over the surface of the ground, as it must of necessity become offensive and cause a nuisance by decomposition and

soakage into the soil. If it cannot be disposed of upon the premises, it must be carried from the house in pipes to a proper outfall.

Sooner or later, every town must be provided with a system of sewers to prevent the collection of filth in and about habitations and frequented places, and to protect the air and soil from pollution. While aiming to carry out this object, the sewers themselves must not be permitted to become reservoirs of filth, which, by stagnation and decomposition, may give rise to a nuisance only less offensive and dangerous than that which it is intended to prevent. It is essential that sewers shall be well constructed and permit of a rapid, continuous, and complete flow of the sewage to the outfall without leakage by the way. They should allow no deposit to take place, and should be thoroughly ventilated. With these conditions maintained, it is scarcely possible for a sewer to become offensive or in any way dangerous to the public health. Ventilation may be effected by having numerous openings into the streets, protected by gratings, and by leaving the sewer-inlets untrapped. In this way a free interchange between the sewer-air and the atmosphere is secured. The openings will relieve pressure upon the house-drains, and if these latter should be left unguarded the danger from the admission of sewer-air will be greatly diminished by the free dilution of the latter with atmospheric air.

The escape of evil odors from untrapped sewer-inlets is not a valid objection to the disuse of the trap, but rather an indication that the sewer does not properly perform its mission, which should lead to the remedy of the fault and not to its concealment. With the conditions giving rise to the nuisance unremedied, it is far safer to permit the escape of sewer-air upon the streets than to subject the inhabitants of houses having connection with the sewer to risk by closing the manholes and using traps upon the inlets, and thus increasing pressure and preventing the diluting effect of the outside air.

Extrinsic flushing will be required when the force of the current of sewage is not sufficient to produce a scouring effect. The cleansing and disinfection of sewers are occasionally required to improve their condition, but at best they are only temporary expedients. Sewers which accumulate deposits and are commonly foul, and which constantly require cleaning out and disinfection, are radically wrong in construction and should be reconstructed without delay.

When sewers are properly constructed and managed and have free ventilation, the air which they contain differs but slightly from the outside air; but as these conditions cannot always be insured, it is a wise plan to have the house-drain disconnected from the sewer by means of an efficient trap, and the system of house-pipes thoroughly ventilated. The disposal of sewage should take place without causing a nuisance in relation either to air or to water. This is a subject of serious consideration in the planning and management of the outfalls of sewers. The sewage of a town should never be discharged into a stream at or near a point from which the water-supply is obtained, or which, from its small volume of water, is incapable of diluting the liquid refuse sufficiently to prevent serious pollution, without first undergoing a proper degree of purification. Purification of sewer-water may be effected by precipitation at the outfall by chemical agents, by irrigation, and by intermittent filtration. If properly managed, any one of these methods may be applied with satisfactory results.

In small towns and villages it may not be practicable to provide a general system of sewers, and hence the disposal of refuse matters, such as excreta and house-waters, must be effected by other methods. As the choice of these plans is more or less directly under the control of the householder, being only exceptionally restricted by local regulations, a variety of methods will be encountered in every locality, including even the large cities. For the disposal of excreta the cesspool or privy-vault, or some one of the dry methods, is resorted to; but the house-slops are not so readily gotten rid of. In towns the open gutter is commonly used for this object, while in villages and in the country the slops are thrown upon the ground. These plans for disposing of refuse matters are everywhere among the chief sources of nuisances, and will constantly claim the attention of the inspector.

Privies of the accumulative sort, with their respective soakings and exhalations, whereby air, soil, and water are polluted, are a very common means of spreading some of the most fatal of diseases, of which typhoid fever may be taken as a type. The utmost watchfulness should be exercised to reduce these nuisances, which exist in all populous places throughout the country, to the lowest degree of dangerousness. Privy-pits and cesspools, if at all permitted, should be made to conform to the most stringent regulations both as to their construction and management. They should not be located too near the house or the water-well; they should be constructed of unabsorbent materials, and should be perfectly water-tight, so as to prevent the leakage of filth into the soil, building, or water; they should be of small capacity, so as to preclude the accumulation of matter, and they should be regularly and methodically cleaned at short intervals, so as not to allow the putrefaction of excrement. Their use should not be permitted for anything but excreta.

To meet sanitary requirements, improved systems have been devised to take the place of the filthy storage-pits, so universally condemned. These are principally the pail-system and the so-called dry systems. The simple pail-system, much used in England, but not yet systematically adopted in the United States, consists in the removal of excremental matter at short intervals, before it has become offensive. As a means to this end, movable receptacles are used which systematically, at short intervals, are to be changed, clean for the dirty, by the scavenger; and which, in order to prevent offence in this process, are provided with tight-fitting lids to be applied to the foul pails under removal. The excrement is removed daily without admixture, except with the ordinary kitchen refuse, and is transported outside the town.

The dry system is adapted to towns and villages and to single cottages. It consists in the admixture of dried earth, coal ashes, or other dried refuse, with the excrement in sufficient quantity to absorb and reduce it to an inodorous form. All slops and sink-water and other extraneous matter must be carefully excluded. The receptacles should be made of impervious materials, and the closet should be located either out-of-doors, or in an isolated part of the building, or in an apartment projecting from the house, where the necessary ventilation can be secured. The dry systems form a convenient, economical, and efficient substitute for water-closets where the latter cannot be made use of, but they must be vigilantly superintended, and in some cases actually managed by the local authority.

It is essential that privies of all kinds, particularly those located in poor neighborhoods, shall be under constant supervision, in order to prevent the violation of the laws and regulations pertaining to their construction and management. But this supervision should not be confined to the privy contrivances and the methods of their cleansing, but should also extend to the ultimate disposal of the matter, which is a most important part of the management of refuse removal.

Nuisances incident to the improper disposal of liquid house-wastes are of frequent occurrence. In towns and villages, the house-slops are either thrown upon the ground near the house, where they are partly absorbed and in time load the soil with impurities; or they are carried away in open or in closed channels to some distant part of the premises, where they gradually soak into the ground; or they are discharged into the roadside or street-gutter, causing a nuisance of a most offensive character. Sometimes the entire sewage of the house is collected in cesspools provided with porous walls, with the object of allowing the fluid parts to drain away, the solid matter being removed only after long accumulation. In the absence of sewers, these nuisances may be avoided by providing tight cesspools with sufficient capacity for one or two days' collection, from which the sewage may

be distributed to the land near by through pipes under the surface of the ground. This is the plan of subirrigation, which is very convenient for the disposal of the sewage of separate houses or groups of houses, where land is available.

Subsurface irrigation may be used for the disposal of slops alone, or for slops mixed with the efflux of water-closets. It is necessary, however, to provide a means for intercepting all solid and fatty matters, which should not be discharged into the drain-tiles, as they would in time clog up the pipes and render the system inoperative. Solid excrement may be disposed of in a cleanly and inodorous manner by the use of the earth-closet, only the slop-water being allowed to flow away in the subsoil drains.

The success of this plan depends on the property of the soil of destroying organic matter, by the aid of the oxygen contained in its pores, and, to some extent, upon the action of the rootlets of grass and plants. The supply must be intermittent, and in order to secure this action a flush-tank is provided, which automatically discharges its contents through all the ramifications of the drain-tiles. When water-closet wastes are disposed of at the same time, an intercepting chamber should be placed between the house and the tank to collect the solid matter, which should be removed at frequent intervals and applied to the land.

The occupants of rural premises will generally be able to satisfactorily dispose of their own refuse matters upon their own premises, without any detriment to themselves or to their neighbors. But when human beings are gathered together on small areas, the disposal of refuse cannot be secured without method. The obligation to designate the correct system of disposal and to supervise its management, so that no avoidable nuisance shall be created, rests upon the sanitary authority.

Frequent inspections will be required in order to prevent nuisances from arising through neglect in the disposal of dry house-refuse, such as ashes, dust, and garbage, and through improper disposal of trade-refuse and the refuse of domestic animals. Provision must be made for the frequent and regular removal of these matters, and, at the same time, regulations must be enforced which shall prescribe that house-refuse, while awaiting removal, shall be so cared for and managed as not to cause a nuisance on the premises. Every facility should be afforded the householder for promptly getting rid of his refuse, so that no excuse can be offered for the accumulation of offensive matters upon his premises.

Faults in house-drainage and plumbing are a frequent and formidable danger to the public health. Until within recent years, this fact has been very imperfectly recognized by architects and builders, and by the public generally, and too much trust has been placed in artisans, who have been permitted to proceed in their work without any carefully wrought plan or expert supervision, and also without their qualifications first having been thoroughly ascertained. As a result of various deficiencies, and prominently that of neglect of competent sanitary supervision, it frequently happens that the evils a modern system of house-drainage is intended to avert, are made worse by careless planning and execution of the drainage arrangements within the dwelling. Owing to the absence of skilled guidance, and frequently through want of conscientious execution, defects in house-drainage of the most flagrant character are constantly encountered, even in the better class of houses. But a greater familiarity on the part of the public with the correct principles of house-drainage, and supervision of the work by boards of health, will tend to lessen abuses, which are responsible for a large quantity of preventable disease. In many places laws regulating house-drainage have been enacted, and entrusted for their execution to the local sanitary authority. Under these laws, rules and regulations are prescribed for the registration of plumbers and for the guidance of artisans in drawing their plans and specifications. In large cities the plans, when approved, are executed under the supervision of trained officers especially appointed for the purpose; but in small towns the work of supervision may be advantageously combined with the duties of general sanitary inspector. The laws and regulations in force in Boston, New York, Philadelphia, and Washington may be cited as examples of the methods adopted for conducting this important branch of house sanitation. The object of these laws is to place the drainage arrangements of houses under skilled surveillance, so that their planning, construction, and management shall conform to standard principles.

The essential conditions of house-drainage are: That the receptacles shall be constructed of such material and in such manner as to be impervious to fluids, and easily permit of cleansing and of being kept clean in all their parts. That the pipes and drains shall be of sound and durable material, and so constructed and laid as to be gas-tight throughout, and to secure a continuous and complete removal of whatever enters them without leakage by the way, or without the formation of deposits or incrustations. That the system shall be so planned and arranged that neither the air of the house nor the drinking-water can in any wise be polluted by the escape into the house of air from the sewer or from the drain. Upon these fundamental principles are based the rules and regulations governing the technics of construction, which should be formulated for the guidance of the architect, builder, and artisan. The law should require that the plans and specifications of the drainage arrangements of every proposed dwelling, and of old houses undergoing alterations, should be submitted for approval to a competent official or board of experts, and that the essential details of such plans should be carried out under skilled supervision. The effect of such a requirement would be to avoid errors in design and construction in new buildings, and to gradually improve the drainage arrangements of old structures.

As the best systems of house-drainage are liable to derangement which may escape the notice of the householder, provision should also be made for the periodical inspection of the drainage-works of every dwelling, in order to guard the occupants against the evil consequences of deficiencies of which they may have no knowledge.

In many places no systematic regulation and supervision of house-drainage is ever attempted, the authorities having to depend for knowledge of existing defects upon complaints made in special cases, upon the results of investigation of the localized causes of disease, or upon discoveries made during a casual house-inspection. This information relates to a small number of the actual defects, the greater number escaping detection in the absence of methodical inquiry. Where no such laws exist, the sanitary authorities may do much toward effecting a reform in the present objectionable methods by adopting and promulgating regulations similar to those in force in the cities already mentioned, for public information, for the instruction of their inspectors, and to serve as a guide in all work which they are called upon to perform. Thousands of houses are annually built in a manner dangerous to the health of the occupants, because the builders are ignorant of the conditions to be observed to make them healthy, and they fall into the errors which might have been avoided had they the knowledge of the correct principles of construction, or had the authorities required their application.

Sanitary Inspection of Public Ways and Places.—The sanitary importance of thorough cleanliness of public ways and places cannot be over-estimated. The deposit and retention of refuse matters upon the surface of streets may give rise to dangerous pollution of air and soil. This is apparent when the composition of the filth of badly-kept streets is inquired into. In addition to the inorganic detritus of the road, it consists of the dung and urine of horses, and sometimes of other animals, of vegetable matter from trees, of refuse from houses—kitchen garbage and house-slops—containing animal and vegetable matter, and, in poor neighborhoods, there is sometimes an admixture of human excrement, both solid and liquid. This mixture of animal and vegetable substances, when converted into dust, fills the atmosphere

with disgusting particles, or when wetted by rain and exposed to heat, soon decomposes and develops effluvia which must be detrimental to health, especially in crowded and ill-ventilated localities. Unless the pavement is composed of impervious materials, liquid matters upon its surface will penetrate into and pollute the soil. These results are due to imperfect drainage, to a bad system of scavenging and refuse-removal, and very materially to badly constructed pavements.

Surface cleansing cannot be made efficient without the provision of suitable pavements—such as will prevent the retention of filth and its imbibition by the soil. It is especially important that this provision should be extended to all small streets, courts, and alleyways, and to the surface areas in all crowded and badly ventilated places, as in such localities the open spaces are likely to be used as common depositories for all kinds of refuse matter, including human excrement.

The construction of public roadways and the conservancy of the surface area of towns are commonly entrusted to a commission or board of public works, but the delegation of these powers to a co-ordinate branch of government does not relieve the sanitary authorities of the duty of closely scrutinizing the work, and noting deficiencies which tend to injure the public health, and of urging the proper remedies.

Under certain circumstances the application of disinfectants to the street surface and gutters will be required, but this precaution will rarely be necessary when proper care is exercised in the construction and cleansing of the pavements. The utmost care will be required in preventing public urinals from becoming nuisances of an offensive character. These conveniences should be washed out daily, and otherwise carefully managed under the vigilant eye of an inspector.

The relation of gas and lighting to the public health is a subject demanding careful investigation. Adequate lighting of the public streets and places is not only essential to public convenience and order, but is a means of restraining the perpetrating of nuisances which are apt to be committed under the protection of darkness. Gas should be maintained of a specific illuminating power and purity. Impurities in gas not only diminish its illuminating power, but tend to injure health by deteriorating the air in the rooms where it is used. The escape of gas from defective joints, or from flaws in the street pipes, has often been attended with disastrous results. The escaping gas may pass through the foundations of houses and poison the air within. This accident is not uncommon in the winter season, when the air in the ground surrounding the house is apt to be drawn into the basement by the aspirating power of the heated air within the building. Gas may also prove injurious by fouling the water of wells. Another danger is from explosion in sewers, and in cellars and cesspools connected with sewers by drains, the gas escaping into the sewers and thence being conveyed upon private premises through badly constructed house-drains and untrapped inlets.

The location of gas-works, with respect to the influence on the health of the neighborhood of vapors escaping during the process of gas-production, and also with respect to the manner of disposal of refuse matters from gas-working, will occasionally require a careful investigation.

The sale of illuminating oils should be restricted to such qualities as are known to be free from explosiveness. The law should make provision for ascertaining the grade of petroleum exposed for sale, and should prohibit the sale of this article at retail when its "flashing-point" is below 100° F. The routine work of testing oils and burning fluids is properly delegated to special officers, but the sanitary government should interest itself in procuring the adoption of laws which will avert accidents and prevent the loss of life.

Sanitary Inspection of Slaughter-houses and Abattoirs.—By mismanagement slaughter-houses may become a nuisance to the neighborhood, or their condition may be such as to affect the wholesomeness of the meat prepared for the market. Wherever located these establishments will always require careful supervision, as from the nature of the business nuisances are readily created by putrescent effluvia, or by filthy soakage or outflow. Particular attention should be directed to the location and construction of the buildings, to the means of water-supply, drainage, and ventilation, to the provision of suitable receptacles for the refuse and its prompt removal, to the means of preventing filthy soakage of liquid refuse within or about the buildings, and to the maintenance of cleanliness throughout the establishment and in every process of the business. By-laws prescribing rules embodying these essential points should be adopted, and their observance enforced by vigilant inspection.

Slaughtering is most commonly done in private establishments, which are seldom constructed, equipped, or managed in strict conformity to sanitary principles. Many of these establishments are extemporized out of buildings constructed for other purposes, and are totally unsuited for the slaughtering of cattle. As they are generally located in densely populated parts of the town, their deficiencies and mismanagement have the widest scope for exerting a pernicious influence. By placing these establishments under the control of the board of health, and requiring a permit to engage in the business, conditioned upon proper location and construction of buildings and good management, a great reform can be effected in a business which is too often conducted in a slovenly manner, to the detriment of the public health.

The concentration of the business of slaughtering cattle in well-appointed and well-conducted public slaughter-houses, or abattoirs, where abundant water, good drainage, thorough ventilation, ample means of cleanliness, and perfect facilities for the work are provided, and where every branch of the business is conducted under constant official observation, is strongly to be advised, as a measure highly advantageous in its economic and hygienic results. The adoption of this practice is gradually being extended as its benefits become understood and appreciated.

The fact that typhoid fever, scarlet fever, and some other diseases have been spread through the agency of milk, makes it imperative that cow-houses, dairies, and milk dépôts should be managed under the provisions of salutary laws and systematically inspected, in order to insure the enforcement of such provisions.

Sanitary Inspection of Markets.—All markets should be placed under the control of the sanitary government. The construction and management of the buildings should be such as to insure ample light, free ventilation, perfect drainage, prompt removal of refuse matters, and thorough cleanliness. Supervision should also be extended to the immediate neighborhood, including the streets and passage-ways, with the view of preventing any avoidable nuisance. The provision of smooth and impervious pavements is necessary, in order to facilitate cleansing and prevent the retention and imbibition of filth.

Sanitary Inspection of Food Supplies.—The supervision of the food supplies of the people is one of the most important obligations of a municipality. While the price and the quality, in a measure, must be left to the ordinary operations of trade, the law must take cognizance of and prevent adulterations, and the manufacture and sale of any articles intended for human consumption that are injurious to health. In order to effect this object the law should clearly define the offence of adulteration in all its various forms, and also designate the kind of food which is unwholesome and the circumstances which render it so, and direct the course to be pursued in condemning, and withdrawing from the market, and disposing of, any diseased, or unsound, or unwholesome food, or food unfit for the use of man. It should also embrace provisions for its own thorough and complete execution.

The organization necessary for carrying into effect such regulations, as well as many other important measures connected with the preservation of the public health, already exists in many States in the form of a State board of health. Vesting such authority in a central board

should not abrogate nor conflict with the regulations of local boards for the inspection of food-supplies, such as meat, fish, game, vegetables, and other perishable articles which require daily supervision; but, on the contrary, would furnish a means of co-operation in effecting a common purpose.

While the main object of legislation against adulteration is the protection of the public health, it yields a further advantage by its economic results. This fact is prominently displayed under the operations of the Massachusetts food-inspection law. Of articles liable to adulteration, such as milk, butter, spices, vinegar, cream of tartar, and some drugs, consumed in that State in 1884, of the value of $15,000,000, five per cent., or $750,000 were saved to consumers through the services of inspectors of food.

Most European countries are well provided with laws, both general and municipal, for regulating the manufacture and sale of articles of food, but, beyond enacting a law prohibiting the importation of damaged and adulterated tea, and regulating the sale of oleomargarine, the United States Government has done little to insure the purity of food. Most of the States have statutes relating to special articles of food, some of which have a purely commercial object, while others are intended for the protection of the public health. Massachusetts, New York, and New Jersey have recently adopted stringent measures for the prevention of the sophistication of food and drugs, which have already been productive of good results. These laws have been ingrafted upon those of the State boards of health. One of their objects is the protection of trade by preventing falsifications which may or may not be injurious to health; but the vital purpose is to take cognizance of adulterations which are deleterious, and to prevent the sale of such articles of food.

Violations of the law are detected by the employment of inspectors and analysts, and its provisions enforced by notification and warnings, or by prosecution and penalties, and in some cases by the confiscation of condemned articles. The same officer may act in the dual capacity of inspector and analyst.

In order to promote the objects of food-inspection public test-offices, properly equipped with all necessary appliances, should be opened for the examination of all articles submitted by the inspectors, and also by the people. Such an office has been established in Paris, where all articles of food, beverages, etc., are analyzed and tested by experts, who also perform the duties of inspectors of markets and among the tradesmen. For a nominal sum, and in some cases gratuitously, anyone can ascertain the composition of any suspected article of food. Articles of domestic use, clothing, colored toys, wall-papers, etc., are also examined in order to detect any poisonous ingredients that may be present.

Adulteration has been practised in a great variety of foods, beverages, and drugs; but the practice is commonly restricted to a limited number of articles. The principal articles liable to adulteration are milk, butter, cheese, spices, vinegar, sugar, ground coffee, tea, oils for consumption, cream of tartar, spirits, and various sorts of drugs, and to these special attention should be directed.

The examination of meats, fruits, and vegetables, and other perishable articles, should be made with great frequency, as the stock is ever changing.

Animals should be examined immediately before killing, and again before the meat is exposed for sale. The concentration of the business of slaughtering in public slaughter-houses or abattoirs will make efficient inspection practicable.

In order to facilitate the labors of the inspector, the law should describe the kind of food which is unwholesome, or the circumstances which render it so; but with the best care as to details, much will have to be left to the discretion of the officer who makes the examination. Study and practice will enable him to successfully discriminate in most cases coming under his observation. Occasionally it will be necessary to refer suspicious articles to the public analyst for the application of chemical or microscopical tests.

It is the practice, in the city of London, to condemn the flesh of animals infected with certain parasites, as *trichina* in pork, the *cysticerci* in pork, beef, and mutton, and *flukes*, which infest the livers of animals; and of animals suffering from fever or acute inflammatory diseases, as rinderpest, pleuro-pneumonia, and the fever of parturition; and of animals wasted by lingering sickness, such as phthisis; and of animals which have died from accident or from natural causes; and also all meat that is tainted with physic, or that is sufficiently decomposed to be discolored or have a putrid smell.

The flesh of animals which have been exhausted, excited, or tortured before death, has frequently proved to be unwholesome.

Sausages are liable to become poisonous on account of a modified putrefaction which occurs in this variety of food when kept for a length of time. The poisonous effects have generally been traced to sausages which are mouldy and soft in the interior, and which emit a strong-smelling odor. Other kinds of animal food, when in a decayed or mouldy condition, may occasionally produce similar results.

Fish, poultry, and game must be examined for signs of decomposition.

Fruit and vegetables must be objected to mainly on account of advanced decomposition. Mouldy food of all kinds is dangerous, and should be condemned.

The testing of canned goods for poisonous substances, and the examination of milk, butter, cheese, coffee, tea, sugar, cocoa, flour, bread, vinegar, drugs, etc., is mostly work to be performed in the laboratory, the duty of the inspector being chiefly confined to procuring samples of suspected articles for analysis.

The officers selected for the responsible service of food-inspection should possess special attainments and undoubted honesty, and in order to secure proficiency they should be required to devote their entire time and energies to the work.

Sanitary Inspection of Manufactures and Trades.—Noxious or offensive trades and manufactures require supervision in order to protect the health of employees and prevent the processes from becoming a nuisance, or injurious to the health both of the work-people and the public generally. The law should not only make it imperative that the ordinary conditions of health shall be observed; it should go a step further, and restrict labor at certain ages, and regulate the hours of work.

The workshops should be well lighted, thoroughly ventilated, and, when necessary, provision should be made for the prompt removal of dust-particles. The speedy removal of deleterious refuse matters and the observance of extreme cleanliness should be enjoined, and all overcrowding prevented.

Trades which produce offensive effluvia, dust, or acrid vapors, are apt to cause nuisances which are injurious to health, or which may simply annoy or inconvenience the public. Nuisances of the latter description are subjects for action at common law. When the public health is imperilled the sanitary authorities are bound to interfere.

The workers at certain trades are liable to suffer in their health from the inhalation of solid or gaseous substances produced by the processes, unless efficient safeguards are provided. The dust in cotton and woollen mills, metallic vapors, filings and grindings, and solid particles of various kinds, when inhaled, are highly injurious. Certain gases and fumes and fetid substances also have an injurious effect, if breathed in confined apartments.

The public also are to be protected from annoyance and from injury to health resulting from the improper conduct of dangerous, noxious, or offensive trades. The businesses apt to create nuisances are very numerous, as will be seen by a reference to the classification adopted by the French Government in 1866, which may be profitably consulted. It is not expected that the inspector shall be familiar with all the details of the various trades therein specified, but he should have a general knowledge of the sources and effects of the offensive effluvia and outflow produced by certain well-known processes of

manufacture, so that when complaint is made he will be able to intelligently investigate these offences and suggest the best means for their remedy. To perform this oftentimes perplexing duty it is necessary that the inspector shall possess good powers of observation, a thorough acquaintance with practical chemistry, and familiarity and experimental knowledge with regard to the uses of various mechanical contrivances and the modes of testing their efficiency. It is only by close personal observation and careful investigation that reliable information can be obtained upon which to base the suggestions of remedies. Suggestions should not be made without extreme caution, and in no case unless there is a strong probability of a successful result. In some few special cases it may be necessary to employ the services of an expert who has greater familiarity with the questions at issue.

With proper precautions, offensive trades and manufactures can be conducted without causing a nuisance. Whenever advantageous and practicable, foul refuse matters should be utilized; but if this cannot be done, other means should be employed for their disposal without causing a nuisance by contaminating either air, soil, or water. Foul matters awaiting disposal should be stored in closed tanks or receptacles. Suitable receptacles with tightly-fitting covers should also be used for removing such matters. Dangerous or offensive gases or vapors should be intercepted and rendered harmless and inoffensive by the use of proper condensers, or scrubbers, or of absorbents, or by combustion in the furnace-fires. A combination of these various means may often be advantageously adopted. All offensive processes, such as fat-rendering, bone-boiling, etc., should be conducted in steam-tight tanks, and the vapors given off should be passed through condensers, and such fetid matters as may not be removed should be consumed in the furnace-fires.

The inspection of mines, and the storage and sale of explosive and poisonous substances, etc., are generally regulated by State laws, and do not require the special attention of the sanitary inspector.

Sanitary Inspection of Public Schools.—The sanitary supervision of schools is an essential part of the administration of every well-ordered system of public education. The object of such supervision is the protection and preservation of the health of the children by securing proper sanitary arrangements of the school buildings, the observance of the laws of health, the enforcement of regulations for the prevention of the spread of contagious or infectious diseases, and by practical instruction in the plain rules of hygiene.

The surroundings in which the child passes the first years of its life should conduce to its healthy development and not impede it, as is so often the case in a large number of our schools. The aim of modern education should be to foster the physical as well as the intellectual and moral development of the child, not only for the advantages of health itself, but also for the sake of establishing a sound physical basis, without which true progress in the culture of the intellect is impeded or prevented.

When the State assumes the responsibility of educating the children, it also obligates itself to carefully guard their health, both physical and mental. This obligation is due to the public who entrust the care and training of their children to others during a large portion of their lives. The State should not be content simply to "hold physical childhood unharmed while mental childhood is getting its schooling;" it should strive to promote physical health and vigor as an indispensable accompaniment to intellectual training, in order to make public education an important measure of public economy as well as a powerful moral agency.

As a means of promoting these objects, the aid of sanitary and medical science must be invoked in the adaptation of the school buildings for healthful occupancy, in supervising the hygiene of the premises and the hygienic care of the children, in preventing the spread of contagious or infectious diseases, in regulating the programme of studies, and in imparting practical notions of hygiene and sanitary law.

The selection of the site, the construction, heating, lighting, ventilation, water-supply, and drainage of the school buildings, and the details of arrangement and management of the buildings and appurtenances, must be in conformity with the principles of sanitary science. The arrangement and adaptation of light and of the school desks and seats, according to the requirements of hygiene and the special needs of the children, are most important considerations. Mental application should be carefully proportioned to the capacity of the child; it should be neither too taxing nor too prolonged, and should be alternated with recesses and physical exercise in the fresh air.

The best-constructed buildings may be rendered unhealthy, and the most perfect sanitary appliances and arrangements may become inoperative, by the neglect of those in charge. Hence it is necessary that the sanitary supervision of the buildings and appurtenances shall be entrusted to qualified officers, who shall be responsible for everything pertaining to the hygienic management of the institutions.

Sanitary supervision is an effectual means of preventing the spread of contagious diseases in, and by means of, schools. The medical inspector, aided by the teachers (who should be instructed how to recognize the premonitory symptoms of contagious diseases), will take advantage of early information of the appearance of suspicious symptoms in any child, by sending the child home at once for his further observation, and treatment if necessary. If the disease be infectious, any other children in the family, though well, must not be permitted to attend school until the cure is complete and all danger from infection has passed.

No child should be allowed to enter the public schools who has not been vaccinated. The medical inspector should determine the evidence of satisfactory vaccination.

A close observation of the children will enable the inspector to determine whether any injury to health is liable to happen, by reason of constitutional disease or weakness, from the course of study or discipline, and advise such modification as the case may require. Children predisposed to consumption, scrofula, lymphatic disease, anæmia, etc., should be the objects of the greatest solicitude of both teacher and physician while under their care.

Besides the provision of favorable surroundings, fresh air, light, proper temperature, etc., special attention should be given to the personal hygiene of the children, to their clothing, proper cleanliness, exercise, and the regulation of studies, so as not to overtax and fatigue the organs of the child.

The medical inspector should have a ready faculty for teaching, as his position will enable him to speak with authority and effect, and to utilize the many opportunities afforded for instructing the children in the elementary principles of hygiene, by means of examples coming under their own personal observation. He should describe to them the dangers from the use of alcoholic drinks and tobacco, the ill effects of want of ventilation and uncleanliness, the reasons for isolating infectious diseases and for the practice of vaccination, the improper use of clothing, either too warm or too thin, the effects of improper attitudes, the causes of near-sightedness, etc. Occasional instruction of this kind will be most serviceable in impressing the lessons in hygiene which should form a part of the regular course of instruction, and in diffusing throughout the community a knowledge of sanitary laws.

Systematic records should be kept, with the use of suitable blanks, of the results of medical inspection, which should be summarized and presented, with deductions and recommendations, monthly or oftener, if necessary, to the board of health or the body having sanitary jurisdiction over the schools, and to the superintendent of public instruction. These blanks will provide for a complete descriptive list, including medical observations

of each pupil who enters the school, upon which list entries may be made from time to time, at least once in each year. There should also be kept a record of diseases, accidents, and indisposition occurring at school during the month, with particular notice of cases of contagious diseases, and statistical information with regard to the premises, embracing notes on the cleanliness of rooms, school furniture, heating and ventilation, thermometric records, lighting, condition of water-closets, urinals, yards, dressing-rooms, etc. Reports should also be made of sanitation and hygienic improvements proposed, and of the matters of personal hygiene which have been the subjects of familiar instruction.

A most complete system of medical inspection of public schools was inaugurated in the city of Brussels, Belgium, in 1874, and has been in successful operation ever since. The thirty-three public schools of that city are subject to regular medical inspection, performed by five medical officers, who devote their whole time to this work. They have the entire sanitary supervision of the schools and buildings, and the watchcare over the health of the children, and, under special circumstances, the treatment of cases of sickness.

The service includes within its scope a consideration of faults in construction, heating, ventilation, lighting, size of class-rooms, seats, desks, windows, etc.; the temperature and daily condition of the air and the causes tending to vitiate it; physical exercise, swimming lessons, and instructive excursions; the care of the eyes, ears, teeth, skin, and body; accurate records of conditions of health determined by physical examination, and the adaptation of studies and discipline to the capacity of the child; careful training of children under the normal standard of health, and measures for preventing the spread of contagious or infectious diseases, including vaccination and revaccination; and proper sanitary instruction, so that the schools shall be the means of diffusing among the people a knowledge of the laws of health.

Sanitary Inspection of Hospitals and Public Charities.—The government of hospitals and public charities is generally entrusted to boards of directors, variously constituted, which are responsible for its proper administration. Efficient sanitary management is a primary consideration, and in securing this object valuable aid is derived from the counsel of the medical officers, who, by education and special facilities for observation, know best the wants, the necessities, and the failings of the institutions with which they are connected, and are therefore competent to speak with authoritative advice on questions pertaining to their sanitation.

Independent of these provisions for responsible government, the State or local authority should have the assurance of the faithful and efficient administration of its delegated powers which periodical investigations will afford, and, among other things, should take cognizance of the sanitary condition of these institutions, either through the State or local health boards, according as they fall under the jurisdiction of the one or the other.

Sanitary inspections should be made periodically, and the results recorded for future reference and use. The primary surveys will necessarily embrace a large number of inquiries, many of which, if satisfactorily answered, need not be made again; the subsequent inspections being confined to conditions liable to variation, and which depend on various contingencies. Much of the information required, such as details of construction, cubic air-space, plans of drainage, ventilation and heating, statistical data, etc., will be available from reliable records preserved by the institutions, so that the inquiries will be directed more especially to the adaptation of the buildings to their uses, the efficiency of the sanitary arrangements, the salubrity of locality, the sanitary condition and management of the buildings and premises, and the management of contagious diseases.

The special points to be inquired into are: The location, nature of the soil, area of grounds, drainage arrangements, materials of construction of buildings, number of stories, floor plans, number and size of wards, floor-room per bed in wards, cubic space per bed, mode of heating and ventilation, position of water-closets, urinals, etc., and their ventilation, provisions against fire, fire-escapes, amount and quality of food, water-supply, overcrowding, prevalence of hospital zymotic diseases, as erysipelas, pyæmia, etc., contagious diseases and their management, disinfection, presence of endemic influence, hygiene of the buildings and premises, and rules, regulations, and statistics on sanitary subjects.

The results of inspection should be recorded in proper form for use in furthering the ultimate objects of the investigation.

Sanitary Inspection of Police and Prisons.—Oversight in all matters of concern to health in these departments should be exercised by the proper sanitary authorities. The station-houses of the police department will require occasional inspection, in order to insure the application of necessary hygienic measures. The buildings should be expressly adapted to their uses, and all necessary appointments should be made for the health and comfort of the officers, and for the decency, convenience, and cleanliness of the prisoners. The air-space per head for the average occupancy of the cells should conform to a standard. Special attention should be given to the ventilation, heating, privy arrangements, and cleanliness of the cells, and also to the facilities for personal cleanliness.

Arrangements should be made for prompt surgical and medical attendance, at all hours, upon cases of injury or sickness, and for the immediate examination of suspected cases of contagious or infectious diseases brought in from the street, so that persons suffering from dangerous communicable diseases may be transferred to the proper hospital, and the cleansing, disinfection, and fumigation of the apartments executed with despatch.

An ambulance system in connection with the police department, for conveying the sick and injured to hospital should be organized and conducted under medical supervision. The regular and systematic instruction of the police force in the manner of rendering first aid to the sick and wounded is a humane requirement, which should be carried out under competent medical direction.

The sanitary inspection of prisons should be carried out upon the general plan suggested for hospitals and public charities. Special attention should be directed to the cubic air-space per head of occupancy of the cells, to the ventilation, heating, and privy arrangements of the apartments, to the cleanliness of the prisoners, and to the means at hand for checking the spread of contagious diseases. Every well-ordered prison should have an isolated building or apartment for the treatment of these diseases, to which all cases at their inception should be removed, if they cannot be at once transferred to the town hospital for contagious or infectious diseases.

The medical inspection of houses of prostitution, in aid of the suppression of one of the worst forms of human disease, must be conducted under the provisions of special laws upon the subject.

Sanitary Inspection of Fire Establishments.—Fire establishments should be included among the institutions subjected to sanitary supervision. The hygienic condition of the premises, water-closet accommodations, facilities for bathing, and the manner of berthing and subsisting of the men are the chief points of inquiry.

Medical attendance should be provided for the sick and disabled. Suitable apparatus for the rescue of life endangered by fire should be distributed over the town, and be under the immediate control of the fire or police department. The inquiry should also be extended to the provisions made for the erection of fire-escapes, and for the inspection of illuminating oils, and the storage of explosives.

Sanitary Inspection of Cemeteries and Burial.—The disposal of the dead without injury to the living is a question of the greatest interest to a community. Cremation, a process by which bodies can be rapidly, completely, and inoffensively disposed of, solves the problem to the satisfaction of hygienic laws, but the

practice is in its incipiency. The common mode of burial by interment requires the strictest sanitary regulation. The location of burial-grounds should be determined only after the most careful inquiry into the sanitary features of the question, and a full consideration of the future, as well as the present, needs of the community. Intramural interment, being in conflict with the laws of health, should be interdicted.

In locating cemeteries the site, character of the soil, facilities for drainage, direction of the ground-water, and distance from inhabited places are prominent considerations. The site should be elevated, so as to afford good ventilation and ample drainage; and it should be well planted with shrubs and trees, in order that the roots may absorb and utilize the products of decomposition. The soil should be dry, and the ground-water never permitted to rise into the graves or vaults. When necessary, artificial drainage should be employed to prevent the accumulation of water in the soil. The drainage should not be allowed to flow into any water-course from which drinking-water is obtained; nor should the flow of the ground-water be toward inhabited places which depend on wells for their water-supply. When there is a choice, a loose, marly soil should be selected, as it permits of the free movement of air and water, conditions which are essential to speedy decomposition. Gravelly soils are not so good, but they are preferable to stiff clays, which tend to retard the process of decay.

The decomposition of bodies takes place by putrefaction with the evolution of effluvia. The products of decomposition are arrested or changed by the earth. Under certain conditions the volatile substances generated by putrefaction may escape into the air, and hence the air over graveyards is liable to contamination. Saponification may take place when the earth about bodies is dense, and becomes saturated with the products of decomposition.

The time required for the decay of bodies varies according to the nature of the soil, the access of air, pressure, etc. Ordinarily, in a loose, marly soil the process may be completed in three or four years, but in other soils of a less favorable character it may be very slow, thirty or more years being required for effecting a complete disintegration. Before interfering with an old graveyard a sufficient time should be allowed to elapse, after the discontinuance of all interments, to insure the complete destruction of the remains. Deep burial is to be preferred, and not more than one body should be placed in a single grave. The earth should come in contact with the coffin, in order to hasten decomposition. The use of strong outer cases is objectionable, as it prolongs the process of decay.

The vicinity of cemeteries is not considered salubrious, owing to the danger of contamination of the air and water, and the escape of effluvia from frequent disturbance of the soil saturated with the products of putrefaction. Most foreign governments prescribe the least distance allowable between graveyards and dwellings; but in the United States there is no general regulation on the subject. Under ordinary circumstances the distance should be at least five hundred feet.

It is customary among the poor to keep the bodies of their deceased friends for days in the same room in which the family live and sleep. Such a practice cannot be otherwise than detrimental to health. In order to avoid the necessity for such detention, mortuaries should be provided in every city and town, where, in these cases, all corpses could be removed at a reasonable time after death has taken place. Burial should not be delayed for more than three or four days, and in hot weather and in all cases of infectious disease the interment should promptly take place. Another advantage of mortuaries is the means they afford of lessening the expenses of the funeral, a point of great significance to those in humble life.

No interment should be permitted without a permit from the board of health, issued over a certificate of death from an authorized person; nor should any grave be disturbed, nor any body be removed into or out of any place, without official authorization.

Special care is required in the management of the bodies of those who have died of contagious or infectious diseases. In such cases public funerals should be absolutely prohibited, and the interment should take place without needless delay.

Vigilant inspection is essential to the efficient administration of the laws and regulations pertaining to cemeteries and burial. This duty may be imposed upon the sanitary inspector, or an officer specially appointed by the board of health, which body should have the power to make rules for the proper disposal of the dead.

Sanitary Inspection in Cases of Contagious or Infectious Diseases.—The prompt notification of cases of dangerous communicable disease is a duty generally imposed by law upon the medical attendant, and its neglect is made punishable by fine. The object of notification is to secure the advantages of prompt investigation of the origin and causes of diseases liable to become epidemic, the discovery of the means by which they are spread, and the application of measures of prevention.

In all cases in which the disease can be spread, either directly or indirectly, from one person to another, the isolation of the patient and the disinfection or destruction of the infectious material are of primary importance. Isolation may be accomplished by removing the sick at the earliest possible moment from the house, or, in some cases, by the removal of the well, if accomplished at the outbreak of the disease. In order to carry out the former object it is necessary to have hospitals exclusively for the treatment of these cases, and special conveyances for the transportation of the patients. In crowded houses the removal of the sick is the only possible way of checking the spread of the disease, and therefore every town should have the means of isolation.

The arrest of the spread of the disease is further to be attempted by thorough ventilation and cleanliness of the sick-room, the prompt disinfection of excreta, the disinfection of bedding, clothing, and all articles in the sick-room before their removal, and, after the recovery or death of the patient, the disinfection of the clothing, rooms, house, cesspool, etc. Disinfecting chambers should be provided by the town authorities for the immediate purification, by heat or other means, of all soiled clothing, bedding, and other infected articles that cannot be properly treated at home.

Small-pox is prevented by vaccination. Some diseases, such as typhoid fever and scarlet fever, may be propagated by the agency of contaminated water, or milk, or other food. Epidemics have originated in this way. The origin of the disease is therefore to be inquired into, in order that measures may be intelligently employed for checking its spread.

During the prevalence of an epidemic unusual measures may be required for the public safety, such as house-to-house inspection for detecting concealed cases of disease and insuring their proper management, the placarding of houses of the sick for preventing intercourse with them, the speedy interment of the dead, the purification of houses and premises by the public disinfector, the erection of temporary hospitals, and the publication of information for the use of the people in dealing with the emergency. The prompt recognition of the first cases of disease is of the greatest importance, as upon it will often depend the possibility of preventing its spread.

Maritime and Inland Quarantine Inspection.—For the object of preventing the introduction of contagious or pestilential diseases from one country to another, quarantine stations have been established at the ports of all civilized nations, where vessels infected or suspected of infection are subjected to sanitary inspection, in order to determine whether such vessels shall be admitted to free pratique or be detained for observation, disinfection, and the application of necessary prophylactic measures. For the same purpose the restriction of intercourse by land with places infected with dangerous communicable diseases is sometimes a necessity. Absolute isolation, or suspension of all communication with the infected place, is impracticable and unnecessary, since the risk of introducing disease from infected places can

be greatly diminished, if not prevented, without stopping or retarding to any considerable extent commercial intercourse, by establishing a system of sanitary inspection of passenger trains, boats, and vehicles conveying persons or goods from such places. In foreign countries the inspection service is conducted by the national government. In this country, in the absence of a national health bureau, it would be best to have such a service organized under the State boards of health, and practised on the frontier, on the lines of travel from the seaboard to the West, and in the vicinity of the infected locality. By concerted action between the State authorities, and with the co-operation of the National Government, the means necessary for restricting or suppressing epidemic disease can be most effectually carried out. Such action would be a guarantee of protection to the public health, which would prevent panic and demoralization, and disastrous obstructions of commerce and the stoppage of trade and travel.

The efforts made to protect the Mississippi Valley against yellow fever, and the West and Northwest against small-pox, by a system of sanitary inspection maintained by the National Government, and carried out along the lines of travel without embarrassing commerce or travel, have been attended with the best results, and prove the value of this service. The stream of immigration which pours into the great Northwest direct from the seaports of the country has made advisable, during the prevalence of dangerous infectious diseases at the ports of embarkation, the establishment of inspection stations at the railway centres along the lines of travel, for the examination of immigrants who may have developed the infection after leaving the seaboard, and for the inspection of baggage and the vaccination of the unprotected.

The inspectors employed for this duty should derive their authority from the National or State Governments, and, in order to facilitate their labors, they should seek the co-operation of local boards of health and of the railway and transportation officers. Provision should be made for the isolation, care, and treatment of the sick, and for the detention and isolation of suspected cases; for the ready use of disinfectants, the cleansing and disinfection of cars and boats, and for the disinfection of the clothing and baggage of the passengers. If the disease is small-pox, all unprotected persons who have been exposed to the contagion should be vaccinated; if they refuse to be vaccinated, they should be turned back, unless exempted for good or sufficient reason. The examination should include all parts of each vessel and train, and each passenger and all baggage, etc.

It is important to know the place from which the passengers have come, and the destination of any persons suspected of conveying or harboring a dangerous communicable disease. All bedding, wearing apparel, or other articles liable to contain infection, arriving from suspected places, should be unpacked and disinfected before being allowed to proceed. When practicable, special provision should be made for the disinfection of clothing in cars while on the route.

The sanitary condition of the cars should be inquired into, and the quality of the drinking-water and the ice used in it closely scrutinized. If from any cause it is unsatisfactory, the fact should be noted, and steps taken for its immediate improvement. The inspecting officers should make frequent reports to the authorities under which they act, and should communicate to local and State health-boards any facts coming within their knowledge which may be of advantage in preserving the public health. Publicity should be given to the objects and requirements of the service, in order to enlist co-operation and prevent needless attempts to evade the law.

The sanitary inspector, in whatever line of duty employed, should form the habit of taking accurate notes of the particulars of his examinations, and of the action taken in each case. These notes will form the basis of more permanent records, and of reports which he will be required to make, from time to time, to the sanitary authorities. The notes should be terse but clear, and they should embody a condensed statement of pertinent observations and recommendations. In order to systematize and render less onerous the work of record-keeping, printed forms containing the subjects of inquiry should be made use of. These forms, with the observations legibly written in ink, if bound, paged, and indexed—a plan advised in making a sanitary survey of a town—will make a valuable record for future reference.

William H. Ford.

SANITARY INSPECTORS, DUTIES OF. Sanitary inspections or examinations have, until within the last few years, been made by members of the medical profession in their capacity either of family physician, or of local health-officer, and in every case have had for their object the study of all possible conditions affecting the health of the individual, the household, or the community which the physician was called upon to investigate.

The opinion, however, is rapidly gaining ground that there are engineering problems involved in preventive medicine worthy the attention of the best talent; and with the growth of this opinion a new department in the engineering science, called "sanitary engineering," has sprung into existence. As a result the requirements of the position of inspector have greatly increased, and now involve special study and training.

The inspector, to be properly qualified, must have a thorough knowledge of medicine, so far as it relates to the exciting causes of the zymotic or preventable diseases; of engineering, so far as it relates to water-supply, sewerage, and the drainage of land; of chemistry, to enable him to determine correctly the characteristics of drinking-water; of plumbing, and of the principles of ventilation. If, in addition to these qualifications, is added a mind not hasty in forming opinions, the result of the examination will usually be a solution of the problem.

The inspector should provide himself with a note-book in which he should record all facts learned by questions and by observation, together with sketches of the location and arrangement of the buildings, their water-supply, plumbing, drainage, etc. He should never trust his memory, but enter every little item, no matter how seemingly unimportant. Besides this, the inspector can much more readily grasp the case and be able to make an intelligent report, by paying attention to small matters. When making an inspection, time should not be taken into consideration. What is required is an absolute mastery of the facts. Besides the note-book it is well to carry a hammer, cold-chisel, screw-driver, a small monkey-wrench, an ounce-bottle of oil of peppermint, about two feet of ¼-inch rubber tubing, a small funnel, and a wet and dry bulb hygrometer such as is used by the Coast Survey. These can be fitted compactly into a small box, so as to be readily portable.

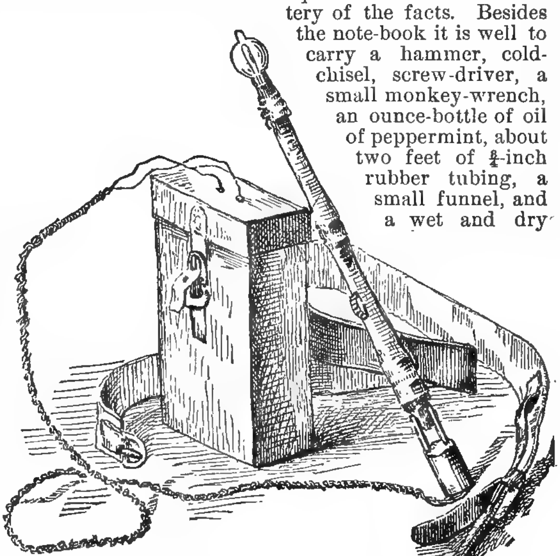

FIG. 3368.—Portable Electric Lamp and Battery, for use in sanitary inspections.

The preceding sketch (Fig. 3368) represents a one-candle power electric lamp and battery, arranged to be strapped around the waist. It is exceedingly convenient, and is free from the objections of candles or wax-tapers. It can also be lowered into a cesspool, drain, or other place difficult of access, and is not affected by draughts of air, the great enemy of naked lights. The only hinderance to the general adoption of this lamp is its cost.

There are three lines of investigation in every inspection: 1, The occupants of the house or the inhabitants of the town; 2, the surroundings; 3, the house proper.

I. The Personal.—This is, perhaps, the most troublesome part of the inspection, owing to reticence on the part of the people when questioned as to their mode of living. This may be dispensed with if there is no disease in the house or locality at the time of the inspection. Usually, however, under our existing boards of health, the only time when thorough inspections in small communities and villages are made, is during or after an outbreak of one of the preventable diseases. In such cases the first point to be learned is the date of the first appearance of the disease in the community; then each case should be marked on a map of the village or town, with the age of the person and the date of the appearance of the first symptoms. If possible, the family physicians should be consulted, and the history of the cases, together with any hereditary or constitutional complications of the patients, be obtained. In the case of the first person taken ill, if the beginning of the period of incubation of the disease corresponds in time with the residence of the patient at some other place than that at which the disease made its appearance, it is safe to assume that the specific germ was taken into the system at that place. When the cause of the disease in sporadic cases has been traced in this way to some remote place, a complete inspection of the premises is, of course, unnecessary, but it would be well to examine them for any sanitary defects that might lower the vitality and check the convalescence of the patient, or might convert the locality into a centre of contagium. When disease is found among school-children, or among persons who are confined to their places of business, the store, counting-house, or school should be thoroughly examined.

II. The Surroundings.—This line of inquiry comprises the geology of the district, the water-supply, disposal of excreta, etc. In cities where the natural water-courses have been subverted by the grading of streets and filling in of ground, the character of the soil has very little effect on the salubrity of the dwellings; but in the country it is quite the reverse, and the presence of sand or gravel, clay or rock, very often determines whether a locality shall be healthy or the reverse. Sand or gravel is the best foundation on which to build, but even this is unhealthy if it exists in the form of a bed superimposed on a depression of clay, or as a thin covering of the rock beneath.

Dampness of soil is now recognized as the prime factor in the production of pulmonary troubles, as well as a necessary attendant of malaria. The remedy is the under-drainage of the land with porous tiles, and the inspector should recommend such work to be done in every case. "Situations at the base of hills are particularly unhealthy, as the ground-water, coming from the higher lands, is checked in its flow by the sudden change in the grade and forced to the surface," making the upper layer of the soil extremely moist. The health of a community is very often affected by the presence of streams, ponds, and marshes. Streams are dammed up and overflow large tracts of land, which are at times laid bare by the subsidence of the water; while the surfaces of ponds and marshes are constantly fluctuating, alternately covering and laying bare large areas of mud. Malarial diseases are the certain result of this condition of things; but they as certainly decrease as drainage is instituted and the water-level made unvarying.

The loss of sunlight, the want of free circulation of air, and the odor of decaying vegetation given off in the autumn by the dead leaves that accumulate about a house that is densely shaded by trees, all conduce to make it damp and unhealthy. A thorough pruning of the trees nearest the house should in these cases be recommended.

The dangers to health from without the house that are most frequently met with in cities are:

1. *Badly Built and Filthy Streets.* Whatever material admits of depressions or cracks, in which surface washings can accumulate and from which they can leach out into the earth below, should be rejected as unfit for the purpose. Surface water from the yards in the rear, and from imperfect roadways and gutters in front, saturates the ground about the houses, and presents conditions favorable to the development of pulmonary diseases. The writer has learned, through a long series of observations, that ninety per cent. of the cellars in the city of New York are damp, if not actually wet, a condition largely due to this percolation from the surrounding ground.

2. *Defective privy-vaults,* fouling the air and saturating the ground.

3. *Offensive Trades.* These will be treated under the proper heads.

Water for domestic use is obtained either from the regular town-supply or from wells and springs. In the first case, it is natural to infer that sufficient care has been taken in the choice of a source and in the protection of the gathering grounds to prevent the contamination of the water. It often happens, however, that towns along the banks of streams are obliged to take water that has been fouled by the discharge of sewage or manufacturing waste from some town above them on the same stream. Although the water of streams thus polluted becomes again fit for drinking by the oxidation of its impurities, it is still a mooted question at just what distance below the point of contamination so desirable a result is reached.

Too much attention cannot be bestowed on the wells of a district, and great care should be taken in examining their location and surroundings, and the influence of the geological formation on the purity of the water.

In making the examination of the water there are three points that should receive special attention:

"1st. To what extent it is contaminated.

"2d. The causes that have led to this result, or that may produce it in the future.

"3d. The tracing of connection between the use of contaminated water and cases of disease that usually have their origin in such use, viz., typhoid fever, diphtheria, etc."

It sometimes happens that the food has more to do with an outbreak of fever than have plumbing and drainage. For instance: "Milk has so often been the carrier of contagium that everything which in any way could affect it should be carefully examined; the dairy from which it comes, the cows, the milk-cans, and the water they are washed in, should all receive attention. Then, again, the ice may be the cause of the trouble. Impure water in freezing does not make pure ice, and hence the pond or other sources from which it is taken should be examined for any possible cause of contamination."

"The only protection for a well that is deemed necessary by the majority of farmers and the like, is to raise the top by banking the earth above the level of the surrounding ground." This does not in any way affect the quality of the water, as the well draws its supply from under ground, in the manner illustrated in the article on Soil.

"Oftentimes wells are found without curb of any kind, and receiving the surface drainage from barns, pigsties, and out-buildings. Wells are sometimes dug under a house, or, having been formerly outside the kitchen door, have been brought under the roof of an 'extension,' perhaps with the pump in the kitchen. This arrangement is sure to lead to contamination of the water, as decay is going on in every conceivable form at their very mouths, and, being closely shut in, there is no chance for ventilation. When the well is near the back door, the slops that are certain to be thrown out on the ground will find their way into it."

These are some of the dangers of contamination of well-water from surface washings; but those that threat-

en the purity of the water from beneath the ground are even greater.

If a well is in a depression or below the level of barns, houses, privies, and the like, even if they be a hundred feet or more distant, its water should be looked on with distrust and a sample should be taken for analysis.

It sometimes happens, as illustrated in the article on Soil, that although the top of a well is at a greater elevation than a neighboring source of contamination, its bottom is far below, and is constantly receiving infiltrations of decomposing matter. These statements go to show that, in making a sanitary examination of a locality, no dependence should be placed on wells unless they have been proved, by absence of improper surroundings, by the geological formation of the ground in which they are dug, and lastly by a chemical analysis, to contain water fit for domestic purposes.

Privy-vaults are so common that they need no description. They are nasty, unnecessary, and extremely dangerous to health. The inspector should set his face against them and condemn them without mercy.

The proper substitute for the privy-vault, in any given instance, depends on a variety of conditions. If the town is provided with sewers, the premises should be connected with them. Country houses without running water might with advantage adopt the dry-earth system. If, however, the building is a large one, with hot and cold water supplied throughout—such as country residences, hotels, public institutions, and the like—the proper method of sewage-disposal is a matter requiring careful consideration, and the services of an engineer familiar with the construction of sewage-works should be obtained. If the town or village under examination is provided with a public water-supply, but no sewers, every argument should be brought to bear to induce the prompt introduction of a comprehensive sewerage system.

"Next to the privy-vault, the pig-sty, as it is usually met with in the country, is one of the most offensive and dangerous nuisances that will be found. These pens are sometimes quite near the house for convenience sake; the excrementitious and liquid filth is always allowed to soak into the ground. The floor is dug out every year and used as a fertilizer, leaving a pit from one to six feet deep. Some of these pits have water standing in them during hot weather, and have fetid mud in them all the time." In hot weather they become very offensive, and, when in populous districts, should be moved without delay.

III. The House.—Less attention is given to the disposal of household dirt than to any of the other questions bearing on the health of the occupants, and yet it should be recognized by the inspector as an important factor. Charles Slagg says: "One must consider that there are two kinds of dirt—the one mineral and inoffensive, the other refuse organic matter. We do not feel defiled by contact with the one, but contact with the other is abhorrent, and there ought to be in every household a sufficient quantity of water to wash it off frequently. Those who suffer the dirt which is caused by the perspiration of the body to linger underneath the clothes, out of sight, are essentially dirty. We cannot all be rich, but we can all be clean." The dust that accumulates on the walls, floors, and furniture of a house is composed of organic and inorganic matter, and would, if sprinkled on the wounds of patients in the surgical wards of hospitals, produce conditions extremely dangerous to life. The cellar should be as clean as the parlor; and yet fully ninety per cent. are so dirty and littered with rubbish that one cannot go into them without soiling his clothes. The front door-step may be taken as a criterion of the character of the inmates of the house. As it is clean or dirty, so will be its owners. "The average American house has its 'company room,' in which the chance visitor is ushered. Here everything is in order, from the gilt frame about the French picture to the velvet carpet on the floor. Go to the kitchen, and you will find the week's wash on the floor, the garbage-pail standing on the hearthstone, the remains of several meals on the table, and cockroaches crawling over everything." Go to the bedrooms and examine those receptacles of rubbish, the closets under the basins; notice the rolls of hair, the burnt matches, and dirty brushes lying on the bureau; open the closet-doors and speculate on the time that has elapsed since those clothes have been aired. All these things are sure indications of the habits of life of the occupants, and the experienced inspector notes them as carefully as he would the syphoning of a trap.

The questions to be investigated inside the house are:

A. The character of the air.
B. The mode of heating.
C. Means of ventilation.
D. Plumbing and drainage.

A. *The Character of the Air.*—The material of the outside walls (whether wood or stone) should be noted; and the rain-leaders and roofs should also be examined, for, if leaky, they are fruitful sources of moisture. The cellar also plays a very important part in the salubrity of a house. Being below the level of the ground it acts like a cesspool, receiving and holding surface-water that finds its way into it from the surrounding ground; and hence it is that cellars are usually damp, except in certain cases where great care has been taken, by concreting or asphalting the floors and walls, and by a system of underdrains, to keep the water out. Every house for at least eight months of the year resembles a chimney. The air inside, being warmer than that outside, is constantly rising and producing a vacuum that must be filled from somewhere. Windows and doors, and even brick or wooden walls, leak air; but this vacuum is partly filled by air drawn from the ground around the house. Ground-air has always more or less decaying matter in it, and has been known to carry contagium. Care should therefore be taken to prevent the cellar from drawing its supply of air from the surrounding ground, by the opening of windows and doors and the sustaining of good ventilation.

The cellars in country houses, as usually found, are very objectionable. "They very seldom extend under the entire house, and are, as a rule, reached by a steep flight of steps from the outside. In many instances the door is the only opening for light and air, the result of which arrangement is that the walls become damp, the beams rot, and the atmosphere is heavy with moisture. In these cellars will be found vegetables, apples, and sundry other household goods stored for winter use." The decay of these things makes the air foul, and more or less affects the atmosphere of the house, as explained above.

Another source of nuisance in the country is the air-space that is often left under a house. Refuse of all kinds—dead animals, etc.—collect here, and being difficult to reach, will never be removed. "When the cold weather comes on, these houses are banked with earth, saw-dust, leaves, manure—whichever is most available. The surface of the surrounding ground is frozen, and thus hermetically sealed. It follows that any sweating of the earth, or movements of air or gases in the soil, must work up under the unfrozen part beneath the house. As the temperature is always above freezing-point, some decomposition goes on all the time; these gases mingle with the others, and all winter they rush through the cracks in the floor into the living-rooms above. Fortunately, most of this class of houses have been rocked by the wind, shrunk or warped by sun and rain, until the entrance of pure air from without balances in most cases the vitiated air within." The effect of cellar-air on the atmosphere of a building should be further determined by the use of a wet and dry hygrometer. The instrument should be set in turn out of doors and on each floor, including the cellar. The readings should be taken not less than fifteen minutes after setting, as this is the minimum time in which the columns of mercury will come to rest.

B. *The Mode of Heating the Building.*—With the mechanical details of steam and hot-water heating the inspector will have nothing to do further than to note the ability of the apparatus to keep the building at a uniform temperature of 70° F. The air-supply to these apparatus,

Sanitary Inspectors.

if heating by indirect radiation, as well as that to the ordinary hot-air furnace, is of the greatest importance, and the position of the inlet and the condition of the flues should be carefully examined. "Cracks or openings in the ducts, or the position of the air-inlet near the drain-opening or other source of contamination, will allow foul air to pass into the heating chamber and be distributed through the house." The air-tight stoves so often met with in country houses are an abomination. The air in the room is heated and reheated, and breathed over and over again until the vitality of the system is so lowered that a person who has been subjected to the bad air for some time experiences a severe chill when passing into purer, fresher air.

Dr. D. F. Lincoln, in the New York State Health Board Report for 1882, makes some extremely good suggestions for the turning of these stoves into ventilating apparatus, and the inspector would do well to familiarize himself with them. Dampers in the smoke-flues of both hot-air furnaces and stoves are a source of great annoyance. When the fire is too hot, these dampers are closed and the carbonic acid gas arising from the combustion of the coal forces its way into the rooms, sometimes to suffocation. There ought to be no dampers of this kind, as it is quite possible to regulate the fire by the doors, if the furnace is properly constructed. When the owner will not dispense with them, there should be a small leak-hole cut in the disk to allow the noxious gases to pass up the chimney.

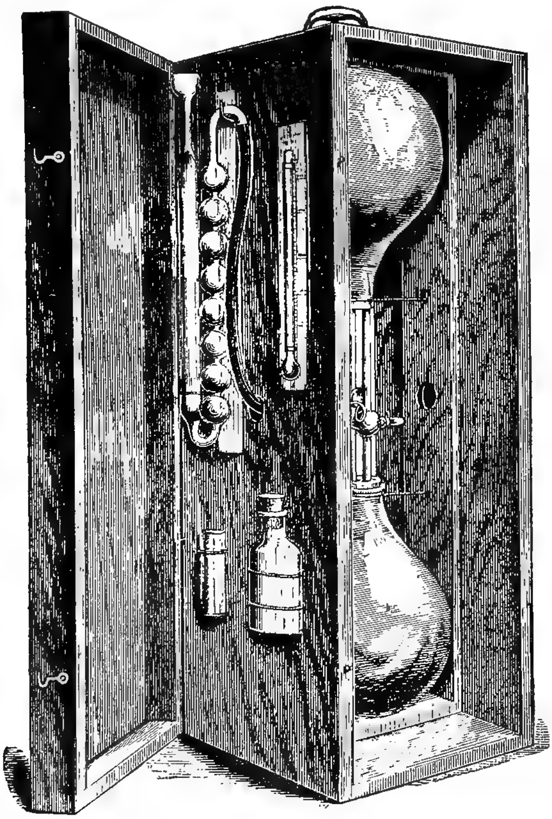

FIG. 3369.

C. *Means of Ventilation.*—Doors and windows are the sole reliance in this direction in most buildings. The air of houses would be very much improved if a good-sized opening, properly protected by louvers, was made in the roof. This would allow the constantly ascending warm and vitiated air of the building to pass out at the roof and be replaced by pure, fresh air. The skylights over stairways and light shafts in city houses will usually be found closed tight. The inspector should recommend them to be raised a couple of inches for the above-mentioned reasons. No part of the house needs ventilating more than the water-closets, and yet in many cases they will be found in the middle of the house, far from any window. The foul odor must of necessity pass out into the rooms and taint the air. Persons who are accustomed to living in city houses do not notice this odor, but it is very perceptible to those whose lungs are usually filled with the pure air of the country. The inspector should look well to this matter of ventilation. When water-closets are very much shut in, he should recommend the carrying of a ventilating-tube from the closet to some point outside the house; and the heating of the air contained in it by a gas jet, or a similar method, which will create an outward current of air at all times. This will prevent the foul air from passing out into the house by creating a strong counter-current.

In the examination of school-houses, dormitories, and the like, it will be necessary to test the character of the air with respect to the presence of carbonic acid, in order to ascertain the efficiency of ventilation. A convenient method, and one given by Dr. John T. Billings, is to take "six well-stoppered bottles containing, respectively, 450, 350, 300, 250, 200, 100 c.c., a glass tube or pipette, graduated to contain exactly 15 c.c. to a given mark, and a bottle of perfectly clear and transparent lime-water." The bottles are filled with the atmosphere to be examined "by means of one of the smaller hand-ball syringes, taking care that none of your own breath is pumped in; add to the smallest bottle, by means of the pipette, 15 ctm. of the lime-water, put in the cork, and shake the bottle. If turbidity appears the amount of the carbonic acid will be at least 16 parts in 10,000." Turbidity in the 200 c.c. bottle would indicate 12 parts; in the 250 c.c. bottle, 10 parts; in the 300 c.c. bottle, 8 parts; in the 350 c.c. bottle, 7 parts; and in the 450 c.c. bottle less than 6 parts.

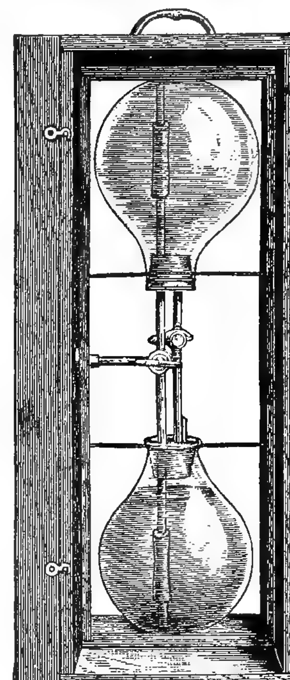

FIG. 3370.

Another simple method, and one devised by the writer, depends on the characteristic action of phenolphthalein, one of the aniline colors, which in an alkaline solution is a brilliant crimson, but in an acid solution is a dull yellow. The method is thus described in the *Sanitary Engineer:*

Fig. 3369 shows the apparatus enclosed in a box. It consists of two graduated glass flasks, Fig. 3370, set in a revolving frame, and connected by a glass tube furnished with a stop-cock. The tubes connect with the three-way cock, which allows air to enter one or the other of the flasks at pleasure. The U-shaped glass, Fig. 3371, has eight bulbs blown on one of the legs to insure the perfect absorption of the carbonic acid by the baryta-water.

To use the apparatus, fill the upper flask to the zero mark with water (this may readily be done by attaching the end of the flexible tube to a faucet); pour into the absorption-tube, through the funnel, from 12 to 15 ctm. of baryta-water containing 3.425 milligrammes of baryta (BaO), which will absorb one-half a cubic centimetre of

carbonic acid gas; turn a three-way cock so as to connect the upper flask with the absorption-tube; turn the stop-cock so that the water will pass from the upper into the lower flask; aspirate slowly till the color disappears; shut the stop-cock, and read on the graduated flask the number of cubic centimetres of water run out, and hence the

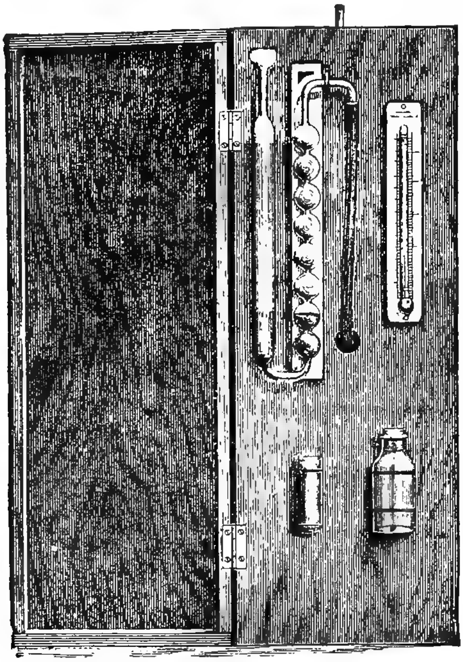

FIG. 3371.

amount of air passed through the baryta-water. If 1,000 c.c. of water have been used, the proportion of carbonic acid is 5 parts in 10,000. As air changes its volume under varying pressures and temperatures, corrections must be made for these in order to obtain absolutely correct results. Should it be necessary to pass more air through the baryta solution than is contained in one flask, turn the stop-cock, close the air-hole in the flask containing the water, revolve the aspirator, open the air-hole in the empty flask, reverse the three-way cock, and proceed as before.

D. *Plumbing and Drainage.*—The defects in this work that may be encountered are almost without number. A list of such defects that have been encountered by a firm of English engineers, has been slightly altered to meet American practice, and is given here as being a concise statement of the experience of the writer: "1. Common brick sewers with flat bottoms, under or near houses. 2. Earthen pipe-drains, either broken or with leaky joints, laid under the cellar floor, saturating the earth with sewage. 3. Pipe-drains, either earthen or iron, laid under houses without sufficient fall, or with the fall the wrong way. 4. Drains, both earthen and iron, without running traps, admitting air from sewer and cesspool to the pipes in the house. 5. Drains without a free current of air moving constantly through them. 6. Rat-burrows from built drains or sewers undermining flags and floors, and admitting foul air to the house. 7. Rat-burrows worked along perfect pipe-drains from street sewers and into houses. 8. Defective connections between soil and waste pipes, and sewers admitting foul air to houses. 9. Soil or waste-pipes without any or sufficient ventilation. 10. Defective water-closet apparatus. 11. Water-closet cisterns with overflows joined to waste-pipe or drain. 12. Safes under closets or basins, connected to soil-pipe or drain. 13. Two or more fixtures with unventilated traps on the same line of pipe, siphoning each other when used. 14. Sink overflow-pipes joined to soil-pipes, untrapped or with trap liable to siphon. 15. Overflows from basins or baths connected with waste-pipe on sewer side of trap. 16. Water-supplies to sinks taken from water-closets or other contaminated cisterns, and used by careless servants for drinking purposes. 17. House cisterns and tanks with overflows direct into soil-pipes or drains. 18. Traps of every description without ample ventilation to prevent them from siphoning. 19. Scullery sinks connected directly with drains, admitting foul air to houses, not only through traps, but through joints of brickwork all around, as shown by the smoke test. 20. Bell-trap with loose covers on scullery sink connected with drains. 21. Gullies or traps in sculleries, laundries, larders, refrigerators, etc., leading to drains usually dry and untrapped. 22. Rain-leaders used as ventilators to drains, delivering foul air to bedroom windows, or under eaves or roofs. 23. Ashpits near larders and pantries; ashpits liable to soak moisture through house-walls. 24. Defects of drainage and rat-burrows from neighbors' houses. 25. Water-cisterns in areas near ashpits or sculleries, and with overflows directly to drain. 26. Wash-basins in dressing-rooms connected directly in any way to drains or soil-pipes. 27. Cisterns of all kinds in houses with overflow connected to drains. 28. Cesspool near houses, and cesspools or defective drains near walls. 29. Neighbors' drains crossing under houses, or joining drains."

The plumbing system of a building may be likened to a tree, the house-drain being the trunk, and the waste-pipes with the fixtures at their extremities representing the branches. The inspector will find it best to begin his examination in the cellar and work gradually to the roof, making sketches of each floor, and the arrangement and connections of all the pipes in the house. Unfortunately, it is too often the case that the pipes are hidden in walls and partitions, and cannot be got at without great inconvenience to the occupants; and yet it is necessary, for a thorough and intelligent examination, that the entire length of piping should be exposed to view. To overcome this difficulty, and also to detect the pin-holes or air-holes which often occur in pipes, and which it is impossible to see with the naked eye, two tests, the peppermint and the smoke, may be employed.

To make the peppermint test, two persons are required, one to handle the oil and the other to search for traces of it through the house. A pailful of boiling water is poured in the top of the soil-pipe, if it extends above the roof; or if not, into the highest fixture in the building. About one ounce of oil of peppermint (or any other pungent volatile substance) is next mixed thoroughly with about a gallon of boiling water and sent down the pipe, followed immediately by another pailful of boiling water. By heating the pipe at first, and then breaking up the oil into minute globules, the oil is, to a certain extent, volatilized and carried into every part of the system. When the end of the pipe on the roof is protected by a return bend, the rubber tube and funnel previously mentioned can be used to advantage for siphoning the water and oil into the pipe. When it is necessary to pour the oil down from the highest fixture, the person using it should shut himself in the closet, and remain there until the inspector has made his search for traces of the odor. Too much care cannot be taken in making this test, and at least ten minutes should be allowed between the time of pouring in the oil and beginning the search, in order to give time for the penetration of the odor to every part of the system of piping.

Quite a novel apparatus has been recently invented by John T. Phelan, of Cambridge, Mass., for making the peppermint test. It is an admirable contrivance for introducing the oil into the plumbing of a building whose pipes are not extended above the roof. "The device represented in Fig. 3372 consists of two pipes, *A* and *B*, connected together by a joint, *C*, in which joint are two openings, *a* and *b*, which extend downward and are separated by a partition, *c*. The joint *C*, is provided with an extension, *d*, on which is a flange, *f*. At the extremity of the pipe *A* is a cock, *D*, and at the extremity of the pipe *B* is a cock, *E*, and attached at right angles to the pipe *B* is a pipe, *F*, which is provided with a cock,

Sanitary Inspectors.

G. To the end of the pipe *F* is attached in any suitable manner an elastic bag of rubber, *H*. Under the joint *C*, and at right angles to the same, is a U-shaped bar, *I*, which is attached by its extremities to the pipes on each side of the joint *C*, and in the lower part of this bar is an adjustable support, *K*, for a flask, *L*, which contains the oil of peppermint or other equivalent substance the vapor of which is to be forced into the soil-pipe. The support *K* is adjusted by a set-screw, *g*. The extension *d* of the joint *B* extends into the flask, and between the mouth of the flask and the flange *f* is placed a rubber washer, *h*, by means of which a tight joint is effected when the mouth of the flask is forced against the flange *f* by the set-screw *g*. In the extension *d* of the joint are two perforations, each of which is in connection, respectively,

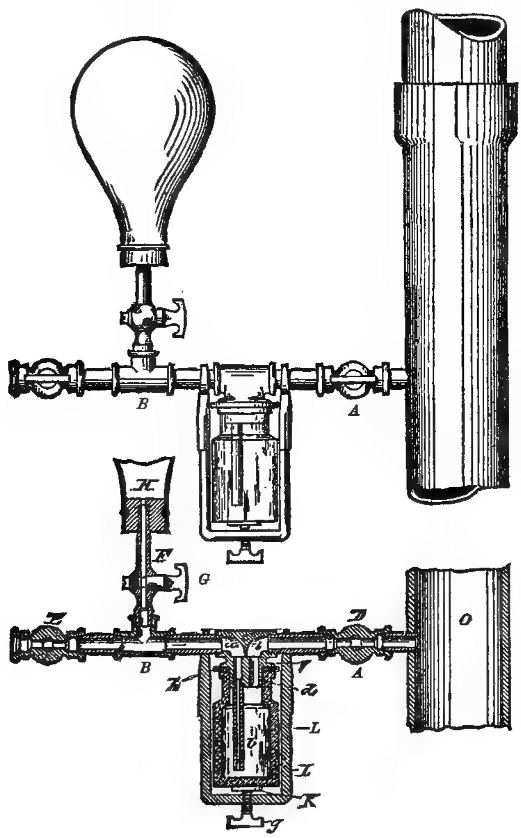

FIG. 3372.

with one of the openings in the joint. A tube, *l*, extending into the liquid in the flask, may be connected with the perforation which is connected with the pipe *B*.

"The mode of operation of the apparatus is as follows: The soil-pipe is first closed at the top and bottom and at all other openings, and the pipe *A* is then attached to a suitable opening made in the soil-pipe, or is otherwise connected with the same. The cock *D* is then closed, and the cocks *E* and *G* are opened. Air is then blown into the elastic bag *H*, through the pipes *B* and *F*, until it is expanded to any desired extent. The cock *E* is then closed and the cock *D* opened, when, by the contraction of the elastic bag *H*, a current of air is forced from the same, and, passing through the opening *a*, pipe *l*, opening *b*, and pipe *A*, carries the vapor of the volatile substance contained in the flask *L* into the soil-pipe *C*."

The accompanying cut (Fig. 3373) shows the apparatus used for making the smoke-test. It consists essentially of a fan, *a*, and a furnace, *b*, in which any substance that will make a good smoke (straw-paper, tobacco-stems, etc.) is placed. All openings in the pipes, with the exception of those on the roof, are closed, an opening is made at as low a point as possible on the house-drain, and the tube *c* is inserted in it and carefully luted. The blast is now turned on, and the furnace kept well filled with combustibles till the smoke begins to pour out of the pipes on the roof. These openings are then carefully closed, and the blast is kept up until the inspector has made his tour. This is a very good test, as the smoke is easily seen and its origin quickly traced. The machine, however, is rather cumbersome for general use, and it is to be hoped that a modification will be devised before long.

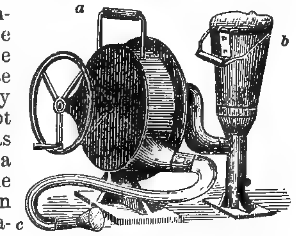

FIG. 3373.

Another form of smoke-test consists in the use of a "smoke rocket" (Fig. 3374), which resembles a Roman candle; being the same length and perhaps three times as thick. The rocket is placed at the foot of the drain, or just inside the intercepting trap, and when lighted gives off a large volume of smoke, which gradually diffuses itself through the pipes and escapes at any open joint or other defect. Although it burns for some fifteen minutes, the rocket is not as satisfactory as the blower, as the smoke can be forced to every part of the system of pipes by the latter, while the former is dependent for diffusion on the currents of air in the pipes. These, as we have seen, may often be down in one pipe and up in another, when the system is somewhat complex.

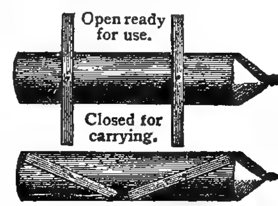

FIG. 3374.—Smoke Rocket.

A recent form of drain-tester is the "drain grenade," made in London (Fig. 3375). "It consists of a cylindrical

FIG. 3375.—Actual Size of Drain Grenade.

vessel, made either of gelatine or thin glass, about two and a half inches long by three-eighths of an inch in diameter. It is charged with either peppermint, assafœtida, or a special pungent compound. The 'grenade' is thrown down the drain to be tested, due care being taken in the case of the glass one that it shall have sufficient fall to break, whereby the content is, of course, released. In the case of the gelatine 'grenade' the filling is, of course, released as soon as the gelatine is dissolved. A little hot water is thrown down the drain after the 'grenade,' in order to flush it through."

When the house-drain is laid under the cellar floor, the smoke and peppermint tests will not detect defects. In such cases the following test should be made: "Select some inlet where you would have a pressure from a head of from two to six feet; plug up all the openings whose outlets are below that level, and also plug up the connection into the manhole or other outlet from the house-drain to the main sewer. The whole system of underground pipes can then be filled with water up to a certain level, care being taken that the outlet at the manhole is perfectly stopped with pugged clay or other means. If the water remains up to the original level, and does not sink or disappear, it is proof there is no leakage from the pipes. The pipes should be filled under the eye of the inspector, so that no tricks may be played; for instance, in the case of new houses where the drains have just been covered in, the inspector should know approximately what quantity of water is required, and should not be content to find the pipes already filled for him, or be

might discover, perhaps, that a false plug had been put in the first length of pipe and the water prevented from passing beyond the first joint. By seeing the removal of the plug from the manhole, such a trick as this might be detected, as the quantity of water used would then show itself if the gradient be known; but the better way is to calculate the cubic contents of the given length of drain-pipes, and measure the number of gallons put in.

When the pipes in the upper floors of a building are so laid that they cannot be reached, and it is desirable to know their exact whereabouts and connections, the work is one of great difficulty. The following suggestions may, however, aid the inspector: To the run of a pipe, allow water to run from the fixtures that are supposed to be located on it, and then go into the closets on the floor below and listen. The trickling sound of water will fix the location. Where several pipes are close together, and only one can be seen, the running of hot water from the various fixtures above, in turn, will usually serve to separate them. To test whether safe-wastes are connected to the waste-pipes from their several fixtures, or are carried by a separate pipe to the cellar, as they should be, pour water through one of the strainers and look for it on the cellar-floor. When it is uncertain whether bath and basin wastes connect with the trap of the adjacent water-closet, or discharge directly into the soil-pipe, cut off the water from the closet; or in the case of a pan-closet, take the bolt out of the lever and drop the pan. The surface of the water in the trap is thus exposed, and by running water in the various fixtures the mode of connection can readily be seen.

To test the efficiency of trap-seals, two methods are employed: First, by the production of a partial vacuum on the sewer side, which destroys the atmospheric equilibrium and forces the water out of the trap, except in cases where the weight of water in the trap is greater than the pressure of the atmosphere. To make this test, all the fixtures above and on the same line of piping are filled with water, and discharged as nearly as possible at the same time. The characteristic gurgle will announce the siphoning. Second, the fixture is filled with water, and all rotary currents are checked; the plug is then gently raised and the contents allowed to rush out. Traps siphoned in this way are siphoned by the momentum of the water. The gurgle is not always a sure indication of the breaking of the water-seal, but the mere fact of a trap being sensitive should be sufficient to condemn it.

The following schedules are given here as suggestions for use in sanitary inspections, and by means of which the sanitary value of a house may be estimated. The first was prepared by Dr. William K. Newton, health-officer of Paterson, N. J., and is designed for country and suburban work. It has been in use for two years, and has proved of great value. The second schedule was prepared by the writer for the use of the New York Tenement House Commission, and is applicable to large cities. The use of similar schedules will be found of great value in tabulating and arranging sanitary statistics, and the writer, from personal experience, strongly recommends their adoption by boards of health.

Schedule for the Sanitary Survey of a House.

(The inspector will cross out all but the correct words, and will fill in spaces.)

Date........................

....................Street, Number............

Street runs N., E., S., W. Width .... feet. Grade........
Pavement.—Cobble, block, Macadam, Telford, none.......
Gutters.—Paved, curbed, smooth......
Sewer.—Material, brick, pipe......; size......; shape......; depth below surface... feet; fall....inches to....foot; runs into........ Street sewer; condition..............................
Condition of street and gutters ....
....
Shade-trees.—How far from house........; prevents sun exposure? ....

Site of House.

......feet above the sea-level.
Soil.—Gravel, sand, clay, loam, rock, made ground, filled in with ......; site of swamp, old water-course, pond, damp, dry. Was site drained before building?......; how?... ..; is surrounding land higher than site, or lower? .....

Diagram of Lot.

w,—well.
c.—cistern.
p.—privy.
c.p.—cesspool.
c.b.—catch-basin.
......drain.

front.

Width of alley, if any......
Yard.—Paved, flagged, cemented, drained, clean, slops, garbage.
Privy-vault.—Stone, brick, board, none, water-tight, connected with sewer, supplied with water, clean; how near living-rooms......
Water-closet.—Style, clean......
Cesspool.—Stone, brick, tight, leaching, connected with sewer......
Water-supply.—City, well......; depth of......; cistern......
Distance of well from source of pollution......
Analysis of water.

House.

Owner......
Agent......
Tenement.—Private, boarding-house......
House faces N., E., S., W.; sun exposure, good, bad; 1-, 2-, 3-, 4-story; number of rooms... ..
Construction.—Brick, stone, wood; sheathed before clapboarding ......; fire-stop......
Roof.—Tin, shingle, slate, tar, gable, flat, French, leaky......; scuttle......; fire-escapes .....
Size of house......; size of lot......; ratio of unoccupied space......
Back-building, distance from house .....
Cellar.—Foundation, stone, brick; how laid......; asphalted or cemented......; damp course......; depth below sidewalk......
Floor.—Cemented, asphalted, stone, board......; dry, damp......
Water-closet.—Condition......
Windows.... ......Is room used for sleeping-room, living-room, shop?
Ventilation of house......
Illumination.—Window-space......
Rooms not connected with external air......
Heating.—Fireplace, stove, furnace, steam; has furnace an air-box?
Plumbing.—Is house connected with sewer or cesspool?......; angle of connection with sewer......
House-drain.—Lead, iron, earthenware; size.....; fall.....; calked joints, cement joints; how fixed in cellar; under ground or exposed ......
Main trap......; inlet for fresh air......
Soil-pipe.—Iron, lead......; size......; joints......; angle of connection with house-drains... ..; extend above roof......
Does ventilating-pipe run into soil-pipe?......
Traps under fixtures......; traps vented......
Water-closets.—Number......; pan, hopper, plunger, siphon......; sufficient wash......
Are there any adjoining nuisances?......
Are fowls, goats, or cattle kept on premises?......

Vital Statistics.

Population of house......
Number under five years of age......
Number of families......
Number to each family......
Number of rooms to each family......
Diseases reported.—Scarlet fever, diphtheria, typhoid fever, dysentery, diarrhœal diseases......
Deaths......

Schedule for Sanitary Survey of City House.

Frederick N. Owen.

SAN PELLEGRINO is a thermal station near Bergamo, in Lombardy, Italy, lying at an elevation of about fourteen hundred feet above the sea. The water of the springs issues at a temperature of 81° F., and contains 1.6 Gm. of saline constituents in a litre. The solids are chiefly chlorides and sulphates, with 0.022 Gm. of sodium iodide per litre. The climate is mild, and the air is delightfully pure and invigorating. The indications for the employment of these waters are said to be chronic inflammatory troubles of the liver, spleen, intestinal tract, bladder, and female sexual organs, gout, syphilis, and the so-called scrofulous diseases of the joints, glands, and skin. San Pellegrino is a favorite summer resort for families in which there are delicate "scrofulous" children. The waters are employed medicinally both internally and in the form of baths.

T. L. S.

SANTA BARBARA. The town of Santa Barbara, Cal., lies in a valley among the foothills of the Santa Ynez Mountains, close to the shore of the Pacific Ocean. The main street of the town runs down to the beach, but its thickly settled portion lies about a mile back from the beach and at an elevation of from twenty to one hundred feet above sea-level. The latitude of Santa Barbara is 34° 28′ N.; two degrees farther south than Algiers; less than two degrees farther north than Madeira. The mildness of its winter climate is, however, due only in part to the comparatively low latitude, being chiefly dependent upon its situation on the western rather than the eastern coast of the North American Continent, and also in great measure upon the trend of the coast-line at this point, and to the protection against northerly winds afforded by the Santa Ynez range of mountains. From Point Concepcion to Carpenteria, a distance of about sixty miles, the California coast-line runs nearly due east and west, a chain of the Coast Range Mountains, bearing the name of the Santa Ynez Range, running parallel to the coast-line, its chief peaks lying some twenty miles back from the shore and rising to an elevation of three or four thousand feet above sea-level. In fact, we have along this part of the California coast a counterpart of the Genoese Riviera; less extensive by half than the latter and backed by mountains less elevated and farther removed from the coast-line, so that the term "cornice" (La Cornice), which is applied to the Genoese Riviera, would hardly be applicable to this far wider Riviera, or coast country, of California. Protection alone gives to the Cornice a mildness of winter climate to which by its latitude it is not entitled; less perfect shelter against northerly winds along the California Riviera is but an adjunct of low latitude and proximity to the warm water of the Pacific in causing the *superior* mildness of its winter climate.

Santa Barbara is the largest town in this part of California (population, about five thousand), and as it is beautifully located, and is one of the most attractive places—perhaps the most attractive place—in all Southern California, it is doubtless destined to increase greatly in size so soon as the chief obstacle to such growth, lack of direct railroad communication, is removed. The water-supply is "abundant and excellent" (Dr. W. M. Chamberlain in New York *Medical Record*, October 30, 1886); of the drainage I find no specific mention. There are excellent hotels, and we are told by a recent writer on Southern California (Wolfred Nelson, C.M., M.D., in the *Planet* of January 15, 1884) that living expenses are moderate. Many of those who resort to Santa Barbara very wisely follow the plan of living in their own cottages rather than at either of the large hotels; boarding-houses also exist for such as prefer them. Dr. Nelson speaks of still a fourth method of living which is adopted by some persons, viz., the renting of furnished rooms near a hotel and taking one's meals at the hotel. Riding is the most popular form of amusement at Santa Barbara; fishing, hunting, boating, and bathing are also in vogue; and the beach is not only a good one for this latter form of recreation, but is so hard as to be likewise available for riding and driving. As to bathing, it may be practised at all seasons of the year, as the sea-water is never very cold; but the season proper begins in May. The mean temperature of the sea-water for each month of the year is given by Dr. Nelson, on the authority of Mr. John P. Stearns, as follows:

January ...60°	April ......61°	July........64°	October.....63°
February ...61°	May........61°	August .....65°	November...61°
March......61°	June........62°	September..66°	December...60°

This would give a mean for the five months, November to March, of 60.6°, a temperature 3.5° higher than the mean surface-temperature of the Mediterranean during the same season at Cannes, as quoted by Dr. Sparks from a paper of Dr. Tripe's (see Sparks's "Riviera," p. 7).

CLIMATE.—The chief objections to the Santa Barbara climate appear to be that it is less dry than that of inland and higher-lying stations in Southern California, is liable to fogs, and is rather exceptionally windy—exceptionally, that is, for a South California station. Dr. H. S. Orme, president of the California State Board of Health, speaks of the land- and sea-breezes as "nearly always to be found" along the coast of this part of the State, and as being "very noticeable at Santa Barbara, Santa Monica, and San Pedro; perhaps less so at San Diego" ("The Climatology and Diseases of Southern California").

I have no data showing the force of the winds at Santa Barbara, but at San Diego we see, from column S of the chart published under that heading, that the mean velocity of the wind is remarkably small. From column K of the accompanying chart it would appear that Santa Barbara possesses a drier atmosphere than San Diego; yet hardly so dry as to warrant the assumption that it is what can be rightly termed a dry place, and Dr. W. M. Chamberlain (*loc. cit.*) evidently regards it as very inferior in this respect to the inland California resorts. "Like San Diego," he tells us, "it is very damp, as the moss-covered roofs and lichen-encrusted fences indicate. More than San Diego it is windy, for it lies in a trough between the hills opening to the southeast and northwest; up this valley the fogs roll in the early hours of the day, and whatever winds there may be are compressed and accelerated to an unusual force." In other respects, the Santa Barbara climate appears to be all but ideally perfect—warm, sunny, and equable; and, lest what has just been said concerning its liability to fogs and *comparative* liability to winds should produce an unduly dark impression of its claims as a health-resort, I introduce the following passage, quoted from Appleton's "Handbook of Winter Resorts" (1886–87). The "only serious drawback" to the climate of Santa Barbara, according to the writer in this guide-book, is the fog which "sometimes comes in from the sea." Such a fog occurs, on the average, perhaps twice a week between May and September, he tells us, but he adds that these fogs "disperse at nine in the morning, and the succeeding weather is delightful."* "Mr. Nordhoff," he says, "expresses the opinion that there were but 'five days, either in Santa Barbara or San Diego, in December, January, and February of this year (1871), in which the tenderest invalid could not pass the greater part of the day out of doors with pleasure and profit. In Santa Barbara there were not a dozen days during the whole winter in which a baby I know did not play on the sea-beach.'"

The following "record of the weather at Santa Barbara for one year, kept by ———, an invalid with advanced pulmonary disease," is quoted from Dr. Nelson's paper already cited.† According to the observations of the gentleman in question, made during a leap year (366 days), there were "310 pleasant days, so that an invalid could be out of doors five or six hours with safety and comfort; 29 cloudy days, upon over twenty of which an invalid could be out of doors; 12 showery days, upon seven of which an invalid could be out an hour at a time several times on each day; 10 windy days, confining the invalid to the house all day; and 5 rainy days, also confining the invalid to the house during the whole of that time."

Santa Barbara not being a station of the United States Signal Service, I am obliged to rely on the reported observations of various volunteer observers for the data quoted in this article and presented in the accompanying chart. All the figures of the chart are either copied from or calculated from those given in Dr. Nelson's article. The headings of the various columns of the chart sufficiently indicate the value of the data in each as an index of the habitual weather, or climate, of Santa Barbara. One of Dr. Nelson's tables shows the temperature observed at 7 A.M., 2 P.M., and 9 P.M. of every day during the year 1879, and the average daily temperature at the hours specified during each month of that year, the observations having been taken by Dr. L. N. Dimmick. Another of Dr. Nelson's tables gives the highest, lowest,

* How frequently these morning fogs occur during the months between September and May we are not told.

† Dr. Nelson gives the name of the gentleman who kept this record, which name I omit, not having asked permission to publish it in the HANDBOOK.

and average temperatures for each month and year from January 1, 1871, to December 31, 1879. A correspondence which exists between the maximum and minimum temperatures of the year 1879 in this table, and the figures of Dr. Dimmick in the table first mentioned, shows that the averages are derived by the formula $\frac{7\text{ A.M.} + 2\text{ P.M.} + 9\text{ P.M.}}{3}$ and that the maxima and minima are such as were noted at the regular tri-daily hours of observation; not such as would have been recorded from self-registering instruments. Hence I assume that the same is true of the averages and the maximum and minimum figures of each of the other eight years, 1871–78. The figures of Column K, showing the mean relative humidity for one year, are quoted by Dr. Nelson on the authority of Dr. I. B. Shaw, M.R.C.S., of Santa Barbara. Those of Column O and of Column OO are based on a table presented by Dr. Nelson, which is quoted from records of Drs. Shaw and Tebbetts. This table shows the actual total rainfall of each month and of each year from January, 1867, through December, 1878. A careful examination of the table reveals the fact that, in the course of this period of twelve years, there occurred three winter droughts, viz., in December, January, and February of each of the three winter seasons, 1869–70, 1870–71, and 1875–76. During the first of these three the total rainfall was but 4.35 inches; during the second it was only 5.75 inches; and during the third it was only 3.35 inches. In the case of this last winter season, the excessively small total rainfall of December, January, and February was no doubt, in great measure, compensated by the very exceptionally heavy rainfall of the preceding November (November, 1875), which was no less than 6.53 inches. But in neither of the other two cases of winter drought do we find any compensation. The combined rainfall of October and November, 1869, was only 0.95 inch, while during the nine months of March, April, May, June, July, August, September, October, and November, 1870, the total rainfall amounted to only 3.72 inches. In other words, a winter drought (4.35 inches of rain) was preceded by a rainfall of only 0.95 inch in two months, and followed by a rainfall of only 3.72 inches in nine months. The winter drought of 1870–71 (5.75 inches of rain) was preceded by a rainfall of 1.31 inch in October and November, 1870, followed by nine months, March to November, 1871, having a total rainfall of 4.04 inches. From March 1, 1869, to December 1, 1871—a period of thirty-three months—the total rainfall was only 21.44 inches. On the other hand, in the single month of December, 1871, there fell 6.56 inches of rain; and in January, 1874, there fell 14.84 inches! These facts abundantly establish the truth of what is said concerning the irregularity of the winter rains of California in Blodget's "Climatology of the United States." "They are sometimes much later or much earlier than their average," he tells us, "and sometimes in great excess as well as in great deficiency." As to the rainlessness of the summer season, that is a never-failing phenomenon, as may be seen from the data set down in Column OO. The most extreme case of summer rainlessness recorded in Dr. Nelson's table was that occurring in 1872, when between March 1st and December 1st—a period of nine months—there fell only 0.05 inch of rain.

It is not possible to establish any accurate comparison between the climate of Santa Barbara and that of San Diego or of Los Angeles, based upon the data of the charts for these places, because of the different hours of observation adopted at Santa Barbara, and the shortness of the period of observations upon which some of the data are based. In Dr. Orme's pamphlet we find a brief table (*op. cit.*, p. 7) giving the mean summer and winter temperatures of each of these three places for a period of four years; from which it would appear that, both in winter and in summer, Santa Barbara is the warmest of

the three. Column F of the chart presented in the present article, shows an absence of frost and of very low temperatures at Santa Barbara throughout nine successive winters. But neither this column nor column E can fairly be compared with corresponding columns of the San Diego and Los Angeles charts, because in these latter self-registering instruments supplied the data; in the former such does not appear to have been the case. Dr. Nelson gives an interesting and practically useful table, showing throughout the course of seven years the number of days on which the mercury was observed to fall below 43° (probably either at 7 A.M. or 9 P.M.), and the number of days on which it was observed to rise above 83° (probably at 2 P.M.). This table is presented below.

	1873.	1874.	1875.	1876.	1877.	1878.	1879.
Below 43°............	7	9	4	17	15	23	13
Above 83°	1	6	22	4	10	8	15

Average below 43° F., 12 days; above 83° F., 9¼ days.

The figure 13 in the year 1879 is very likely a misprint, for on referring to his table for 1879, based on Dr. Dimmick's observations, we find that the 7 A.M. observations of January in that year gave a temperature of 41° F. on two occasions, of 40° F. on three occasions, of 39° F. on two occasions, and of 38° F. on one occasion; in February of that year we find three 7 A.M. minima under 43° F. (viz., 42° F., 40° F., and 39° F.); in November two such minima (42° F. on two occasions); and in December of the same year, *i.e.*, the first month of the following winter season, seven such (viz., 42° F. on two occasions, 38° F. on one occasion, 37° F. once, 35° F. once, and 33° F. twice). That is, we get the figure 20 instead of the figure 13 representing the total number of days having a minimum under 43° F. As to the figure 15, showing the number of days, in 1879, having a maximum at 2 P.M. above 83° F., a careful examination of Dr. Dimmick's figures verifies its accuracy. The actual figures for the fifteen days in question were as follows: March, 89° F. once, 84° F. once; May, 92° F. once; June, 97° F. once, 95° F. once, 90° F. once; August, 85° F. once, 84° F. once; September, 86° F. once; October, 90° F. twice, 89° F. once, 88° F. once, 87° F. once, and 86° F. once.

We have now presented all the data at our command which are likely to help the reader toward an accurate understanding of the Santa Barbara climate, at least so far as it has been possible to do so within the just limits of the present article; and the sum and substance of all recorded observations appears to be a demonstration of the fact that Santa Barbara possesses a winter climate as mild in temperature as any in Southern California, perhaps the mildest of all; and that it has (like all other stations lying to the west of the Coast Range Mountains) a very moderate degree of heat in summer, with cool nights, and with temperatures, even at mid-day, which are usually much below those found at that season in the eastern and central portions of the United States. Fogs and winds are the chief blemishes in its winter climate, and it is at that season unsuited for residence by those having a tendency to rheumatism, and is less suitable for most phthisical patients than are the inland stations.

The upper part of the town is the best for residence by those desiring to avoid dampness, and at El Montecito, a suburb two or three miles to the east, there is said to be better shelter against the sea-breeze than at Santa Barbara itself.

THE OJAI VALLEY.—About thirty miles east of Santa Barbara is the Valley of the Ojai, which, according to Dr. Orme (*op. cit.*), is sheltered from ocean winds and fogs. The little town of Nordhoff in this valley has an elevation above sea-level of about 1,500 feet, and stands fifteen miles back from the coast. The Ojai Valley is a resort which seems likely to become one of the most popular in Southern California. Interesting views of Santa Barbara, and rather attractive (although far less instructive) views taken in the Ojai Valley, may be found in *Harper's New Monthly Magazine* for November, 1887.

Huntington Richards.

SANTA FÉ. [For a detailed explanation of the accompanying chart and suggestions as to the best method of using it see article "Climate," vol. ii., pp. 189–191.] Santa Fé, the capital of New Mexico, and the largest town in that Territory, lies at an elevation of seven thousand feet above sea-level, upon the western slope of the Rocky Mountains, the eastern slope of the Valley of the Rio Grande, and, roughly speaking, at a point equi-distant from the crest of the mountain chain and the river. The little river Santa Fé, one of the chief branches of the Rio Grande among those running into the latter from the east, bisects the town. The distance from Santa Fé to the Rio Grande in a "bee line" is about seventeen miles; in a southwesterly direction to the point of junction between the Santa Fé River and the Rio Grande, it

is about twenty-three miles. The main chain of the Rocky Mountains near Santa Fé attains a very considerable elevation, and less than thirty miles to the northeast of the town are peaks between twelve and thirteen thousand feet high. Santa Fé does not lie in a valley, but upon a great plateau; "in a wide plain surrounded by mountains," are the words used to describe its location by the writer in the "Encyclopædia Britannica;" while the authors of an army circular, quoted by Dr. W. Thornton Parker in his interesting pamphlet "Concerning the Climate of New Mexico," say that the town is "pleasantly situated on an extensive plateau," etc. We are told by the authors just cited, that although "large pines and cedars are found on the hills toward the mountains . . . the country for miles about Santa Fé is," nevertheless, "destitute of trees," *i.e.*, of trees of any considerable size, although "stunted cedars and pines are very common." They add that "this want of vegetation detracts much from the natural beauties of the town and vicinity." Of the water-supply they say: "The river water is very extensively used for drinking purposes, and is excellent; good water, but a little impregnated with lime, may be obtained by wells at a depth of from ten to forty feet." Of the matter of drainage they remark that although "the natural drainage of Santa Fé is excellent, and is materially assisted by an extensive system of *acequias* or canals around the town, still little attention is paid to the subject, and many of the narrow streets and lanes of the city are excessively filthy." The soil about Santa Fé they describe as "dry, light, and sandy, and yet very fruitful."

I shall attempt no discussion in this place of the claims of Santa Fé as a health-resort. The reader desirous of particular information on this point is referred to Dr. Parker's pamphlet just mentioned. A general discussion of the climate of New Mexico, considered from a sanitary point of view, may be found in the article entitled New Mexico, and in particular toward the close of that article, vol. v., p. 182. In Dr. J. Hilgard Tyndale's papers on "The Climate of New Mexico" (see *Boston Med. and Surg. Journal*, 1883, vol. i., pp. 265 and 313) may be found various tables and data illustrative of the climate of Santa Fé; but the figures presented in the accompanying chart, together with such as stand in Tables A, B, F, and H in the New Mexico article (of which Table F is quoted from Dr. Tyndale), and the data given in the table on page 238 of vol. ii. of this Reference Handbook, will doubtless suffice to convey an abundantly accurate idea of the local climate of this town. *H. R.*

SARANAC LAKE. Saranac Lake lies in the northwest portion of the Adirondack region of New York State, at an elevation of 1,539 feet above the sea-level. Having at command no special climatic data for this resort, and having no comment to make upon its claims as a health-station other than what may be found under the title Adirondacks, in vol. i. of the Handbook, the writer will confine himself in this article to a brief mention of the institution known as the "Adirondack Cottage Sanitarium," which was established near Saranac Lake three or four years ago. This institution, intended for such phthisical patients as, in the opinion of its medical staff, would be likely to derive benefit from a sojourn in the Adirondack country, provides good accommodations and medical supervision, at the exceedingly moderate price of five dollars a week, being supported chiefly by voluntary contributions, and with the object of providing a chance for climatic treatment to persons in moderate or reduced circumstances. The plan wisely adopted in building this institution is the cottage plan, each cottage accommodating from two to four persons, and intended for use simply as a dormitory; the dining-room, general "sitting-room," kitchen, etc., being in the main building, about which the cottages are grouped. This main building is described as "a quaint, irregular, red cottage, with unexpected corners, delightfully original and ample windows, a deep piazza, and a range of offices and store-rooms at the rear." ("The Adirondacks as a Health-resort," by Joseph W. Stickler, M.S., M.D.) The custodian's apartments and four bedrooms for patients are on the second floor of this building.

The site for this institution was admirably well chosen, being a shelf-like plateau "on the shoulder of a hill which overhangs the valley of the Saranac River,"—a "natural terrace on the spur of the hill, with a steep descent of about one hundred feet to the Saranac River in front, and an equally sharp and still higher rise to the crest of the ridge in the rear." (*Op. cit.*) The exposure is toward the southeast. The little plateau commands a fine view of the higher peaks of the Adirondacks, some fifteen miles distant toward the east and southeast. The steep wooded hill-side behind the terrace protects it from the storm-bearing winds of the region. The soil is sandy; the natural drainage facilities are of course excellent. It is much to be desired that similar institutions should be established at other leading sanatoria of the United States. *H. R.*

SARATOGA SPRINGS. *Location and Post-office,* Saratoga Springs, Saratoga County, New York.

Access.—To Albany, N. Y., by the various railroads centring there, thence to the springs by the Saratoga & Champlain Division of the Delaware & Hudson Canal Company's Railroad, extending from Albany north to Montreal, Canada.

Therapeutic Properties.—The characteristic ingredients of the waters of this famous resort are common salt and alkaline carbonates. They are therefore classed as alkaline-saline. The proportion of contained carbonic-acid gas is unusually great, and the waters in great measure owe their popularity to their sparkling appearance and agreeable taste. Altogether there are about thirty springs, six of them spouting. The High Rock, Congress, Washington, Hathorn, Geyser, Empire, and Star springs can be taken as types of the Saratoga waters.

Some are cathartic, some contain iron, sulphur, and iodine. The tonic and cathartic properties of these waters have made them the most popular in America of all adapted to the treatment of catarrhal diseases of the digestive and urinary organs, gall-stones, urinary calculi, jaundice, torpid liver, etc.

Saratoga is situated in the northeastern part of New York State, thirty-two miles north of Albany. Its permanent population is about ten thousand, but this number during the "season" is quadrupled. The streets are wide, well graded, and bordered by large elm-trees. Hotels and boarding-houses abound, and there are many handsome residences. Probably nowhere in the world are there caravansaries constructed upon such a scale as to size and comfort. The attractions at Saratoga are few besides the interest connected with observing the ever changing multitude of fashionable visitors, and listening to the fine music provided at the leading hotels and in Congress Park.

* Alumina and sesquioxide of iron.

The High Rock is the oldest spring, its medicinal qualities having been known to the Indians, and by them shown to the whites as early as 1535. Derick Scowton built the first log-cabin here in 1773, and in 1784 General Schuyler erected the first frame-house and made other improvements toward rendering the place more accessible and providing for visitors.

The season extends from the middle of June to September. During July and August the weather is apt to be excessively hot. Yet the air is pure and is generally acknowledged to be tonic. Shade-trees on the streets, in the park, and in the extensive and attractive courtyards of the leading hotels, in a great measure temper the atmosphere and compensate for the absence of a cooler climate. *Geo. B. Fowler.*

SARCOMA. In defining the various tumors of which we have treated in this work, it was possible to compare them with some normal tissue, either in the character or in the arrangement of the cellular elements. We come now to the consideration of a tumor most forms of which do not agree, either in structure or in the character and arrangement of the cells, with any of the tissues of the adult body. The sarcoma has most similarity in structure to the connective tissue, and its affinity to this is still more clearly shown by the fact that it always originates in this tissue. The chief difference between the sarcoma and the other connective-tissue tumors is that the connective tissue which forms the type of the sarcoma is represented, not by the adult, but by the embryonic form of this tissue. The different varieties of sarcoma may be said in a general way to represent the different phases which the embryonic connective tissue passes through in the course of development. This difference between the embryonic and the adult connective tissue is chiefly found in the greater abundance of cells in comparison to the formed material, the intercellular substance; and a similar difference exists between the sarcoma and the fibroma. In the fibroma we have a tumor composed of a tissue which in nowise differs from the adult connective tissue, and which cannot be distinguished from it, macro- or microscopically. The same is true of the osteoma and chondroma. The tumors are typical. The sarcoma may not differ from the fibroma, save in the number of its cells, nor from the osteoma or chondroma, save in the fact that the bone or cartilage in the tumor is atypical, as compared with the adult tissues, and resembles that formed in the first stages of the evolution of the skeleton. We may have different species of sarcoma, which are more unlike each other than two tumors of wholly different names.

The tumors which are now included under the term sarcoma were formerly known under a great variety of names. The name sarcoma is a very old one, and was used to describe all manner of fleshy growths (σάρξ, flesh). Galen described under this name fleshy polypi of the nasal cavity, and afterward all sorts of fleshy growths; and later authors used the term to describe all growths which had the appearance and consistency of muscular tissue. Still later the conception was extended until, at the beginning of the present century, it came to include every sort of tumor which had not a cystic structure, or was not extremely hard, or had not an especial tendency toward ulceration. The influence of Abernethy was felt in this; he proposed to make a very large group of tumors, which received the general name sarcoma, and which was further subdivided, according to general appearances and clinical course, into a number of species. Only the cystic tumors, the exostoses, and cancers were left out. As soon, however, as the tumors began to be studied histologically, those for whose tissue a type could be found in some one of the adult tissues were separated from what had been known generally as sarcomas, and an attempt was made to abolish this name. Still, it was found that many tumors did not agree exactly with the forms of connective tissue, though they were evidently derived from it. Lebert, in France, designated the most common of the sarcomas, and the one most frequently taken as a type of the tumor, the spindle-cell sarcoma, fibro-plastic tumor. Robin separated from the general group certain tumors which, though having much analogy with the fibro-plastic tumors, yet in their structure more nearly approached that of the embryonic tissues, and to these he gave the name embryo-plastic. In England, Paget, studying the tumors more from a clinical than a histological stand-point, found certain tumors which, though similar in appearance to the fibromas, differed from these by their greater malignity, as shown by a tendency to return after removal. To these he gave the name of recurrent fibroid. Paget named other tumors, from the similarity of their structure to the marrow of bones, myeloid tumors. We owe to Virchow the first scientific classification of these tumors; and his views, as expressed in his "Geschwülste" (1864), have since then undergone but slight modifications.

We will first consider the sarcoma as a single tumor, then under separate heads the various varieties. The sarcoma, in general, is distinguished from all other tumors by the abundance of its cells, and the diagnosis of the particular species is in great part made from the character of these cells. In the case of the simple tumors of the histoid group, as the fibroma, myxoma, etc., the diagnosis is made, not so much from the character of the cells as from the tissue which they produce. In the carcinoma and other tumors of the epithelial type, the diagnosis is made, not only from the character of the cells but by their grouping. The great strength of Virchow's description of the sarcoma lies in his comparison of the tumor to embryonic tissue. Billroth does not agree with him in this, but considers the sarcoma-tissue as most similar to embryonic muscular tissue. This applies especially to that variety of sarcoma which is composed of spindle-cells. The type of the sarcoma-tissue may also be found in the adult tissues, in some pathological conditions. The tissue covering the floor of an ulcer, the granulation-tissue wherever found, is similar to the tissue of some of the sarcomas. This granulation-tissue passes through the same steps in the formation of connective tissue as does the embryonic tissue. In its earliest form it is composed almost entirely of cells which present some differences of form, and whose general character is represented by a round cell about the size of a leucocyte, with a relatively large nucleus. Not infrequently large protoplasmic masses, containing many nuclei, may be found in this tissue. The blood-vessels are peculiar in that, in many cases, they appear to represent nothing but channels surrounded by cells, and are altogether lacking in a supporting meshwork of connective tissue. Granulation-tissue varies in some degree in the various tissues in which it arises; that coming from the marrow of bones, as in cases of fracture, etc., is similar to the embryonic marrow. We may have represented by it not only the general type of the sarcoma, but also some of its distinct species. The difference between the sarcoma and the inflammatory granulation-tissue is to be found, not in the histological character of each but in the termination to which each tends. When the granulation-tissue is produced in consequence of a wound or a chronic disease of the bone or articulation, it never passes beyond a certain point of growth, tends to the production of a typical tissue, and ceases to be when the conditions which favored its development no longer exist. In all cases a tendency to, or a beginning production of, a typical formed tissue can be seen in some part of the granulations. In the sarcoma, on the other hand, there is no such tendency to the production of tissue, but the cells simply increase in numbers. The character of the cells of a sarcoma is but slightly influenced by its seat; every variety of cell may be found in tumors arising from the subcutaneous cellular tissue.

The close connection of the sarcoma with the typical connective-tissue tumors is further shown by the formation of mixed forms with these. In a fibroma the whole tumor, or certain parts of it, may contain more cells than can be regarded as typical for fibrous tissue; in other words, it approaches the type of connective tissue found in the embryo. This connection with sarcoma is expressed by the compound name fibro-sarcoma, myxo-

sarcoma, etc. Virchow says that a tumor may also represent a mixed form between the sarcoma and carcinoma, in which certain parts are sarcomatous and others carcinomatous. Such tumors he has named sarcoma carcinomatosum, and he ascribes to them the malignity of both the sarcoma and the carcinoma. He does not think that in such cases the tissue of the sarcoma passes over into that of the carcinoma, but that they both develop simultaneously from the same tissue, growing like two branches of the same stem. When we regard the carcinoma as a pure epithelial tumor, and the sarcoma as a connective-tissue tumor, such combined forms must seem extremely improbable, and the tumors in which such a combination appears to exist will be found, on careful examination, to be either carcinomas with a stroma very rich in cells, or sarcomas in which the arrangement of the cellular elements resembles somewhat the alveolar structure of the carcinoma, the alveolar sarcoma of Billroth.

Regarding, then, the sarcoma as a pure connective-tissue tumor always arising in this, it will be seen that it holds the same relation to this tissue that the carcinoma holds to the epithelial tissue. Both are atypical tumors, the sarcoma showing this departure from the regular type of connective tissue by the abundance of its cellular elements, and the carcinoma showing its departure from the type of epithelial tissue by the number and arrangement of its cells. Each may begin as a typical tumor. The sarcoma may first appear as a fibroma, and then, by an excessive development of cells, without any further development of formed tissue, become a sarcoma. The carcinoma may in like manner begin as an adenoma, and become atypical by the epithelial cells forming solid cylinders and growing into the connective tissue. There may be the mixed form of adeno-carcinoma, just as there may be the mixed form of fibro-sarcoma. The sarcoma bears the same relation to the fibroma that the carcinoma bears to the adenoma, but between the sarcoma and the carcinoma we have not only a morphological, but a histogenetic, difference.

No one sort of cell can be regarded as typical of the sarcoma. Almost every variety of cells may be met with, and even in the same tumor there may be found round cells similar to the granulation-tissue, spindle-shaped, and giant cells. The form of the cells, in great part, depends upon the physical conditions to which they are subjected in the tumor. When the intercellular substance is relatively abundant, and fluid or semifluid, the cells are subjected to the same pressure in all directions, and they are then round. When the intercellular substance exists in but small amount and is more or less solid, the cells are then pressed against one another, and they take various shapes. If the pressure is exerted laterally they become elongated and spindle-shaped. On such cells facets can often be seen, caused by the pressure of opposing surfaces. The different characters of the cells may best be studied on small pieces of the tumor which have been macerated for a long time in one-third water and two-thirds alcohol, as recommended by Ranvier, or in Müller's fluid. The latter method gives in many cases excellent results.

Spindle-cells are found more often than any other sort of cells in sarcomas. These are long cells terminating in long pointed extremities. In the middle the cell is swollen and contains a single nucleus, and rarely more than one. The nucleus is more refractive than the remainder of the cell, and often contains a bright nucleolus. In some cases more than one process is given off from an extremity, giving the cell something of a stellate appearance. These cells may vary a good deal in character in the different tumors. In many cases cells are found which present a spindle appearance only when viewed in profile; on the side they appear as flattened epithelial scales. These cells are formed by pressure on the sides. Stellate cells are often found with long, branched processes, which may communicate with neighboring cells. The round cells vary much in size and general character; some are found which are about the size of white blood-corpuscles, and contain a nucleus which is very large in comparison with the cell. In other tumors large oval cells, closely resembling epithelial cells, are found, and between these two extremes there may be numerous other varieties.

Whatever may be the character of the sarcoma-cells, they are always in the closest connection with the connective tissue. Even in those tumors which are richest in cells there is always a certain amount of intercellular substance between the cells, and there is not the same sharp contrast between the cells and the stroma which carries the blood-vessels, that exists in the epithelial tumors. In these the cells are arranged in groups like the glandular organs, with the stroma surrounding the groups of cells, but not entering into them. This is a diagnostic point of the greatest importance between the sarcoma and the carcinoma. Even in the case of the alveolar sarcoma the separation of the cells into alveoli is only apparent, and on closer examination it will be found that small masses of connective tissue, and even blood-vessels, enter into the alveoli.

Of late numerous growths, which were formerly considered under the sarcomas, have been removed from the list of true tumors. This is the case with the pearly nodules which are found on the serous surfaces of cattle, and which Virchow placed among the sarcomas. They have been shown to be identical with tubercle-nodules, and to be due to the specific virus of tuberculosis. The same thing is true of actinomycosis. Before it was known that this disease was caused by a definite organism, the large tumor-like masses which it produces in the jaws of cattle were classed with the sarcomas, as a species of osteo-sarcoma, and it is probable that there may be other tumors, now classed with the sarcomas, which will be shown to be due to a specific virus.

All sarcomas are very vascular, and, as a rule, only the larger vessels have any considerable amount of connective tissue around them. The smaller vessels are in direct contact with the cells, they are more voluminous than vessels of a similar character in normal tissues, and their walls are composed of cells which in many cases are similar to those of the tumor. On section they appear simply as spaces surrounded by the tumor-cells. They are similar to the vessels found in granulation-tissue. The close connection between the cells of the tumor and the blood-vessels is of great importance, and explains the course taken in the formation of metastases.

In forming a classification of sarcomas, the only basis that we have is the character of the cells. As said before, there may be different forms of cells in the same tumor, but one type will be found to be dominant. When divided into different species in this way, it will be found that, though there are a good many points of similarity in histological character, a study of the clinical features of each species will make these differences in structure still more evident. Some of the forms into which they may be divided will be found to be of much more clinical importance than others. The classification which we have adopted, one based principally on the character of the cells, is as follows:

1. Round-cell sarcoma syn.; granulation-sarcoma, sarcome encephaloïde, lympho-sarcoma, embryo-plastic tumor. A tumor composed of a tissue similar to that of the upper layer of granulations. The cells are round, and there is a very small amount of intercellular substance between them.

2. Spindle-cell sarcoma; syn., sarcome fasciculé, fibroplastic tumor, recurrent fibroid. A tumor composed of spindle-cells which are generally arranged in bundles. The intercellular substance is small in amount.

3. Myeloid sarcoma. A tumor composed of cells similar to those in the bone-marrow, and among these large multinuclear, protoplasmic masses known as giant-cells.

4. Osteo-sarcoma. A tumor somewhat resembling the myeloid sarcoma, but in which there is a tendency for the embryonic tissue to organize and form more or less complete bony masses.

5. Melano-sarcoma. A tumor whose cells contain a dark-brown or black pigment, which differs from the pigment formed from blood-extravasations.

6. Alveolar sarcoma. A tumor composed of cells often resembling epithelium, and having, in the arrangement of the cells into alveoli, some similarity to the carcinoma, but with the difference that the separation of the tissue into cell-masses and connective tissue is not absolute as in the carcinoma.

7. Angio-sarcoma. A tumor which combines an extensive new formation of blood-vessels with an active growth of the cells forming their walls.

Some authors have subdivided the sarcomas still further, making twelve or more species. The division here given will embrace most of the forms of sarcoma. The mixed forms, with other tumors, have already been treated of. See Fibroma, Myxoma, etc. Any classification that can be made, either from the histological or from the clinical features, is at best an artificial one, and cases are often found in which it is difficult to say to which one of the species mentioned it belongs.

Round-cell sarcoma. The cells of which this tumor is composed may be very small, resembling those found in granulations, with a nucleus almost entirely filling the body of the cell, or may be larger, similar to some epithelial cells. They are round and surrounded by an inter-cellular substance which is very soft or semi-fluid. On section of the fresh tumor a small amount of juice, more transparent than that which comes from a carcinoma, escapes; but after the tumor has been kept for from twelve to twenty-four hours, and the inter-cellular substance has been softened by cadaveric changes, this juice is more abundant. It is probable that the inter-cellular substance is not naturally fluid, but of a jelly-like consistency; or if fluid, it is held in the meshes of the tissue just as the fluid is retained in dropsical tissues. When the fresh fluid is examined large numbers of cells will be found in it. In many cases the amount of fibrillar connective tissue is so small, that it is only by careful shaking and brushing the section that it becomes visible. Some of this connective tissue is undoubtedly newly formed, but part is the old connective tissue of the place of origin of the tumor, simply pushed apart by the rapidly-growing cells. Some spindle-shaped cells are always seen, either around the larger groups of round cells or along bands of connective tissue. When a thin section has been shaken for a long time in a test-tube with water, most of the cells will be washed away, and if the section has been examined before this, one will be surprised at the amount of connective tissue which is now visible. There may be an almost perfect reticulum, which can surround every cell in much the same way as in a lymphatic gland. The blood-vessels are always very large and abundant. They seldom have normal vascular walls, and on section appear as spaces between the cells. Only the larger ones are surrounded by any connective tissue. Along these vessels, and generally throughout the tumor, blood extravasations are common. The connection of the tumor with the surrounding tissues is a very close one, and it is often difficult to say just where the tumor ends. The most striking resemblance between this tumor and an inflammatory focus is often seen. These round-cell sarcomas are very malignant; they grow rapidly and diffusely, invading the surrounding tissues, and produce metastases. When the cells are large and have more the appearance of epithelial cells, the malignant course is not so pronounced. Most of the tumors known as encephaloid come under the head of round-cell sarcomas. The term encephaloid refers simply to the pulpy, brain-like character of the tumor, due to the number of the cells and the softness of the material between them.

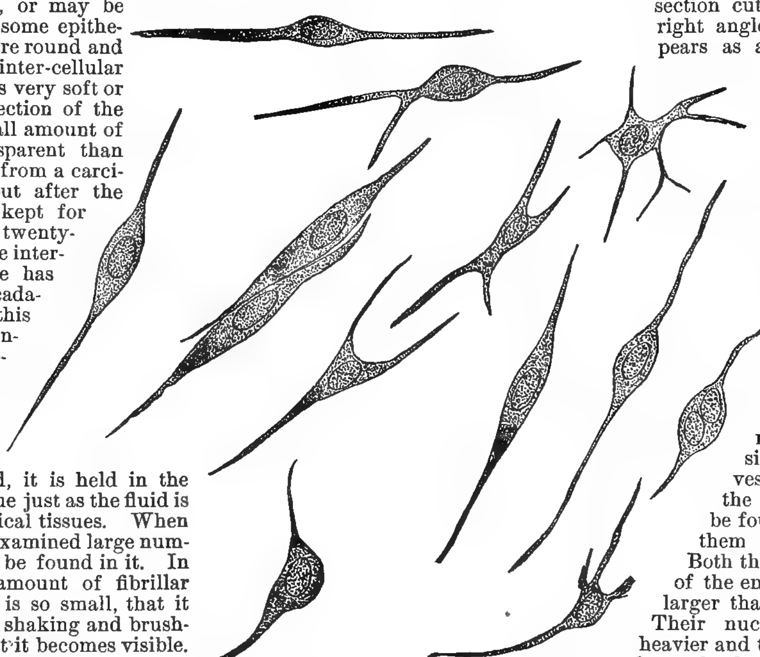

FIG. 3376.—Cells from a Spindle-cell Sarcoma of the Periosteum; isolated by maceration in Müller's Fluid. × 300.

The spindle-cell sarcoma is more frequently met with than any other form, and this tumor has been generally regarded as the type of the sarcoma. The tissue of the tumor is arranged in fasciculi, and this is so evident that it has given rise to many of the names which the tumor bears. This arrangement into fasciculi can best be studied by roughly tearing apart tumors which have been hardened in alcohol. The trabeculæ are composed of spindle-cells and fibrils, all running in the same direction. Often several of these fasciculi seem to arise from the same point, and take a more or less spiral course. They run through the tumor in every direction, and are sharply separated from one another. Sections made through the tumor cut them in every plane. When the section cuts one of them at a right angle, it no longer appears as a spindle, but as a round cell. A blood-vessel generally traverses the centre of one of these bands, and in its walls every transition between the thin wall of a capillary and the thicker wall of an artery or vein can be seen. The smaller of them consist of endothelial tubes, the cells composing which can be seen without treatment with nitrate of silver. Besides these vessels passing through the bundles, others will be found which surround them like a long spiral. Both the cells and the nuclei of the endothelium are much larger than in normal vessels. Their nuclei, especially, are heavier and thicker, they project above the level of the cells, and are seen in the lumen of the tube as slight elevations. As a rule, these blood-vessels are much wider than vessels of a corresponding structure in normal tissues. Either the entire vessel may be wider, or there may be dilatations at intervals, which may reach a considerable size. The spindle- or oat-shaped cells, of which the tumor is principally composed, early attracted attention when the histological structure of tumors began to be the subject of systematic study. For a long time they were considered as characteristic of the sarcomas and of the malignant tumors in general. These cells are not always pure spindles in shape, but often show various transitions approaching the stellate form. They consist of an elongated mass of protoplasm, which at each extremity runs out into a long, thin process. Sometimes two or more processes are given off from a single extremity, and these in turn may have lateral processes. The surface of the cell is rarely perfectly round and smooth, but is indented in various ways, and may be flattened into a membranous form. The protoplasm of the cell is finely granular, and more refractive than that of the white blood-corpuscle. Occasionally one or more fat drops are found in a cell. The nuclei are ordinarily visible without the aid of acetic acid or any coloring agent. They lie in the

middle of the cells and occupy the entire body of the cell at this point. Rarely more than one nucleus is found in a single cell. The cells are not always of the same size, even in the same tumor. The smallest of them are about 15 μ long and 5 μ broad, while in other cases they are 100 μ long and 15 to 30 broad. This difference in the size of the cells has led to a division of the tumor into large and small spindle-cell forms. In general the cells are smaller in those tumors which have the most rapid growth, or in those parts of a tumor where the growth is most recent. The cells all lie in the same direction in the bundles, dovetailed into one another, with the largest part of one cell in contact with the smallest part of its neighbor. In a perfectly fresh tumor it is difficult to separate the cells from each other. A certain amount of fibrous tissue is always to be found in these tumors, and even in the bundles where the cells lie thickest careful observation will show some fibrils between the cells. These fibrils often appear to be in direct continuity with the cells. The name fibro-plastic was given to this tumor on account of the supposed tendency of the spindle-cells to form fibres. Bands of connective tissue in which the cells are very numerous, are sometimes found between the larger cell-bundles. The slower the growth of the tumor, the more connective tissue is found in it. The spindle-cell sarcomas vary much in density, but are always much firmer than the round-cell form. Some of them are fully as hard as a myoma, and on section resemble this very much. The firmness of the tumor depends upon the amount and character of the intercellular substance. In the fresh state the cells are difficult to isolate, and on scraping the cut surface a clear, transparent fluid, containing but few cells or fragments of cells, will be obtained.

The myeloid sarcomas are soft tumors whose tissue is similar to that of the embryonic bone marrow. The cells lie in close relation with each other, and the intercellular substance is small in amount and more or less fluid. Some of the cells are small and spherical, like those of embryonic bone marrow, and like the early embryonic cells in general. They have little protoplasm in comparison to the size of the nucleus, and are similar to those described in the encephaloid sarcoma. Sometimes numerous spindle-cells are found, but these have not the definite arrangement into bundles that is found in the spindle-cell sarcoma, and their processes are not so long. There are other cells, which though sometimes met with in other species of sarcoma, more properly belong here. These are large protoplasmic masses containing a great number of nuclei, frequently one hundred or more, and have received the name of giant cells. They are found in considerable numbers in embryonic bone marrow, but never reach the size that is met with in tumors. They may be round, or oblong, or irregular in shape, and provided with numerous processes. The nuclei are sometimes arranged at one or both ends of the cell, or may be packed closely together in the middle. They are rarely scattered evenly through the cell-substance. The typical arrangement of the nuclei along the periphery of the cell, with their long axes pointing to the centre, which is so often found in giant cells elsewhere, notably in tubercles, is seldom found here. These cells may fall from their places in sections, and the empty spaces which were occupied by them may give the tissue an alveolar appearance. It is not uncommon to find them in great numbers in one part of the tumor, while other parts may not contain them at all, or only isolated examples scattered here and there in the tissue. The nuclei of these cells are large and refractive, and in most cases can be seen without the aid of any reagent. The cell-substance itself is composed of a thick, finely granular material, which frequently has a slight yellowish or greenish tinge; in these cases the cell may be so dense that the nuclei only appear when the protoplasm has been rendered more transparent by acid. The size which these cells frequently attain fully justifies their name. They may reach a diameter of one-fifteenth to one-tenth of a millimetre or more, and can be seen with the unaided eye. Although most frequently found in the myeloid sarcoma, they are often found in the other varieties also, especially in the spindle-cell sarcoma. The myeloid sarcomas are almost always seated in a bone, and originate in the marrow. They gradually destroy the bone, but as the tumor grows a new capsule of bone is formed around it.

Osteo-sarcoma. See Osteoma.

Alveolar sarcoma. This name was first used by Billroth to designate certain sarcomas whose histological structure somewhat resembled the carcinomas, in that the cells were grouped together into alveoli. So striking is the similarity to carcinoma, that Billroth himself says that in many cases he is unable to make the differential diagnosis. It has been contended by many pathologists that the term was a misnomer, and that any tumor of such a structure must be a carcinoma. However similar the structure of the two tumors may be, a careful investigation will always show points of difference. In the strictest sense, no sarcoma has the alveolar structure of the carcinoma. Still, tumors which certainly originate in the connective tissues, and which, from their general structure, must be regarded as connective-tissue tumors, are occasionally met with, which, on a superficial examination, appear to have an identical structure with carcinoma. The cells are round or irregular in shape, are very similar to epithelial cells, and are arranged in groups which are surrounded by connective tissue. These groups of cells may be smaller or larger in the different tumors, and the connective tissue also varies in amount. In all cases the tissue around the groups of cells is richer in cells than ordinary connective tissue, and may be composed of spindle-cells. On closer examination it will be found that the connection between these groups of cells and the tissue around them is much closer than is the case in carcinoma. When thin sections are made of carcinomas which have been hardened in alcohol, it will be found that in many cases the groups of cells have fallen out in the manipulation of the specimen, or have shrunken, leaving the connective tissue around them as a sharp, clear line. On shaking such sections in a test-tube with water, or carefully brushing them, it is possible to remove all the groups of cells, leaving the connective-tissue framework intact. In specimens which have been injected, it is never possible to follow a blood-vessel into an alveolus. In the alveolar sarcoma the case is different. It is never possible to remove the cells as completely and easily as can be done in a carcinoma. After brushing the specimen to remove as many of the cells as possible, it will be found that fine filaments of connective tissue enter into the apparent alveolus, and in some cases every cell is enclosed in a delicate meshwork. This is much better seen when the section is examined in water, as the fine fibrils are more refractive in this than in any other medium. The difference between the two tumors is also apparent from a careful macroscopic examination. On scraping or squeezing the cut surface of an alveolar sarcoma, a juice will be obtained which is never so abundant as that which comes from a carcinoma so treated, and on microscopic examination of this juice, numerous cells of various shapes and sizes will be found in it. The compact groups of cells so often found on examination of the juice from a carcinoma, and which evidently represent the contents of an alveolus, will not be found. These tumors are very vascular, the connective tissue between the alveoli contains numerous large blood-vessels, and fine capillaries given off from these penetrate the alveoli. The tumor is frequently found in the testicle, and the soft and rapidly growing tumors of this organ generally belong to this variety.

The most malignant of the sarcomas, and in many respects the most malignant tumor that is met with, is the pigmented sarcoma, the melano-sarcoma. This is characterized by the presence of a dark pigment, similar to that in the choroid of the eye, in the cells. The melanotic sarcomas, as a rule, appear only in places where some pigment in the connective tissue is normally present, as in the choroid of the eye and in the skin; they have also been seen in the lymphatic glands. Other sarcomas containing pigment may be mistaken for these

tumors. Hæmorrhages are common in every variety of sarcoma, and the blood-pigment which results from this and is taken up by the cells may be mistaken for the essential melanotic pigment. In these cases, besides the pigment in the cells, some will be found free. This free pigment either results from the breaking down of cells which contained it, or it is formed by a metamorphosis of the blood-pigment which has taken place, not in the cells, but in the interstitial tissue. In both this accidental and the essential autochthonous pigmentation, the pigment-granules may be brown or dark-brown, and in some cases it is not easy to decide, except by a careful examination, what the nature of this pigment is. In the melanotic sarcoma in course of development, all of the cells are not impregnated with pigment, and in no case do all the cells of the tumor contain this pigment in equal amount. As a rule, a section of such a tumor will show various zones of coloration, the color being deeper in those portions of the tumor which must be regarded as the oldest. The oldest portions are black, and the younger portions on the edge of the growth may be only brownish or not pigmented at all. Although this partial pigmentation is the rule, some tumors are found which are black in their whole extent. The pigment-granules are most often disposed around the nucleus, but they may fill up the entire cell. No pigment is ever found in the nucleus. The pigment which results from a metamorphosis of blood coloring matter usually has a reddish tinge, which is absent in the true melanotic pigment. The cells of these tumors have no particular arrangement or form. The tumor may present the most typical appearance of a spindle-cell sarcoma, but as a rule they belong to other forms, the arrangement of the cells into alveoli being especially frequent. When such tumors are scraped a blackish, often inky, fluid is obtained, which contains many pigmented cells, but also free pigment-granules in great numbers. These free granules have an active molecular movement. The source of this pigment is a subject which has for a long time occupied the attention of pathologists. In the consideration of this question, the fact that the tumor rarely originates in tissues except those in which pigment is normally present, is of the first importance. As we have said before, the favorite places of origin are the choroid of the eye and the skin. It does not appear primarily in the other pigmented tissues of the body, as in the liver, the supra-renal capsules, and the seminal vesicles. The pigment is very similar to that found in the connective-tissue cells of the corium in the negro race. Virchow believes that the pigment is formed in the cells themselves as the result of their own metabolism. This view is the one in favor of which most facts speak, and is the view most generally accepted. Gussenbauer, on the other hand, believes that the pigment is formed directly from the blood-pigment, and calls attention to the frequency with which hæmorrhages are found in such tumors. Most strongly against this view speaks the fact that the secondary tumors always show the same sort of pigmentation as do the primary. In no tumors are such minute metastases found as in these, some of the secondary growths being composed of but a few dozen cells, and being evidently of such a recent date that sufficient time would not have been given for the formation of pigment from blood extravasation, even were extravasation present. Besides this, blood extravasations cannot be said to be more common in the melanotic sarcoma than in any other. Akerman, in his interesting monograph on sarcoma, has called attention to the situation of the pigment in Addison's disease, and of the pigment which is often found in the skin of certain parts of the body of dark-skinned people. These pigment-cells lie in the neighborhood of the small vessels of the skin, are of long spindle shape, and contain a diffuse or granular brown coloring matter. He supposes that these pigment-cells are specific and have no connection with the ordinary cells of the connective tissue, and that the melanotic tumor may arise from a proliferation of these cells. In the skin the tumor most often originates from small, congenital, pigmented nævi. Many of these, which are to all purposes perfectly benign, show on section the most typical sarcomatous structure. In connection with these tumors, Virchow calls attention to the melano-sarcomas in horses. It is a well-known fact that white and gray horses are especially subject to these tumors, which appear principally on the tail or around the anus. The tumors have not the malignant course that similar tumors have in man, and ordinarily do not reappear after com-

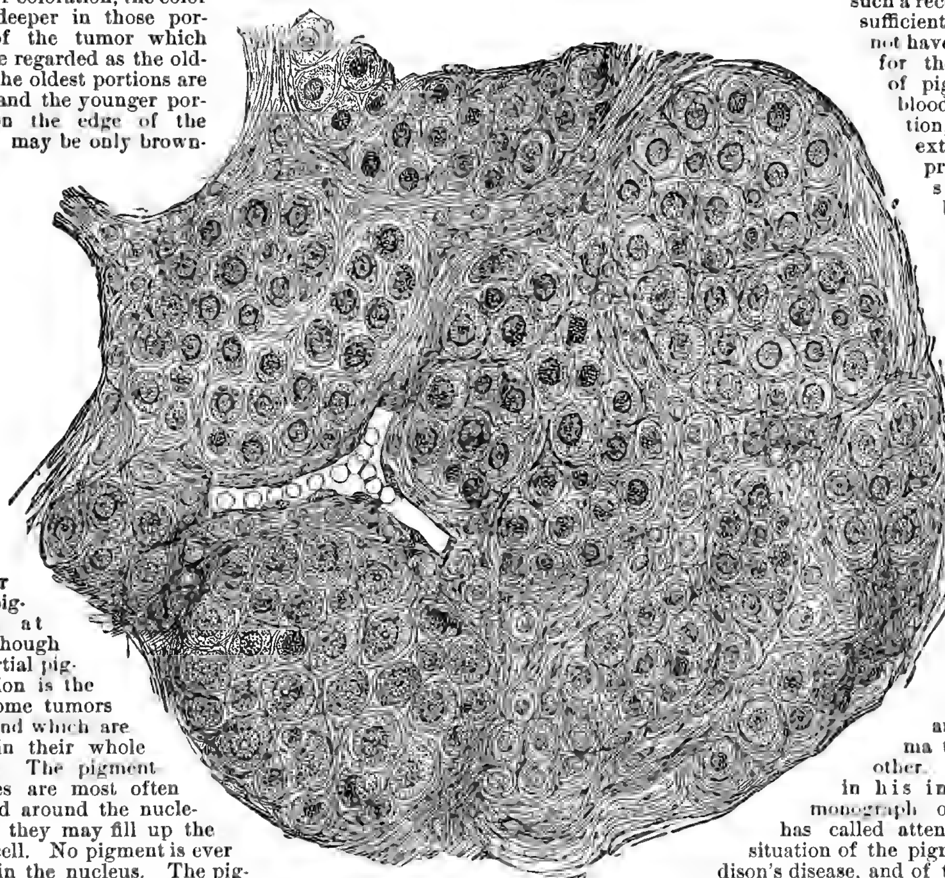

FIG. 3377.—Section of an Alveolar Sarcoma of the Testicle. × 400.

plete excision. A tendency to the development of these tumors is transmissible in high degree, especially by the stud; the offspring, both male and female, especially those of a whitish color, being liable to it. Virchow sees in the absence of color in such horses a weakness or lack of resistance in the skin.

The angio-sarcoma is a tumor formed by an extensive development of blood-vessels and a sarcomatous growth of their walls. The tumor appears to be made up of long filaments, which are loosely attached to each other and may be isolated for considerable distances. Each filament contains a blood-vessel in its centre, and around this an extensive formation of cells. There is no distinct wall to the vessel, save that formed by the tumor cells. The cells are distinctly epithelial in appearance, and are divided into groups by the formation of capillaries. This tumor may develop in any part of the body, grows rapidly, reaches a large size, and is very malignant. The metastases which result from it have the same general structure as the primary tumor, but the arrangement of the blood-vessels with the cells surrounding them is not so well marked.

After this description of the histological structure of the different forms of sarcoma, we will consider the tumor more as a whole, especially its macroscopic characters, most frequent seat, clinical course, etc.

The growth and the general clinical characters of the sarcoma are so different in the several forms that we can find in this group of tumors representatives of completely benign as well as of the most malignant growths. Beyond doubt, in this regard, the separate varieties of the tumor have individual characteristics. The pigmented sarcomas may be regarded as the most malignant of tumors, not only on account of their local destructiveness, and rapid and unlimited growth, but also from their tendency to form metastases. The small-cell encephaloid varieties are but little behind these in malignity. The osteo-sarcomas come next, and the spindle-cell and myxo-sarcomas are in general only malignant locally. The spindle-cell sarcoma is the more malignant the smaller are its cells, and the more numerous they are in proportion to the amount of intercellular substance. As a rule, it does not form metastases, but cases in which extensive secondary growths appear are not uncommon. When the sarcomas are compared with the other tumors of the connective-tissue type, it is evident that they have a much greater malignity, and this is shown in all by their tendency to return after extirpation. This tendency to local return, even in cases in which the entire tumor and much of the surrounding apparently healthy tissue have been removed, shows that the sarcoma is not a sharply circumscribed growth. The microscopic investigation of the periphery of sarcomatous tumors will often show that the tumor-cells have entered much more deeply into the surrounding tissue-spaces than is apparent on a mere macroscopic examination. The cells not only have an extreme degree of proliferative energy, but the tissue of the sarcoma, which is so much looser than that of any typical connective-tissue tumor, favors this outward growth of the cells. In addition to this direct outgrowth of the cells into the tissues, it is very probable that the cells of many sarcomas have the power of amœboid movements. This would explain the presence of small foci separated by a greater or less interval from the parent tumor. Virchow advances the view that the sarcoma cells can excite the cells of the tissues with which they come in contact to a similar growth. This can take place both about the original tumor and in those places where the cells may be carried by the blood and lymph currents. Most of the recent authors do not accept this view as to the mode of formation of secondary tumors, but believe that these result from a direct growth of the cells or collections of cells which have been carried from the tumor and deposited in distant organs. The power of the sarcomas to produce secondary metastatic nodules in the most different organs is not confined to any special species, though some show a much more decided tendency in this direction than others. In some cases the secondary nodules are of such small size, and appear in so many places in the body, that the condition is known as sarcomatosis. These nodules, from their very small size, may be mistaken for miliary tubercles. The path of the metastases is almost always along the blood-vessels, the sarcoma in this again contrasting with the carcinoma, in which metastases follow the lymphatics. Although this mode of infection is most common in sarcoma, there are exceptions in which the lymph-glands are early infected. This is notably the case in sarcoma of the bones. The course that the metastasis usually takes is easily explained, when we consider how intimate the relation is between the cells of the tumor and the blood-vessels, the latter being in many cases without essential walls, and representing little more than channels between the tumor-cells. It is by no means rare to find a sarcoma growing directly into a large vein, and it may extend in this for a considerable distance as a long, fleshy polypus, moving freely in the blood-stream, and apparently nourished by the surrounding blood. Billroth mentions a case in which a sarcoma of the testicle grew into the spermatic veins, some of its cells being carried thence through the inferior cava into the heart, and producing numerous metastases in the lungs. As we should suppose, metastases are most commonly found in the lungs, and next in the order of frequency come the spleen, the kidneys, and the liver. Infection of these organs is generally secondary to infection of the lungs. The metastases are often much larger than the primary tumor, and are the most frequent cause of death.

The clinical importance of a sarcoma does not depend altogether upon the histological structure. The seat of the tumor is of great importance, for it is evident that, when seated in an organ whose functional activity is necessary for the life of the individual, the tumor may be very dangerous, even when it does not show any special tendency to the formation of metastases. The glio-sarcomas of the brain are malignant, though they are always confined to this organ. It is also well known that the mediastinal tumors are dangerous in consequence of the pressure on the great blood-vessels which they exert. This primary danger of the tumor in great part depends upon the rapidity of its growth. In general, it may be said that the growth is most rapid, and the tendency to metastases strongest, in those tumors in which the cells are smallest and most abundant. This growth may be restricted in various ways by the local relations of the tumor. The sarcomas of the bone grow slowly, and do not produce metastases as long as they are surrounded by the bone; but when the surrounding osseous tissue is broken through, they show a very rapid growth and produce metastases.

Although, from what has been said, it is seen that the sarcomas have a greater clinical malignity than the other tumors of the connective-tissue type, still, in comparison with the carcinomas, they may almost be considered benign. This is shown, apart from the lesser tendency of the sarcoma to metastases, in the influence which the two types of tumors respectively exert on the general constitution. A condition known as the cancerous cachexia is the ordinary result of a carcinoma, even when it is confined to a single organ, while an enormous sarcoma will not ordinarily produce such a condition. This difference is in great part due to the lesser tendency of a sarcoma to ulceration, and to the fact that the degree of pain experienced from the sarcoma cannot compare with that produced by the carcinoma. This lesser tendency to ulceration may be explained by the abundant vascularization of the sarcoma, and by the slight tendency of its cells to degeneration. In still another way is the minor malignity of the sarcoma, in comparison with the carcinoma, manifest. Even those sarcomas which are shown to be very malignant in their later course by a general extension in the body, have a primary period when they may almost be regarded as benign. The carcinoma, on the other hand, from the moment it first appears and can be recognized as being such, is malignant, and shows this by the early infection of those lymphatic glands which stand in relationship to it. The sarcoma in its beginning may be a perfectly circumscribed tumor, but the carcinoma never is.

The benign period of the growth of a sarcoma is shown by its slow and circumscribed growth. In this early benign period the entire tumor is often enclosed by a connective-tissue capsule, and in those developing in bone this connective-tissue capsule may be substituted by an osseous capsule. The rapidity of the primary local growth varies in the different species of sarcoma. In many cases the growth is so rapid that we are reminded more of the extension of an inflammatory process than of the growth of a tumor. The tumor itself, in these cases of primary rapid growth, is generally a round-cell, encephaloid sarcoma, and may be very similar, even in its histological structure, to an inflammatory focus.

This primary benign period that a sarcoma passes through is of great clinical importance, and shows that the tumor should be removed as early as possible. In this removal care should be taken not only to remove all of the tumor that is apparent, but a considerable amount of the surrounding tissue as well. Even when this appears to be unaffected, it may contain, at a comparatively early period in the history of the tumor, long prolongations of tissue extending from the tumor. Any of this tissue left behind will serve as a point of departure for a returning growth. The known tendency of the sarcoma to return, after apparently complete extirpation, is only to be explained by imperfection of its removal. When a sarcoma is seated in the marrow of bone, it is impossible to say how high up the marrow is affected, and in this case disarticulation is a better operation than amputation.

The seat of the sarcoma is most often found in the skin and subcutaneous tissue. In the intermuscular and muscular connective tissue, in the fascia, and especially in the periosteum, the spindle-cell sarcoma is a very common tumor. Other varieties of the sarcoma show an especial predilection for certain tissues, as the melanosarcoma for the eye. The alveolar sarcoma is most often found in the testicle. Among the most interesting sarcomas, from a histological point of view, are those which develop in glands. These almost always include some of the glandular elements, which undergo various changes of form. In general, glandular structures show a comparative immunity from the development of sarcoma, though there are exceptions to this rule. The female breast is often attacked by sarcoma, which forms here large, round, lobulated growths, often very elastic to the touch. The tumor grows slowly, causes little or no pain, and is separated from the remainder of the gland. On section, small fissures are seen in the tumor, and often a mass of tumor-tissue will project like a polypus into one of these fissures, and be almost surrounded by it. On microscopic examination these fissures are found to be lined with epithelium, and are certainly formed by the dilated and flattened glandular ducts. The entire tumor may be enclosed in one of these fissures. Cysts formed both by degenerative processes in the tumor, and by an accumulation of secretion in gland-ducts, may be met with. The growth of these tumors is a very slow one, and is painless except when they attain a very large size. Many of them have the peculiarity of swelling up and becoming more painful during the menstrual period. Return after extirpation is not to be feared in young patients, but it may occur in patients thirty or forty years of age or older. Sarcomas also appear in the salivary glands, especially in the parotid, and here they are accompanied by a growth of the epithelium. The inner surface of the dura mater, and the substance of the brain or spinal cord, may be the seat of sarcoma. In the cord they may be multiple, one case having been seen by the writer in which four tumors, which varied in size from a small pea to a bean, were found at various places along the cord. The largest, which reached the size of a bean, was found in the cervical swelling, completely enclosed by the cord.

Concerning the etiology of sarcoma, what little there is to be said will be found in the article on Growths. It is an interesting fact that those tumors whose structure is most like very early embryonic tissue are most malignant.

W. T. Councilman.

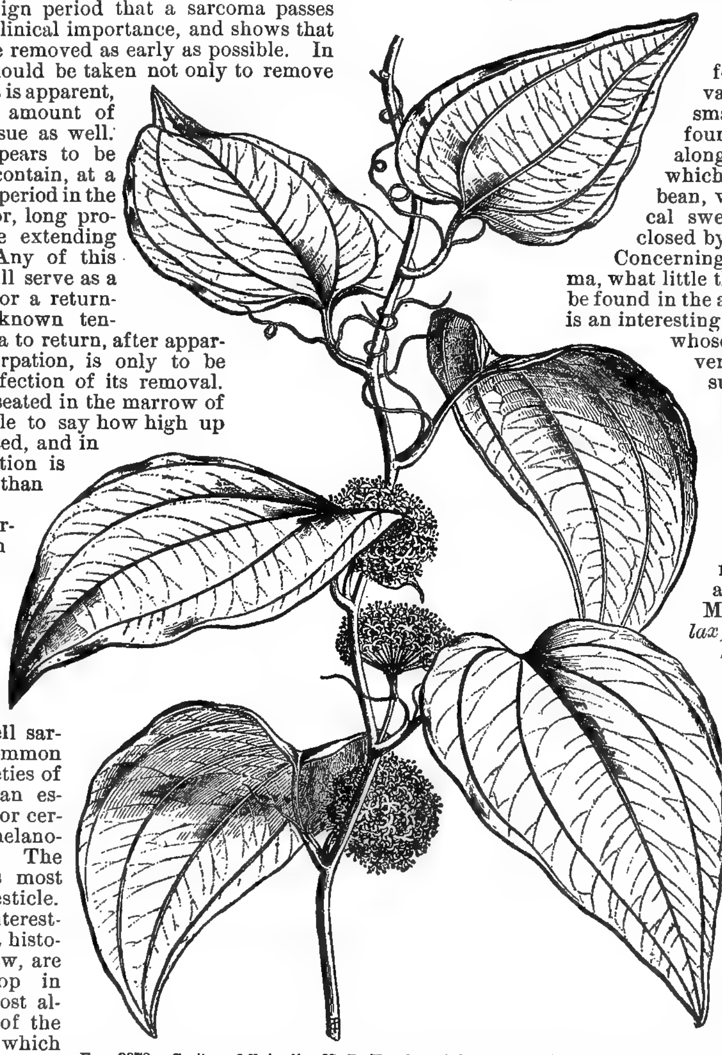

FIG. 3378.—Smilax Officinalis, H. B. K., the origin of Jamaica sarsaparilla; male plant. (Baillon.)

SARSAPARILLA, U. S. Ph. (*Sarsæ Radix*, Br. Ph.; *Radix Sarsaparillæ*, Ph. G.; *Salsepareille*, Codex Med.). The long, cylindrical roots of several Central and South American or Mexican species of *Smilax;* order, *Liliaceæ* (tribe, *Smilaceæ*). The Smilaxes are perennials, with woody, often very long and slender roots, and generally with tough, woody (rarely herbaceous), climbing or wandering stems. These are generally green and smooth, or pubescent, round, square, or several-angled, and armed with strong, flattened, recurved, sharp prickles. The leaves are alternate, generally two-ranked, petiolate, with, in most species, a long, strong tendril, arising on each side of the petiole below the middle. Blade usually oval, ovate, or heart-shaped, from three- to five-nerved, reticulate between the principal nerves; often coriaceous, and evergreen. Flowers small, greenish-white, in axillary umbels, diœcious or polygamous; perianth three- to six-parted (or more). Stamens in the male flower usually six, attached to the bases of the sepals; anthers introrse, apparently one-celled; pistil rudimentary—in the female flower, pistil three-celled, with two (or one) ovules in each cell; staminodes six, three, or variable. Fruit, a one- or two-seeded berry. The genus contains toward two hundred species of tropical or temperate plants, some of which make the most impenetrable

underbrush. Some are not spiny, a few are not climbers, and a smaller number have herbaceous, annual stems. The genus is well represented in the United States by toward a score of species, among which *S. rotundifolia* Linn., the common Greenbrier, and *S. herbacea*, the Carrion Flower, with its horribly fetid odor when in bloom, are familiar examples. The former is a very good representative in appearance and habit of the medicinal Smilaxes. Of these, it is surprising how little exact knowledge we have; specimens have been collected of most of them, but never in bloom, and the botanical details are therefore wanting, so that how much the different varieties of the drug owe to difference in species, and how much to difference in climate or cultivation, cannot in all cases be said.

1. *S. officinalis*, a large, coarse, woody climber, with a short, thickened rhizome, whence are given off numerous long, cylindrical, horizontal roots, and several or many round, erect stems, soon becoming more or less angled, and branching into quadrangular, very long, flexuose, climbing branches, armed with stout, sharp prickles. Leaves very large, or smaller on the upper portions of the plant, round, heart-shaped, ovate, or broadly lanceolate; in short, it is like a gigantic greenbrier. It is a native of New Granada, and appears to be the plant introduced into the West Indies. It probably yields "Jamaica Sarsaparilla." Female flowers and fruit not seen.

2. *S. medica* Cham and Schl., a large climber, with mostly unarmed angular branches, and frequently auriculate or lobed leaves. It grows in Mexico, and supplies the Mexican variety.

S. papyracea Poiret, with a many-angled stem; flowers unknown; of Guiana and Brazil; may be the source of Para Sarsaparilla, etc. Of several other imperfectly known species there is a suspicion of probable connection with the drug, but no certain knowledge.

Sarsaparilla was first carried to Europe about 1536–45, and first or early employed as a cure for the same disease with which it has been since most generally associated, and for which another smilax, "China," had previously been used. The use in numerous other slow diseases, especially in eruptions and as a "blood-purifier" in general, followed, and has continued extensive until the present time. Although now it has been nearly discarded as a serious medicine by physicians, it is still a much-prized popular remedy.

Collection.—This has been observed several times, and consists in selecting clumps where numerous stems indicate plenty of roots, clearing away the dirt and other roots around them, and carefully digging up the long, whip-like sarsaparilla; the crowns and remnants are then covered with dirt and leaves, and left to sprout again, or in some countries collected with the roots. The collected roots are simply dried and packed in more or less characteristic bundles.

Description.—Sarsaparilla comes in long, simple, or sometimes forked, longitudinally wrinkled (when dry), flexible, slender, rope-like roots, in some varieties thicker in the middle than at either end, often one or two metres in length, and from two to five or more centimetres in diameter; surface light or dark brown, with scattered fine roots, and sometimes short, velvety hairs. The rhizome—a dark, irregular, woody "chump"—is present in some varieties. The roots vary considerably in their plumpness, owing to a very variable amount of starch in their tissues, which fact has given rise to their division into two general groups: *a*, Starchy, or mealy—Honduras, Guatemala, Brazilian, Para, etc.; *b*, non-starchy—Jamaica, Mexican, Guayaquil, etc. There is no important difference in their medicinal qualities, but the non-mealy varieties are darker and rather stronger-tasting. These varieties are more easily told sometimes by their mode of packing than by their individual appearance.

Honduras Sarsaparilla is pretty plump and smooth, with more or less "beard." Near the middle the roots contain a thick zone of white, starch-laden tissue. They are packed in hanks seventy or eighty centimetres long, wound with a flexible root, and bound in bales with hide. *Guatemala Sarsaparilla* is yellowish, with a brittle bark. *Brazilian* comes in very large, long, closely wound bundles, cut smooth at either end. "Jamaica Sarsaparilla" (the most esteemed in England, and from Central America, instead of Jamaica), is in short bundles, half a metre or so long, rather carelessly done up, wound like the others by a long, flexible root of the same; it is a slender, deeply furrowed, dark root, brown within as well as without. *Mexican* is pale, not made into bundles, and often contains also the chumps and bases of stems. *Guayaquil* comes loose in large bales. It has a large, coarse-looking root, accompanied also by the rhizomes and some stem-bases.*

The histology of Smilax roots has been studied with more care and detail than their unimportance deserves. (See Berg's "Atlas zur Pharm. Waarenkunde.")

The (endogenous) woody portion is collected in a central core, and surrounded with a false bark of thin-walled, parenchymatous, starch-laden cells, of varying, often considerable, thickness. The woody column consists of a parenchymatous centre of thin-walled cells, surrounded by a progressively increasing number of scattered woody and vascular bundles, compacted into a hard, porous wood near the circumference of the column.

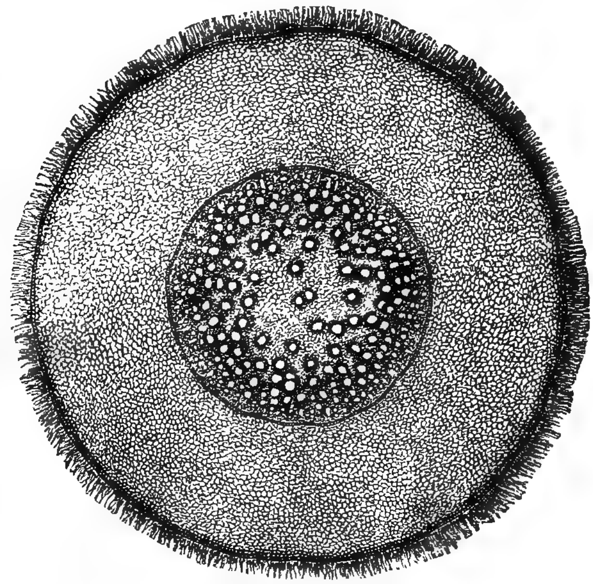

Fig. 3379.—Root of Smilax Officinalis, Enlarged Section. (Baillon.)

Composition.—Most earnest attempts have been made to find a tangible and useful active principle in Sarsaparilla, with only partial success. *Starch* in most varieties is abundant, but unimportant. *Essential oil* in minute quantity, a little *resin*, "*extractive*," etc., may have some value, but the most characteristic substance is *parillin*, of which about two per cent. may be obtained. It crystallizes in white scales or needles, permanent in the air, neutral, odorless, at first tasteless, but afterward bitter and acrid; but little soluble in either cold water or alcohol, freely so in hot. It is more soluble than in either alone in a mixture of alcohol and water. Parillin is a glucoside, yielding *parigenin* and *sugar* if treated by dilute mineral acids (Flückiger). Parillin is, as yet, of doubtful composition, but is nearly related to *saponin*.

Action and Use.—This paragraph will seem short compared with the preceding descriptions. Parillin, in doses of half a gram or so, produces nausea, vomiting, and retardation of the pulse; in larger doses, constriction in the throat, weakness, sweating. It has been tried to a slight extent in syphilis, without marked results (Husemann). Sarsaparilla itself, in large doses, only produces

* Hanbury and Flückiger.

gastric disturbance, so from the physiological action of this remedy little therapeutic value can be predicated, and it probably has not much. Yet, on the other hand, not only this, but other products of Smilax (China, Eastern Sarsaparilla, etc.) are used the world over for syphilitic and scrofulous diseases, in the United States perhaps less seriously than elsewhere. It does seem possible that Sarsaparilla in fair doses is beneficial in some cases of dyspepsia or mal-assimilation arising from winter diet or improper food, and hence its popularity in "Spring medicines;" but the bitters in general, and some laxatives (Gentian, Dandelion, Frangula, etc.), are equally or more efficacious. Its use in "scrofula" is diminishing. In syphilis it is still a good deal prescribed, especially in England, India, etc.

ADMINISTRATION.—Smilax is never given in substance, but the theoretical dose may be stated as from four to eight grams (ʒ j.–ʒ ij.). The best preparations are the Fluid Extract (*Extractum Sarsaparillæ Fluidum*, U. S. Ph.), strength, $\frac{1}{1}$; the Compound Fluid Extract (*Ex. Sarsaparillæ Comp. Fluid.*, U. S. Ph.): Sarsa., 75; Glycyrrhiza, 12; Sassafras, 10; Mezereum, 3; Glycerin, 10; alcohol and water enough to make 100; strength, $\frac{1}{1}$; the Compound Decoction (*Decoctum Sarsaparillæ Comp.*, U. S. Ph.): Sarsa., 10; Sassafras, 2; Guaiacum, 2; Glycyrrhiza, 2; Mezereum, 1; water enough to make 100; strength, $\frac{1}{10}$, and the Syrup, more used than the others, because used as a vehicle. It is composed as follows:

Sarsaparilla	150	parts.
Guaiacum	20	"
Pale rose	12	"
Glycyrrhiza	12	"
Senna	12	"
Sassafras	6	"
Anise	6	"
Gaultheria	6	"
Sugar	600	"

Water and diluted alcohol enough to make 1,000 parts. The Infusion and Fluid Extract are the best forms where full doses are to be given.

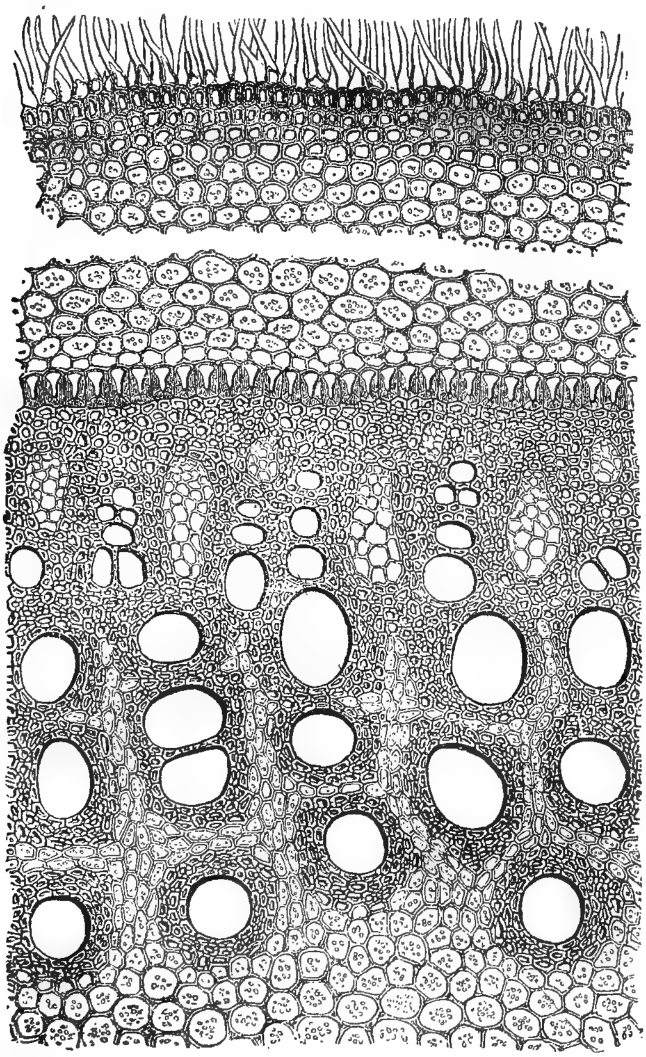

FIG. 3380.—Magnified Section of One-half Diameter of Root of Smilax Officinalis. (Baillon.)

ALLIED PLANTS.—The suborder *Smilaceæ* forms a rather distinct division of the great modern group collected under the name *Liliaceæ;* it includes but little more than the great genus *Smilax* described above. China Root, from *Smilax China* Linn., in large, Jalap-like tubers, is used in the East for the same purposes as sarsaparilla. For the order, see SQUILL.

ALLIED DRUGS.—In the treatment of syphilis and scrofula, and many of the conditions for which Sarsaparilla was once highly esteemed, Mercury, Iron, and Iodine have long since taken the principal place. There is, however, a long list of dubious remedies from the vegetable kingdom, which have a reputation, mostly local, as "alteratives," or anti-scrofulous and anti-syphilitic substances; few of them are more than household drugs. China, just mentioned, Hemidesinus or Indian Sarsaparilla, our False Sarsaparilla, are among them. Guaiacum, Mezereum, etc., are more generally used; Colchicum, Stillingia, Sanguinaria, Chelidonium, Dulcamara, and Arsenic also help to fill up this heterogeneous collection. *W. P. Bolles.*

SARSAPARILLA, FALSE, *Aralia nudicaulis* Linn., order *Araliaceæ.* This little plant, generally known among country-folks and herb-gatherers as "sarsaparilla," has no botanical relation whatever to the preceding drug; in taste and in the shape and size of the roots there is a little similarity. It consists of a long, slender, perennial root, about as large as a pipe-stem, and two or three metres in length, with a light-brown surface and soft, flexible texture. It has a rather pleasant, aromatic odor, and an aromatic, somewhat sharp taste. The stems, which arise at intervals of from twenty to fifty centimetres, are only one or two centimetres long, barely emerging from the ground, and give rise, each, to one twice ternately or quinately compound leaf, and one three-branched scape supporting three globular umbels of small greenish-white flowers. This *Aralia* is common in moist places over most of the United States, and is in some popular demand for the same complaints that sarsaparilla is reputed to benefit. Dose indefinite. Composition not known.

ALLIED PLANTS.—The genus contains thirty species, mostly Asiatic, of herbs, or rather shrubs, of mild, indefinite medical properties. *A. racemosa* Linn., American Spikenard, and *A. quinquefolia* D. & P., American Ginseng, are other native species employed in popular medicine. The Ivy (*Hedera Helix*) also belongs in the family.

ALLIED DRUGS.—See SARSAPARILLA.

W. P. Bolles.

SASSAFRAS, U. S. Ph.; Codex Med. (*Sassafras Radix*, Br. Ph.; *Lignum Sassafras*, Ph. G.). *Sassafras officinale* Nees, one of the very few plants of the Laurel family growing wild in this country, is a medium- or

good-sized tree, or, near the northern boundary, a shrub or small tree, with irregular, spreading, brittle branches, covered like the trunk with rough, furrowed bark, gray without, fawn-colored or pinkish when freshly cut, within. Wood light-colored, with darker heart. Twigs and smaller branches bright green, glossy; pith large, very mucilaginous. Leaves bright-green, smooth, oval, pointed at each end or blunt at the apex, entire, or else, especially those coming later in the season, deeply three-lobed; between these shapes are various intermediate ones, lobed on one side, and not on the other, or merely auriculate on one or both sides. Both kinds of leaves are usually seen on the same tree. Flowers vernal, appearing with the leaves, in small racemes; small, regular, diœcious, yellow. Perianth six-parted. Stamens nine; the three inner ones glandular at the base; anthers four-celled, each opening by means of a little valve. Pistil one, one-celled, with one pendant ovule. In the staminate flowers the pistil is rudimentary; in the pistillate ones there are six sterile stamens. Fruit a blue berry, on a reddish, cup-shaped receptacle. All parts of the tree are fragrant, especially the bark of the root; the growing parts contain also considerable mucilage.

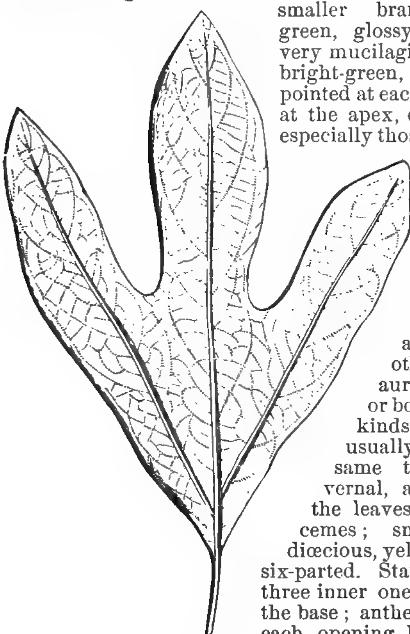

FIG. 3381.—One of the Three-lobed Leaves of Sassafras. (Baillon.)

Sassafras has a wide range over the United States, extending slightly into parts of Canada, etc. In many regions it is very abundant, New Jersey, Pennsylvania, Maryland, and Virginia supplying large quantities both of the bark and oil. It has been valued since the settlement of the country, and is said to have been used by the aborigines even before. Although its reputation as a medicine is a thing of the past, as an agreeable flavor and cheap perfume it is in steady demand. There is very little call for the whole root in this country, excepting what is used on the spot in the manufacture of the oil; but considerable is exported to Great Britain and the Continent, the Bark of the Root (technically called Sassafras, U. S. Ph.), being preferred. The officinal description is as follows: "In irregular fragments, deprived of the gray, corky layer; bright rust-brown, soft, fragile, with a short, corky fracture; strongly fragrant, sweetish, aromatic, and somewhat astringent." Sassafras Pith (*Sassafras Medulla*) is "in slender cylindrical pieces, often curved or coiled, light, spongy, white, inodorous, insipid. Macerated in water it forms a mucilaginous liquid, which is not precipitated on the addition of alcohol."

COMPOSITION.—Of the wood and bark: The most important constituent here is the *essential oil* (*Oleum Sassafras*, U. S. Ph.), of which the wood contains perhaps one per cent., the bark of the root from two to four per cent. It is a heavy (sp. gr. 1.087+), white, or by age yellow, and then reddish-brown, very fragrant liquid, of an agreeable aromatic taste and a neutral reaction. Soluble freely in alcohol. By the action of cold, or upon standing, it can be separated into *Safrol*, or sassafras camphor, which comprises its principal portion, and *safrene*, a hydrocarbon; both have the same odor. Both bark and wood contain also a little *tannin*, and the bark contains a *red coloring matter*, perhaps derived from the tannin.

Sassafras Pith contains a peculiar non-adhesive *mucilage*.

ACTION AND USE.—Sassafras, like Cinnamon, to which it is related, is an aromatic tonic and carminative, with little or no peculiarity of action to distinguish it from others of its class. It is said to be a stimulating diaphoretic, but probably is not more so than most aromatics, or essential oils, when given in hot "teas." It is, however, of an agreeable flavor, and for this quality it is freely used as an adjuvant in medicine, and as a flavor for confections, soaps, and other household luxuries. The mucilage of the Pith (*Mucilago Sassafras Medullæ*, U. S. Ph., $\frac{2}{100}$) is used rarely as an eye-wash, or as a gargle or demulcent drink for pharyngitis.

ADMINISTRATION.—Oil of Sassafras may be given in doses of from five to ten drops or more on sugar, or in emulsion with mucilage, or otherwise, for the same purposes as oil of Cinnamon or Checker-berry, or an infusion may be made of the bark. Sassafras Bark is an ingredient of the Compound Extract, the Compound Decoction, and the Compound Syrup of Sarsaparilla.

ALLIED PLANTS, ETC.—See CINNAMON.

W. P. Bolles.

SASSY BARK, *Mancona Bark.* The bark of *Erythrophlæum quinense* Don.; order, *Leguminosæ* (*Cæsalpinieæ*), a good-sized, acacia-like tree, growing in tropical Africa, and employed by the tribes of the west side like Calabar Beans, as an ordeal. It was made known in Europe and America about forty years ago, and was revived as a medicine about ten years since. It is a ponderous bark, heavier than water, of a dull red color, a fissured external surface, and a short fracture. Odor slight, taste astringent. The active principle of Sassy Bark is *Erythrophlæine*, a crystalline alkaloid, first obtained by Gallois and Hardy. It is an active heart-poison of the digitalis kind, producing slowing of the pulse, increase of blood-pressure, and in experiments upon animals death, with the heart in systolic contraction. The powdered drug is a powerful sternutatory. But little use has been found for this potent medicine. It is said to be employed at home in dysentery, etc., with benefit, as well as in intermittent and other fevers. In full doses it is nauseating and emetic, as well as somewhat narcotic.

ALLIED PLANTS, ETC.—See SENNA. *W. P. Bolles.*

SAUNDERS, RED (*Santalum Rubrum*, U. S. Ph.; *Pterocarpi Lignum*, Br. Ph.; *Santal Rouge*, Codex Med.). The heart-wood of *Pterocarpus santalinus* Linn., order *Leguminosæ* (*Dalbergieæ*). A small tree with red wood, alternate trifoliate leaves, small yellow, papillionaceous flowers on axillary racemes, diadelphous stamens, and a flat, orbicular, wing-margined, one- or two-seeded, stalked, indehiscent fruit. It is a native of the Madras Presidency, but not common, and is now being cultivated.

Red Saunders is imported in billets three or four feet in length, and from two to eight or nine inches in diameter, the bark and sapwood being removed. It is of a bright blood-red color within, but darker upon the surface, becoming sometimes nearly black with age and exposure. For pharmaceutical use it is usually cut into chips or powder. There is a slight astringent taste, but little or no odor. Alcohol and ether extract its constituents, but not so with water, which it scarcely colors. The important principle is *Santalin*, or *Santalic acid*, discovered by Pelletier. It crystallizes in minute red prisms, which are soluble as above, and in alkaline solutions and a few essential oils. Besides this, a number of less important or ill-defined substances are described.

Saunders is essentially a dye-stuff. In medicine it has no employment, excepting as a harmless coloring agent. The Compound Tincture of Lavender contains eight parts in the thousand.

ALLIED PLANTS.—KINO; see also SENNA.

ALLIED DRUGS.—Saffron, Annato, Cochineal, etc.; also the red coloring matter of Kino, Red Cinchona, Krameria, etc. *W. P. Bolles.*

SAVINE (*Sabina*, U. S. Ph.; *Sabinæ Cacumina*, Br. Ph.; *Summitatis Sabinæ*, Ph. G.; *Sabine*, Codex Med.). The leaves and young twigs of the European *Juniperus Sabina* Linn., order *Coniferæ*. This is a compact, horizontally spreading, evergreen shrub or small tree, resembling our common juniper on a small scale, and bearing similar berries. It is widely distributed through the north temperate zone of the Old World, and is also met within the Northern United States (in the Great Lake region) and in Canada. The medical supply comes from Europe, in "short, thin, sub-quadrangular branchlets, leaves in four rows, opposite, scale-like, ovate lanceolate, more or less acute, appressed; imbricated, on the back with a shallow groove containing an oblong or roundish gland; odor peculiar, terebinthinate; taste nauseous and bitter."

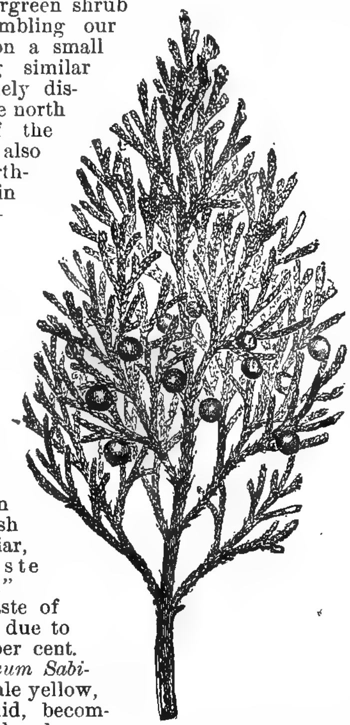

Fig. 3382.—Savine, Fertile Branch. (Baillon.)

The odor and taste of Savine are mostly due to from one to two per cent. of *essential oil* (*Oleum Sabinæ*, U. S. Ph.), a pale yellow, terebinthinous liquid, becoming thicker and darker by age, colorless if redistilled, of a specific gravity of about 0.910. It has the odor of Savine, a sharp, bitter, camphoraceous taste, and is more rubefacient and irritating to the skin than others of its class. *Tannin* and *resin* are less important constituents of Savine.

ACTION AND USE.—Savine and its oil are essentially like, but more intense than, oil of turpentine in physiological and therapeutical properties; irritating to the skin and mucous membranes, to the urinary apparatus by which they are eliminated, and to the uterus, which they may cause to abort. Besides these effects, convulsions and coma may follow. Vomiting, diarrhœa, gastro-intestinal inflammation, strangury, with or without convulsions or unconsciousness, these are the usual symptoms of Savine-poisoning; abortion may or may not take place. This potent drug is not much employed. It has been given as an emmenagogue, also as a hæmostatic, for leucorrhœa and other purposes mostly connected with the uterus. It is not infrequently used with criminal intent to produce abortion, usually without success, unless it nearly or quite kills the mother also; externally it is the basis of some moderately useful stimulating ointments, liniments, and "hair-restorers."

In this country the Oil of Juniper, which is milder, is perhaps generally substituted for Oil of Savine.

The dose of Savine (leaves) is about half a gram (0.5 Gm. = gr. viij.); of the oil, from one to four or five drops. A Fluid Extract of the former (*Ex. Sabinæ Fluidum*, U. S. Ph.) is an eligible preparation and the basis of the Cerate (*Ceratum Sabinæ*, U. S. Ph., strength about $\frac{25}{100}$ Savine).

ALLIED PLANTS.—See TURPENTINE; also JUNIPER.

ALLIED DRUGS.—TANSY, RUE, TURPENTINE, CAMPHOR, CAJEPUT, etc. *W. P. Bolles.*

SAVORY, SUMMER (Sarriette, Codex Med.). The herb of *Satureia hortensis* Linn., order *Labiatæ*, a well-known European mint, now cultivated everywhere as a flavoring herb for soups and sauces. It has no properties not common to other mints and aromatics in general, and is only employed for its agreeable odor and taste.

ALLIED PLANTS, ETC.—Hyssop, Thyme, Patchouly, Lavender, etc. See PEPPERMINT. *W. P. Bolles.*

SCABIES (Latin, *scabies*, an itching eruption, from *scabo*, I scratch). Synonyms: The Itch; German, *Krätze*; French, *Gale*. Scabies is a contagious disease of the skin, wholly local in character, due to the presence in, and upon, the skin of an animal parasite, the *acarus* or *sarcoptes scabiei* (see vol. i., p. 34). The eruption present may vary from the smallest amount imaginable, a few papules, up to the most severe development of inflammatory lesions, even such as to render the patient helpless; the subjective sensations may vary from a slight pruritus, which is described as not unpleasant when relieved by scratching, up to an itching which is almost unendurable, causing restless nights and distressing days.

The most common sites for the lesions of scabies are the hands, especially about the wrists, in the soft skin between the fingers, and on the sides of the hands. But in many cases the eruption is entirely absent from this locality and is well marked elsewhere. In males the penis seldom escapes, and in females the region of the nipples is very apt to be affected; the anterior fold of the axilla is a very common seat of the lesions, and the elbows and extensor surface of the forearms are sometimes most severely affected. In those who sit a great deal the buttocks often present an abundant eruption. In infants and children the softer parts of the feet and ankles generally exhibit lesions. It may be said that the head is never affected by scabies.

The eruption of scabies exhibits the greatest variety of lesions, from the smallest papules and vesicles to large pustules, often ecthymatous in character, and in weakly children pustular bullæ may form on the hands. The bulk of the lesions is papular, although small vesicles can generally be seen on tender portions of the skin during some period of the disease. Mingled with these primary lesions there are generally found the results of scratching, abraded surfaces, and those covered with crusts.

The only single pathognomonic sign of scabies is the *cuniculus*, furrow, or burrow (German, *Milbengang*; French, *Sillon*), which is caused by the penetration of the female beneath the epidermal layer of the skin in the search of a place to lay her eggs; the male seldom, if ever, goes beneath the skin. This cuniculus consists of a minute dark-colored line, generally somewhat beaded in appearance and curved, appearing much as if a bit of dark sewing-silk had been run beneath the surface, rarely as long as a fourth of an inch, more often half that length; this may generally be seen to terminate at one end in an inflamed papule or vesicle, or sometimes to run over a pustule. The female insect will be found at that end of the furrow, and the dark line is her track, which is found to be filled with eggs in various stages of development, and, among them, black particles of fæces. If the skin is washed these dark lines, instead of being removed, become more apparent; but in recent cases, or in individuals who are very cleanly or have undergone treatment, it is often impossible to discover any of these cuniculi, although the disease may still exist, and, if left alone, will increase and may be communicated to others.

Scabies is not a very frequent disease in this country, forming only about 1.5 per cent. of a large number of skin cases analyzed. In other countries it is more common, and in Glasgow it formed twenty-five per cent. of ten thousand cases analyzed by McCall Anderson.

DIAGNOSIS.—Considerable care is often required to diagnose a mild or unusual case of scabies, and cases sometimes go unrecognized for some time. The disease most commonly confounded with it is eczema, which may present almost identical appearances, except that there are no cuniculi; when these latter are positively

found the diagnosis is certain. The location and distribution of the eruption, the history of contagion, and the multiform character of the lesions are generally sufficient to establish the diagnosis. Scabies may also be confounded with lichen, pityriasis, prurigo, pruritus, and urticaria papulosa.

ETIOLOGY.—There is but one cause of scabies, the presence of the parasite, acarus or sarcoptes scabiei (see article Acari in vol. i. of this HANDBOOK), whose removal or destruction is followed by the cessation of the disease. It often occurs, however, that the treatment employed may occasion an amount of artificial eruption or dermatitis which may mask the true affection, and may even remain after the real cause of the disease has been destroyed; this second eruption may require a very different treatment, of a soothing character.

PATHOLOGY.—The only pathological lesions, aside from the presence of the cuniculus, which is a channel beneath the epidermis and just above the papillæ, filled with the female acarus, its eggs, and fæces, are those connected with inflammation of the skin (see article Dermatitis). The lesions are simply inflammatory masses of greater or less size, caused either by the direct irritation of the burrowing insect, or by the scratching or other measures employed for the relief of the itching, or both. When the local irritation is removed the eruption ceases; if the acari could all be removed mechanically, picked out, there would be no eruption. In patients who are paralyzed on one side, or who have been unable to scratch, there is very little eruption on the portions of the skin which are out of reach.

TREATMENT. — The treatment of scabies is purely local, and consists in such measures as destroy the life of the parasitic insects and their eggs. The patient first takes a warm bath, using plenty of strong soap, rather alkaline in character, such as the sapo viridis or the common laundry soap, rubbing the affected parts so as to break the furrows as much as possible. After drying, the affected parts, or even much of the body, should be well rubbed with an ointment of which sulphur is a chief ingredient. The ordinary sulphur ointment diluted once, with the addition of a drachm of liquid storax to the ounce, answers as well as anything. After thorough friction with this for at least half an hour, the patient puts on underclothes, which are to remain on night and day until the end of treatment. The ointment should be freshly rubbed in twice daily for several days, and a bath is to be taken on the third day, the ointment being again rubbed in and a fresh suit of underclothes put on. After three days more of treatment another bath may be taken, and it is then to be expected that the cure is complete. But frequently some of the cuniculi will be found to have escaped being broken, or new infection may come from the clothing or elsewhere, and in such case the treatment must be repeated. Sometimes an artificial eruption is excited by the treatment, when soothing remedies are required. The clothing should always be treated; the underclothes should be boiled a long time and very thoroughly ironed; the outer garments may be baked or very thoroughly ironed on the wrong side. Patients should be more or less isolated, although when they are under treatment the chances of communicating the disease are very small.

PROGNOSIS.—The prognosis is, of course, favorable; there can never be the slightest harm in curing even the most inveterate or severe cases of scabies. In the hospitals abroad it is claimed that a cure is effected in a few hours, but it is questionable if, in the large majority of cases, the relief is more than temporary, a portion only of the parasites being killed. Practically, cases require treatment for a number of days, or even weeks, to make the cure certain; when the skin is delicate the active parasitic treatment may have to be interrupted, owing to the dermatitis excited, and occasionally it will be found difficult to use remedies strong enough to effect a cure.

L. Duncan Bulkley.

SCABIOUS (*Scabieuse*, Codex Med.); *Morsus Diaboli, Succisa pratensis* Mönch, order, *Dipsaceæ* (*Scabiosa succisa* Linn.). A European herb, whose roots, leaves, and heads were formerly in vogue as a remedy for leucorrhœa, diabetes, throat affections, and skin diseases. It is now obsolete.

ALLIED PLANTS, ETC. — *Dipsacus Fullonum* Linn., in the same family, is the teazle used by woollen weavers. "Sweet Scabious" (*Erigeron*) is an entirely different plant. *W. P. B.*

SCAMMONY (*Scammonium*, U. S. Ph., Br. Ph.; *Scammonée d'Alep*, Codex Med.; also *Scammoniæ Radix*, Br. Ph.). The impure resin obtained from the root of *Convolvulus Scammonia*, order *Convolvulaceæ*. This is a perennial with a long, thick, cylindrical, several-headed, but otherwise usually simple, milky-juiced root, and numerous hollow, herbaceous, slender, smooth, twining stems, two or three metres long. The root, which is an article of English trade, is up to a metre in length, and a decimetre in diameter at the crown, light brownish-yellow without, white within, fleshy, and resinous. The leaves are infrequent, alternate, long-petioled, triangular, halberd- or arrow-shaped, pointed at the apex, with one or two obtuse dentations near the cordate base. Flowers five or six centimetres across, pale yellow, solitary or in cymes of three, on long two-bracted peduncles. Calyx five-parted; corolla conduplicate in the bud, broadly funnel-shaped when open, with an indistinctly five-parted border. Stamens five, attached to the corolla tube, pistil two-celled, four-seeded.

FIG. 3383.—Scammony-plant in Blossom. (Baillon.)

This pretty plant is a native of the Levant—Greece, Asia Minor, Syria, etc. It is also cultivated in botanic gardens. The resin is collected by cutting off the root

at the crown, and either scraping off the exudation as it appears or putting a shell or some receptacle at the lower side to receive it as it runs down. It is then dried at once, constituting a very high grade of the drug, or more usually the separate collections are laid aside until enough is accumulated to make a "cake," when it is all moistened and kneaded together. In this way the bubbles and sour odor are developed, and what is known as "Virgin Scammony" is produced.

Scammony is in "irregular, angular pieces, or circular cakes, greenish-gray or blackish, internally porous, and of a resinous lustre, breaking with an angular fracture; odor peculiar, somewhat cheese-like; taste slightly acrid; powder gray or greenish-gray." The porous, bubbly texture, and the sour, cheesy smell are results of fermentation during the process of drying. It is soluble to the extent of three-fourths in ether. The costliness and opaque color of Scammony render it especially liable to adulteration. Lime, flour, ashes, gum, etc., are among the common admixtures. The proportion of resin is the best test of purity. This *resin* (*Resina Scammonii*, U. S. Ph.) is obtained by digesting the drug with alcohol and evaporating the tincture so obtained, or by treating the root in the same way. It is a brown, translucent, brittle resin, with a sweet, fragrant odor if obtained from the root; but, as usually seen, from crude Scammony, it is more greenish and dirty in color, and has the odor of Scammony itself. The action and value of the two products are about the same.

COMPOSITION.—The peculiar resin of Scammony, unfortunately called *jalapin*, first obtained in a state of purity by Johnston, in 1840, differs from the *convolvulin* of jalap by its solubility in ether. When purified it is a colorless, translucent, brittle, non-crystalline resin, tasteless and odorless, of nearly neutral reaction, and freely soluble in ether. It is a glucoside, and resolvable into *jalapinolic acid*, a crystalline substance, and sugar. Good Scammony contains eighty or ninety per cent. of this resin.

ACTION AND USE.—Scammony and its resin are to be counted among the very active drastics, excelled only by croton-oil and elaterium. Their action is similar to that of jalap, but considerably more intense. They are used as derivatives and hydragogue cathartics in cases of cardiac and renal troubles associated with dropsy. Scammony resembles the action of jalap, but is more intense. Aromatics and carminatives are appropriate adjuvants. Dose, of good Scammony, half a gramme or so; of the *Resin*, three or four decigrammes. The compound Extract of Colocynth contains fourteen per cent. of Resin of Scammony.

ALLIED PLANTS, ETC.—See JALAP. *W. P. Bolles.*

SCAPULA: DISEASES AND INJURIES OF THE CORACOID PROCESS. The coracoid process (Syn.: Processus Cornicularis, Hawk-bill Process) is usually described as a short, thick, curved process of bone, rather more than one inch in length, which arises by a broad base, and projects beneath the outer end of the clavicle from the anterior part of the upper margin of the scapula. It is first directed upward and inward, then, becoming smaller, it changes its direction and passes forward and outward. The horizontal portion is irregular and flattened from above downward, the under surface is smooth, while the internal and external borders are roughened for the attachment of ligaments and muscles.

The ligaments are—the origins and insertions corresponding to the situations named—the coraco-clavicular, coraco-acromial, and coraco-humeral. The muscular attachments are the short head of the biceps, and the tendons of the coraco-brachialis and pectoralis minor muscles. In position the coracoid process is almost unique, being uncommonly well protected by the circumjacent bony and muscular structures. The clavicle is arched above, the head of the humerus protects it from external injuries, and the deltoid and pectoral muscles complete the defence with a buffer-like elasticity, shielding it from all assaults directed from either above or below. The development of this process takes place from two centres of ossification, one in the body and the other near its base. It remains as an epiphysis until near the twenty-fifth year, a portion at birth being cartilaginous. Allen ("Human Anatomy," sec. 11, p. 171), says: "This process is homologous with the coracoid bone of batrachian reptiles and birds; as seen in these animals, the coracoid bone extends between the sternum and scapula very much after the manner of the clavicle in the human subject." In persons of moderate muscular and adipose development this process can be felt just beneath the mesial portion of the outer third of the clavicle, a short distance to the inner aspect of the head of the humerus. The hand should grasp the shoulder, the fingers at the same time steadying and pushing the scapula forward against the back of the chest; it can then, ordinarily, be recognized, by the thumb being pressed in front, as a bulbous protuberance about the size of a large bean. The arm during the manipulations should be extended and rotated outward, which, by producing traction upon the accessory ligament, brings the process forward and facilitates its detection. There is one fact which deserves to be specially mentioned because of its importance in regard to diagnosis. In the normal subject, where no disease nor injury is suspected, the coracoid will frequently be found intolerant of rude manipulation or pressure; therefore, it should be impressed upon the observer, when making examinations in this region, that a precipitate diagnosis should not be made from the mere presence of pain uncorroborated by other morbid indications.

DISEASES.—The literature of this class of affections is very meagre. Nothing seems to have been recorded that would demand any special therapeutic measures, beyond what is usually comprehended by ordinary established rules, and such as are applicable to bone disease situated in analogous structures elsewhere. It may be worthy of mention here—rather as a matter of curiosity—that the coracoid process is sometimes thought to become the seat of reflex neuralgic manifestations, due to some indefinite disturbances in the abdominal viscera. Pain felt in the right process has been attributed to vague hepatic derangement, while that of the left side is supposed to be connected with morbid conditions operating in the spleen. How far these are to be credited as demonstrations of disorder in these organs cannot at this time be determined; but it would be wise to regard these relations as extremely conjectural, and as such quite insufficient to warrant much serious consideration.

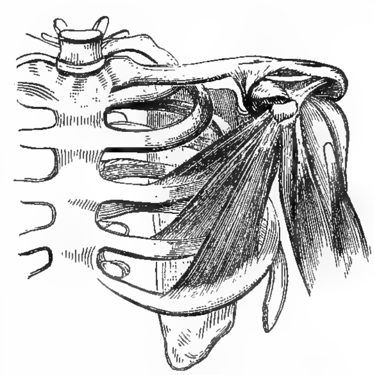

FIG. 3384.—Fracture of the Coracoid Process, showing action of muscles in its displacement.

Periosteitis, simple and tubercular osteitis, caries, and syphilitic necrosis have occasionally been observed in this process. It may be also said of these that the principles governing the management of such common forms of disease will be found the same here as elsewhere. It will, therefore, be amply sufficient for all purposes to limit our observations here to osteitis alone, this being in the common run of cases the form of disease most likely to be met with.

"Osteitis of this process occurs with greatest frequency in the period of adolescence, before the epiphyses have consolidated, and is liable to be confounded with scapulalgia, osteitis of the head of the humerus, or even cervical Pott's disease. The diagnosis may be made by

the location of the pain on pressure, and by the presence of tumefaction, or of an abscess. The latter is found usually in the subclavicular region rather than in the scapulo-humeral, or on the internal aspect of the arm, the pus following the sheath of the coraco-brachialis muscle, or the short head of the biceps.

"*Treatment.*—This consists of resection of the process by means of a T-shaped incision. In case of tubercular osteitis union by first intention cannot be hoped for, and it will be necessary to provide for free drainage" (Poncet, *Lyons Bull. Gén. de Thérapeutique*).

FRACTURES.—Injuries of this class involving the coracoid process have always been considered as remarkably rare, the ordinary surgical authorities and text-books enumerating not above a dozen examples, which are generally accepted as constituting the entire list of authentic cases. These statistics are, however, misleading, and sufficient data are not wanting, as will be shown in the tables below, to prove that the lesion is much more common than is usually believed. Writers have seemed to be possessed with the idea that this process is so well protected that fracture is wellnigh impossible without the infliction at the same time of such an extensive injury to the surrounding structures as to overshadow the coracoid trouble. This *à priori* reasoning has in time become dogmatic assertion. Experience, however, has shown that this process is not disproportionally exempt from simple fractures. The rarity of fracture of the coracoid process has been greatly exaggerated in the past, and there can be no doubt that a careful investigation, at any time during the past century, would have shown that very many anatomical collections contained specimens of this injury. The result of such a study would have been to prevent the emphatic and misleading language of Lizars, which is as follows: "The coracoid is said to be broken off, but this I question very much; it must be along with the glenoid cavity, or there must be a fracture of the neck of the scapula." No less pronounced are the remarks of the eminent Malgaigne. "This fracture is excessively rare, and does not occur except in company with other serious injuries." Holmes, Erichsen, South, and Bryant bear similar testimony, regarding it either as highly improbable or exceedingly rare, unless accompanied by marked complications, rendering it a very serious accident.

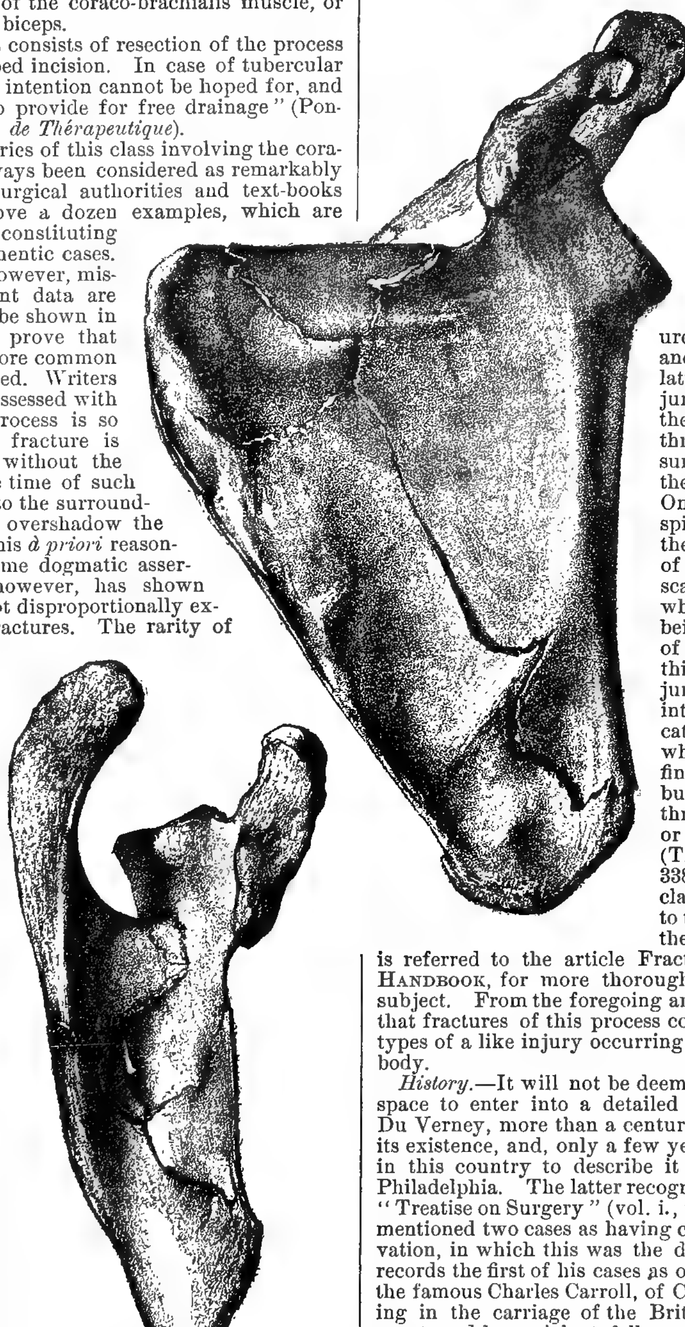

FIG. 3385.—Green-stick Fracture of Coracoid Process, with Multiple Fracture of Scapula.

Varieties.—There are three principal forms of this fracture that have been observed. The first of these, which is the most frequent of any, may be defined to embrace all fractures limited to the process proper in which the line of fracture is simple and complete. The second variety is denominated partial green-stick, or incomplete, fracture, an example of which is shown in Fig. 3385, taken from a case the dissection of which was reported by Bennett, of Dublin, to the Academy of Medicine of Ireland. This may be pronounced the most unique of specimens, and probably is the only case of the kind ever verified by an autopsy. An examination of the coracoid shows two fractures, one at the apex and another at the base; the latter break runs from the junction of the process with the glenoid cavity, on through the entire concave surface which is related to the subscapularis muscle. On looking at the supraspinous fossa (Fig. 3385), there is no trace whatever of the fracture visible. The scapula came from a man who died a few hours after being crushed by a quantity of falling masonry. The third division of these injuries is that known as the intra-articular or complicated. This is a fracture in which the break is not confined entirely to the process, but continues into, or runs through, the glenoid cavity or the subscapular fossa. (This is also seen in Fig. 3385.) Those of the latter class belong more properly to the subject of fractures of the scapula, and the reader is referred to the article Fractures, in vol. iii. of this HANDBOOK, for more thorough information upon the subject. From the foregoing arrangement it will be seen that fractures of this process correspond to the ordinary types of a like injury occurring in the other bones of the body.

History.—It will not be deemed necessary to sacrifice space to enter into a detailed history of this fracture. Du Verney, more than a century ago, called attention to its existence, and, only a few years later, among the first in this country to describe it was William Gibson, of Philadelphia. The latter recognized its importance in his "Treatise on Surgery" (vol. i., p. 258, 1835 edition), and mentioned two cases as having come under his own observation, in which this was the diagnosis arrived at. He records the first of his cases as occurring in the person of the famous Charles Carroll, of Carrollton, who, while riding in the carriage of the British Minister, Bagot, was upset, and by a violent fall upon the shoulder this process was broken off. Gibson remarks, "The subject being a remarkably thin one, I was able to distinctly feel and move the fragments one upon the other." Of his second case he makes no further mention than to say it was in the person of a sailor. The following reports of cases, though not arranged to illustrate any particular feature of these injuries, will be found to describe this fracture when resulting principally from falls and violence imparted to the humerus and the shoulder-joint as a whole. As an apology for entering the reports of cases

in a work like this, it can be said to best justify the general purpose of it, which is to present reliable information lucidly and briefly.

Case I.—A milk-woman, aged thirty years, fell from a cart upon her right side into the street. The motions of the arm were not impaired, she could raise her hand to her head without any difficulty. The clavicle, humerus, and acromion were entire, there was neither deformity nor flattening; but on attempting to grasp the coracoid process while the arm was freely moved up and down, a looseness and crepitus could be distinctly felt, and a grating was also perceptible in the axilla. The arm was secured to the side by means of a sling and bandage, and fomentations were applied. There was very little swelling, but the woman complained of pain which was increased by motion. (London *Lancet*, 1840–41.)

Case II.—Male, aged forty-five years, very thin and spare, fell down a steep flight of stairs feet foremost, striking heavily upon his left elbow, which was thrown backward in an effort to protect himself. Examination showed the arm shortened, elbow carried a little backward and slightly separated from the body; motion, especially forward, greatly restricted. To the inner side of the acromion was felt a prominence, which was the head of the humerus, dislocated but easily reducible. Crepitus was obtained by making traction upon the arm and carrying it outward and forward; this crepitus was felt by the thumb when placed upon the coracoid process, and was plainly marked, though consisting of but a single click. Pain was localized at the point of crepitus. (Taken from Streeter's case, *Medical Record*, 1887.)

Case III.—Male, aged twenty-four years, fell down an open hatchway of a vessel, some twenty feet. The right hand at the time of the fall was in the pocket of his trousers. The injuries were fatal, and a dissection disclosed a fracture of the coracoid process. The line of fracture ran obliquely from the inner and upper border of the process, just beyond the attachment of the coraco-clavicular ligament, downward and outward toward the tip, and terminated on the external border, a fourth of an inch from its summit. There was no displacement of the fragment, the head of the humerus was dislocated forward, and at the moment of its passage from the glenoid cavity the upper portion had fractured the process by pushing against its under surface. (Bennett: *Dublin Journal of Medical Science*, 1873.)

Case IV.—Male, aged seventy-six years, fell, striking his right shoulder against a projecting board. . . . The right arm was powerless, the shoulder somewhat swollen, and there was a contusion one and a half inch below the acromion, and slightly to the posterior side of the humerus. Movement was very painful, and occasional crepitus could be distinctly felt when the arm was rotated. The head of the humerus was thrown a little forward and inward, but readily answered to all movements imparted at the elbow. No pain or crepitus was found over the clavicle, the acromion was intact, and there was no break about the glenoid cavity. There was unmistakable bone crepitus, and pain was felt over the coracoid process. (Johnson: *Medical News*, 1885.)

Case V.—Elderly woman, who slipped down in a narrow alleyway and struck her elbow, driving the head of the humerus forward. The symptoms were loss of function of the coraco-brachialis and pectoralis minor muscles, tenderness, and crepitus on pressure of the coracoid process. (Packard: *Charleston Medical and Surgical Journal*, 1859.)

Case VI.—Male, aged thirty-three years, slender build, scanty adipose tissues, bony landmarks prominent. The patient had recently undergone an amputation of the forearm a few inches below the elbow, the stump remaining unhealed and tender. He was found supporting his stump with the opposite right hand, nervous, pale, and evidently suffering intense pain. The information was that, while endeavoring to avoid the wheels of a vehicle in the street, he had lost his footing and fallen backward into the gutter; in doing so he had, to use his own words, "knocked his shoulder out of joint." Further questioning as to the exact manner of the accident elicited the fact that, while falling, he had struggled to recover his lost equilibrium, and, as a consequence, landed heavily and awkwardly upon his left shoulder.

The arm, it was ascertained, had been raised above the head and thrown outward, possibly instinctively as it were, to protect the sensitive stump, and in this position the bulk of the traumatism from the fall was sustained by that portion of the shoulder corresponding to the space between the deltoid insertion of the humerus and the dorsal aspect of the acromion. Upon exposing the limb for inspection it was found to hang lower than its opposite fellow, the elbow being held away from, and slightly to the front of, the body. The hand, in passing carefully along the clavicle, acromion, scapular spine, and head of the humerus, then into the axilla and the space corresponding to the coracoid process, detected no anomaly, excepting a slight subluxation forward of the head of the humerus. A little extension reduced this to position, and, the parts presenting their normal contour, the patient was assured that everything was in its place and nothing broken. Notwithstanding this assurance he continued, with considerable misgivings, to complain of severe pain. In order to convince him, the arm was immediately put through several brisk manipulations, as if nothing was the matter; while carrying the limb outward and rotating, distinct crepitus was heard, which the patient was quick to notice, and remarked that he "felt it grate, and something must be broken." A careful repetition of these movements, with the fingers pressed gently into the coracoid space, revealed the irregularity there. Any increased pressure from the fingers while the limb was moved, caused crepitus, and so augmented the pain that the patient energetically protested against its being repeated, flinching each time the process was touched. He was then directed to shrug the shoulder, and was unable to do so. This peculiar movement of shrugging the shoulders (*hausser les épaules*) has not been before alluded to by writers when discussing this injury; it is, however, of considerable value as an element in diagnosis. It will be recalled that the pectoralis minor muscle draws the scapula forward and downward, and at the same time causes it to execute a rotating motion, by virtue of which the inferior angle is carried backward and the anterior depressed; if the arm be fixed the coraco-brachialis assists these movements, and in order to perform them it is necessary that the entire set of ligaments of this process should be in an intact condition. If a fracture be present in which there is separation of the fragments, with an alteration in the position of the ligaments, these combined movements cannot take place. In this case the arm was elevated and abducted; the force was severe, the whole weight of the body striking the curbing, and the head of the humerus, in partial dislocation, was directed against the process. There were localized pain and crepitus, with swelling and a suspension of the function of the muscles corresponding to the parts. (Byers: "Coracoid Fractures," pamph., 1885.)

There is little doubt, in this case, that when the head of the humerus was driven forward it pressed forcibly against the process, and caused rupture of the coraco-acromial ligament, the fracture being produced by one bone striking against the other.

Allen says: "The coracoid process acts as a check to this inward movement of the head of the humerus, and, unless it be broken off, subclavicular dislocation can scarcely occur." Rotation of the head of the humerus outward, in a great many of the cases reported, produces crepitus, and appears at the same time to effect a reduction of the piece broken off. The mechanism of this crepitus and restoration of the fragment has not been satisfactorily explained. The late Dr. Hamilton, upon one occasion, saw an instance in which the apex could be replaced, but how and upon what principle he confessed his inability to state, unless perhaps it was by drawing upon the muscle attached to the process. The most plausible explanation, however, would appear to reside in another and entirely different source, namely, traction exerted by the accessory ligament. This arises from

the outer border of the coracoid and passes over across the capsular ligament—being partially blended with its fibres—and is inserted into the greater tuberosity of the humerus. It can now be seen that tension upon this ligament, caused by outward rotation, will produce results directly opposite to the ordinary action of the muscles mentioned. The action of the muscles is to displace downward, while traction exerted upon the accessory ligament lifts and carries the process outward.

The foregoing cases are found to illustrate this fracture chiefly when it occurs as the result of violence imparted to the humerus, this being by its displacement the principal factor in its production. Some cases will now be presented to show how it may be a consequence of violence applied to the process directly from the front. These two causes are found to be the most important ones in a large number of these accidents. The opinion has been entertained that force applied to any portion of the scapula, and especially from the front, would cause it to rebound upon its muscular supports, and that this would so mitigate the force as to render it virtually incapable of fracture. Agnew is of the opinion that the head of the humerus alone is capable of fracturing even the glenoid cavity when forcibly driven against it. That the hypothesis of its being protected by the muscles is not consistent with experience, will be seen from a study of the cases that follow:

Case I.—Male, aged twenty-seven, fell in the dark, striking his shoulder against the edge of a door standing ajar. The pain was excessive, so much so as to render him unconscious for some little time. Upon a careful examination of the part no objective signs of the injury were at first evident. There was inability to place the hand upon the head, and also extreme tenderness on pressure, limited to a space just inside of the acromial end of the clavicle and just below it. No crepitus was at this time present, nor was there deformity. Next day there was tumescence, circumscribed to the injured spot, with impairment of the functions of the muscles attached to the process, and crepitus was now plainly perceptible over the seat of the injury. (Huse: *Chicago Medical Examiner*, 1879.)

Case II.—Male, aged sixty-six, while walking along the street was struck full on the right shoulder by a runaway horse, lifting him bodily off his feet and violently throwing him against an iron column. Upon making an examination, pain was found about the shoulder, very severe, the patient complaining that his arm was broken. But no false point of motion was found until the coracoid process was reached. Manipulation here caused exquisite pain; some crepitation was made out, and there was a slight degree of displacement. (Borcheim, in *Atlanta Medical Journal*, 1886.)

Case III.—Male, aged fifty-six, stout farmer, thrown down by a colt and kicked badly. Examination showed no displacement nor fracture, until by chance crepitus was noticed at a point in front of the right shoulder. The humerus was in place, and every motion of the arm could be made passively, the spine of the scapula and clavicle were entire, the crepitus being strictly localized to a point internal to the shoulder-joint and beneath the clavicle. (Higgins: *Philadelphia Medical News*, 1885.)

Case IV.—Male, laborer, of intemperate habits, was struck by a plank falling from a great height, the point striking him full upon the tip of the shoulder. The arm hung helpless by the side of the body. The adjacent bones were all entire, crepitus was felt by manipulating the arm, and motion of a loose fragment could be detected on examination through the axilla; the line of fracture probably extended into the glenoid cavity. (S. W. Smith, N. Y., unpublished case.)

Agnew and Hamilton have each observed cases in which violence, as a blow in front, was a cause.

Diagnosis.—The detection of this injury may at times be a matter of difficulty, especially when the presence of other complications more important, such as swelling, dislocation, and other fractures, masks it. The history, with a knowledge of the kind and direction of the force, will frequently be of material service in its recognition. Crepitus can usually be produced by outward rotation of the arm, and mobility of the fragment is occasionally seen and felt; localized pain and tumefaction, with an inability to shrug the shoulder, and an absence of other injuries capable of producing analogous symptoms, are further aids to diagnosis. These will usually lead to a correct solution of the difficulty, should any be presented. Holden, in his valuable "Landmarks," says: "On the front surface of the clavicle, not far from the acromial end, there is, in many persons of mature age, a spine-like projection of bone. This is liable to be confounded with the coracoid, and it would be well to examine the opposite side to see if there is a corresponding projection also, in order to clear up any possibility of error from this source.

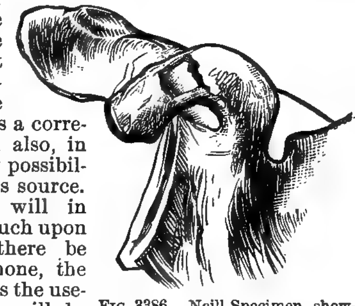

Fig. 3386.—Neill Specimen, showing Process Reunited by Two Parallel Fibrous Bands.

Prognosis. — This will in most cases depend much upon complications, if there be such; if there be none, the final result as regards the usefulness of the limb will be good, and assurances may be generally given to this effect.

The exact seat of the fracture, as compared with its ligamentous arrangement, will be a matter to be determined, if it is desired to obtain perfect union. If the fracture is in immediate proximity to the base, and if the acromial and clavicular ligaments are also ruptured, we certainly shall expect to find very marked displacement of the broken fragment. This will be evidenced by an unusual degree of passive mobility, and by a more or less total suspension of the functions of the corresponding muscles. The union, as a consequence, will necessarily here be by an intervening fibrous band, since no sort of retentive apparatus is capable of acting as a perfect splint in these circumstances. Again, if the break be anterior or between the ligaments, and if their clavicular and acromial attachments escape rupture, the area of displacement will be materially abridged. If the process be broken in such a manner as to hinder or prevent its easy reposition and retention—as when the base is drawn down and tilted forward, or when there are spasms of the muscles—the union will be fibrous, and there will doubtless also be a permanently movable process. This condition is shown in Fig. 3386, and is the common sequence in a majority of cases. Hamilton mentions several examples in which the process could be moved months after the accident. These movable processes will occur in all those cases where the bones have been widely separated, and where there has been a failure to retain the surfaces in proper apposition during the reparative effort. However, this fibrous or ligamentous union does not mar the ultimate usefulness of the process, the shoulder usually presenting nothing uncommon excepting, at times, an awkwardness observable solely by the patient. Many of the specimens contained in museums show ligamentous union as a result, but very few manifest anything like an attempt at genuine osseous deposit, this being rare. Fig. 3387 is taken from a photographic plate in the possession of Marcy, of Boston. The specimen is to be found in the

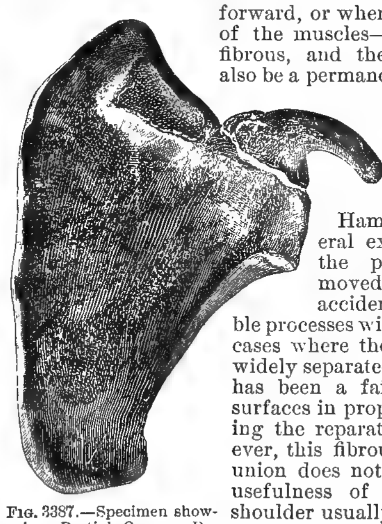

Fig. 3387.—Specimen showing Partial Osseous Deposit. (Warren Anatomical Museum, Boston.)

No.	Sex.	Age.	Cause.	Evidence.	Complication.	Reference.	Results.	Side.
1	Male.	45 years.	Fall backward.	Pain, crepitus, swelling, and mobility of process.	There was some, but not stated.	Dr. F. B. Streeter, Med. Record, vol. i., 1887.	Not stated.	Left.
2	Male.	66 years.	Thrown bodily against an iron column.	Pain, crepitus, and mobility of process.	There was some, but not stated.	Dr. L. E. Borcheim, Atlanta, Ga., Med. and Surgical Journal, 1886.	Not stated.	Right.
3	Male.	33 years.	Fall backward.	Pain, crepitus, mobility, and loss of function.	Subluxation forward of head of humerus.	Dr. J. Wellington Byers, pamphlet, 1885.	Ligamentous union.	Left.
4	Male.	56 years.	Kicked by a horse.	Crepitus, pain, and mobility of process.	Not stated.	Dr. F. W. Higgins, Phila. Med. News, Dec., 1885.	Union by ligaments.	Right.

Warren Museum of the same city, and is catalogued as No. 983, deposited by Warren, 1847. An examination of it shows that the edge of the fracture, which extends into the glenoid cavity, has undergone no effort at repair, yet, upon the superior border of the neck, there is an abundant formation of new bone, filling the suprascapular notch, and extending along a fissure running nearly the whole extent of the supraspinous fossa. Bennett mentions a case in which the result was osseous union and unbroken periosteum, as was shown at the post-mortem examination. Two other cases, by Drs. Alan Smith and R. W. Johnson, of Baltimore, have been reported, but not confirmed, however, by autopsies.

Treatment.—This can be set forth briefly and in a very few sentences. The indications, in the light of what has been already stated, are plain. Usually we should endeavor to restore the part broken off to as near its original position as is possible, and to retain it there by means of suitable apparatus. This can best be accomplished and the requisite indications fulfilled by first relaxing the muscles causing displacements. To effect this the forearm should be flexed, and rotated outward, bringing the fragment back to its normal position; then the arm, still flexed, should be carried across the chest and secured there by means of a Fox apparatus, a Velpeau, or a four-tailed bandage.

It is advisable to combat the inflammation that sometimes follows in the loose cellular tissue by anodyne lotions. The effusions are abundant when they take place, frequently reaching to the elbow. The apparatus should be worn for six weeks, when osseous union may be expected. At first the muscles should be used carefully.

Remarks.—To summarize these reports of cases and the tables that are shown on preceding page, it will be seen that in all those which were not fatal there were associated with the fracture changes in the head of the humerus. Pain and crepitus are the most frequent symptoms met with. One-half of all the cases tabulated were verified by post-mortem dissections, these being principally reported by the older authorities; whereas nearly all of the recent cases were diagnosed and clearly illustrated by the symptoms during the life of the subject. Of those not terminating fatally, seventy per cent. were the result of falls. No particular manner of falling seems essential for the production of this injury, since it is seen to occur while the arm is elevated, abducted, thrown backward, or by the side, the body falling either backward, forward, or sideways. Flower saw two cases in which the hands were stretched forward during the fall. Twenty-five per cent. of the cases occurred in adult males, five were women and young girls, the sex of the remainder being undetermined. The ages will be found to extend from fourteen to seventy-six years, a large per cent. certainly occurring after a consolidation of the epiphyses; the only cases showing any liability toward criticism from this source are those of Bryant, Paule, and one of Hamilton. The Neill specimen has been objected to on account of this, but the scapula is large, well-developed, and doubtless came from an adult. As to this fracture being confounded with separation of the epiphyses, this term is only applicable when the line of fracture is identical with the remaining interosseous cartilage, which during the years of adolescence merges into the bone of the scapula proper. Separations of this bone are only possible prior to the twenty-fifth year, unless, as a result of some malformation or disease, the cartilaginous medium has persisted later in life. Therefore the attempt of some to pronounce all these injuries as merely separations of the epiphyses, rather than true fractures, is unwarrantable. As to direct violence being the principal cause of this injury, as is generally taught, an examination of fifty examples shows that this was the means in only six cases. Two cases are reported as the result of muscular action, but these, it is fair to assume, were associated with osteomalacia or other diseases. Gurlt's "Knockenbrücher" is said to contain a description of about twenty cases of coracoid fracture.

SCARBOROUGH, a city of about thirty-five thousand inhabitants, on the east coast of Yorkshire, is one of the best known and most popular of English watering-places. There are two mineral springs here, which are known as the North Well, or iron spring, and the South Well, or saline spring. The following are the analyses of these two springs, made by Phillips (Rotureau). In 1,000 parts of water there are of

	North Well.	South Well.
Sodium chloride	2.016	3.140
Ferrous bicarbonate	0.210	0.192
Calcium bicarbonate	5.517	5.066
Calcium sulphate	11.877	11.713
Magnesium sulphate	19.734	23.884
Total	39.354	43.995

The waters of Scarborough are used to some extent in therapeutics for the same purposes as are other saline and ferruginous springs, being prescribed especially for those suffering from anæmia who are also troubled with constipation. But the visitors are, as a rule, attracted more by the fine sea-bathing than they are by the springs.

T. L. S.

SCARLET FEVER. Synonyms: Scarlatina (English and Italian); Scharlach (German); Scarlatine (French); Escarlatina (Spanish).

Definition.—Scarlet fever is an eruptive contagious fever. Its incubative period is brief, rarely less than twenty-four hours, usually lasting from four to six days, and not often exceeding this duration. This period is succeeded by a period of invasion which is ushered in by fever, usually of considerable intensity, and by sore throat. A scarlet eruption begins to appear before the end of the second day, and marks the end of the prodromal, and the beginning of the eruptive, period. The eruption rapidly becomes general, and the tongue becomes stripped of its coating and assumes a raspberry-red color. The eruption slowly fades after the first few days. The fever persists until the sixth, seventh, or eighth day, or longer. As the eruption fades, desquamation begins and continues for from eight to fourteen days or more. It is peculiar in being lamellar, sometimes occurring in very large shreds and exfoliations. During the attack, and for weeks subsequently, there is an especial predisposition to renal inflammation. Scarlet fever attacks children more especially. It usually affects an individual but once.

History.—Scarlet fever is probably a disease of very ancient origin, though until three centuries ago medical writers had not recognized it; indeed, definite knowledge of it as a specific, independent affection dates back hardly two hundred years, although as early as 1589 an epidemic, which we now presume to have been scarlet fever, was described as having occurred in Sicily in 1543 (Paulus Restiva).[1] It was not until 1676 that Sydenham definitely separated this malady, as "*febris scarlatina*," from measles, and gave it an established position. The observations of writers had already been leading them toward similar views, and within a few years scarlatina became recognized all over Europe. Although its place of origin can never be known, it is probably of European birth; for it is a remarkable fact that scarlet fever has never succeeded in gaining a firm foothold in Asia or Africa. According to Hirsch, in whose most

valuable work these facts have been recorded, the coast of Asia Minor is the only Asiatic district which is frequently visited with scarlatina in its severe forms. In nearly all other parts of Asia it occurs not at all, or only sporadically. Wernich, in 1871, declared the disease to be quite unknown there. In Africa, Hirsch states that it is only in Algiers and in the Azores that it is at all common. Following the carefully recorded data of Hirsch, scarlet fever appeared first in America, in New England, in 1735. It extended as far south as Philadelphia in 1746, and penetrated to Ohio in 1791. Not until 1851 was it seen in California. In 1830 it began to be generally observed in South America. In the West Indies it was first observed in 1802, in Martinique, as a mild epidemic. Greenland has heretofore escaped with but a solitary case. Australia and Polynesia appear to have escaped until 1848. In the Polynesian islands, except Tahiti, scarlatina has not been known. It is unquestionable that scarlet fever has never occurred in some localities only because the inhabitants have not been exposed to its influence; but there can be no doubt that in other countries influences prevail that oppose the development of the disease. Whether these are climatic or racial, or due to other causes, is at present unknown. The American Indian is not exempt from its ravages, nor can any different degree of susceptibility be observed in the negro race in the United States. Frick,[2] however, noted a somewhat more pronounced tendency in the negro to scarlet fever. In the epidemic in Baltimore, between the years 1850 and 1854, of every ten thousand inhabitants 13.8 whites and 10.8 negroes died. This would indicate a relatively greater predisposition in the negro, as in the total population the whites were largely in the majority. Frick's observations were too limited to secure an unhesitating acceptance of his conclusions. It must be noted, however, that in this country the negro is rarely of unmixed African descent. He may have inherited from white progenitors some of their especial liabilities to disease. Drake and others have shown that scarlet fever prevails less in the Southern than in the Northern States. It is also probably true that the disease is more frequent in cold than in hot countries. Yet it cannot be determined that the differences depend upon temperature; Greenland has remained without an epidemic, while Algiers has experienced them frequently.

Scarlet fever at once shows differences from small-pox and measles in not sweeping over localities in great periodic waves. It may, it is true, sometimes invade very wide areas of territory with astonishing rapidity, but the intervals between epidemics are often very great. Without obeying any well-defined periodic law, measles is often known to prevail with noticeable violence every third or fourth year, frequently disappearing completely in the interim: so, too, small-pox usually exhibits unwonted activity at intervals of from five to ten years, or as soon as popular neglect of vaccination renders a large portion of a community susceptible to it. It is not thus with scarlatina. Hirsch has collected very valuable information upon this point. At Münster fifty years elapsed without the disease appearing. At Ulm there was only one small epidemic in seventeen years. At Tuttlingen scarlet fever had not been seen for thirty-five years previous to the epidemic of 1862–63. A number of writers, however, *have* observed an epidemic cycle in scarlet fever. Thus Fleischmann,[3] at St. Joseph's Hospital, in Vienna, observed one of four years. In Dresden, according to Gerhart, there is an epidemic cycle of from four to five years; in Munich, according to Ranke, of three years. On the other hand, scarlet fever often prevails sporadically for a long time in a locality, finally to disappear or to spread suddenly far and wide. Mayr[4] states that in Vienna the register shows that scarlatina has never absolutely died out in fifty years. Scarlet fever is remarkable in the varying intensity of cases occurring during a given epidemic, and in the differing severity of epidemics. At one time it was regarded as an insignificant disorder, almost never proving perilous to life. Even now epidemics of an exceedingly mild type are frequent. Graves has told how, between 1800 and 1834, whenever scarlet fever prevailed in Dublin, it was so uniformly mild that medical men attributed the bad results of their predecessors to improper methods of treatment, and flattered themselves upon their superior skill, until a change in type brought their death-rate quite up to that of former times.

ETIOLOGY.—It is certain that scarlet fever has for its essence some active specific principle, which, conveyed by the atmosphere, or by fluids, or by mediate or immediate contact from one person to another, excites a peculiar morbid train of phenomena. Although, even recently, there have been those who maintain that it may be autochthonous, contemporary writers are unanimous in adopting the theory of a *contagium vivum* in its pathogenesis. The tendency of recent investigation has been to direct attention to certain low forms of vegetable life, belonging to the schizomycetes or bacteria, as the probable cause of this class of specific diseases. It is altogether probable that they maintain a similar relationship to scarlet fever. As yet, however, they have not been identified with certainty. Carpenter, who claimed that the disease may arise *de novo*, asserted that it then results from germs of organic matter which have been given off from vertebrate blood in a particular state of decomposition, and that the decomposition of blood in slaughter-houses is a frequent source of scarlatina. This view has not been successfully maintained. Coze and Feltz[5] detected in scarlatinous blood diplococci (sphærobacteria), and produced in rabbits by inoculation of this blood a fever-like disease. Riess[6] has had similar experience. Recently Löffler[7] has described chain-shaped cocci in the membrane of scarlatinal diphtheria. He claims that if these be introduced into a joint, inflammation soon develops; if simply beneath the skin, an inflammation like erysipelas results. Hallier[8] found in the blood of three patients a greater mass of micrococci than he has ever seen in any other infectious disorder. They were more numerous than blood-corpuscles, swimming free in masses united by a gelatinous envelope, in or on the corpuscles. Exceptionally the white cells, which were unusually numerous, were pervaded with micrococci. Hallier made culture experiments, and concluded that the blood of scarlatina patients contains a micrococcus of unknown nature, and proposed for it the name *Tilletia scarlatinosa*. Eklund[9] recognizes as the cause of scarlatina a micrococcus which he calls *plax scindens*. He finds it in the urine of scarlatinous patients, and describes it minutely. He has not found it in the urine of those who have not had scarlet fever, but has discovered it in the soil, on damp walls, on the margins of swamps, and in other places. Inoculations with *plax scindens* have not been performed, and, indeed, we can only wonder that anyone could be convinced by such insufficient evidence. More recently, Mr. George F. Cooke[10] has described a bacillus found in the nasal discharge and in the sero-purulent exudation from the inflamed lymphatic tissue of the neck in cases of scarlet fever. It occurred in leptothrix-like filaments. Pohl-Pincus[11] and Klamann[12] discovered micrococci in the scaling epidermis after scarlatina. Klein, in investigating the very important relations between scarlatina and a certain disorder in milch-cows, occurring at Hendon under the observation of Mr. Power (*vide infra*), discovered in the ulcers of the teats of affected cows a streptococcus which he was able to cultivate, and with it to successfully inoculate calves, producing a like affection. This streptococcus he also found in some condensed milk which was suspected to have caused an outbreak of scarlatina. He also succeeded in raising some colonies of the streptococcus in nutritive gelatine, etc., inoculated with human scarlatina.[13] Klein's investigations were of a highly meritorious character, and seemed to lead to the identification of the true micro-organism of scarlatina, but doubts of their accuracy have recently been raised by the results obtained by Jamieson and Edington, in Edinburgh, whose conclusions by no means tally with those of Klein. These authors,[14] after experiments and cultures performed under the strictest precautions and with the greatest care, describe

a number of organisms, of which *diplococcus scarlatinæ sanguinis* and *bacillus scarlatinæ* deserve especial attention. The former was found in forty-five per cent. of the cultures made from the desquamation, and in thirty per cent. of those made from scarlatinal blood. The specific cause of scarlet fever, however, is considered to be, by these writers, *bacillus scarlatinæ*. It was discovered "in every case but one of the tubes made from the desquamation, if taken after the termination of the third week, but never before this." It also occurred in every tube made from scarlatinal blood, if taken before the third day of the fever. While these various observations are of the greatest interest, they are so little in accord that one can hardly admit as yet that the pathogenetic organism of scarlatina has been definitely determined.

While we assume the exciting cause of the disease to be an, as yet, undetermined germ, in the presence of which alone scarlatina is possible, the question of the predisposing causes is a much wider one and demands careful consideration.

There is a widespread impression that scarlet fever prevails more especially during the fall and winter months. There is, indeed, some difference in favor of these seasons, but by no means to the extent that is generally supposed. Hirsch has tabulated the records of 435 epidemics. These prevailed 178 times in the winter; 157 times in spring; 173 times in summer; and 213 times in autumn. The same relative prevalence is shown in his tables of deaths from scarlatina. Of more than fifty-five thousand deaths from scarlet fever in London, from 1838 to 1853, 32.1 per cent. occurred in autumn; 25.2 per cent. in summer; 24.6 per cent. in winter; 22.1 per cent in spring. These figures, however, cannot be accepted with perfect confidence, as they must have been influenced by the mildness or severity of the several epidemics. Hirsch's data show also the season of prevalence and the severity of type for two hundred and sixty-five epidemics.

Of 77 winter epidemics	42.2 per cent. were	mild.
	55.8 " "	severe.
Of 50 spring epidemics	54 " "	mild.
	46 " "	severe.
Of 66 summer epidemics	45.5 " "	mild.
	54 " "	severe.
Of 72 autumn epidemics	48.6 " "	mild.
	51.4 " "	severe.

The maxima of malignancy fall in winter and summer; but, as Hirsch remarks, the difference is unimportant. It may be concluded, however, that in the spring epidemics are usually less frequent and milder.

Scarlet fever attacks nearly all of those who are exposed to its influence for the first time. It is chiefly observed in young persons, because older people are generally protected by a former attack. Nevertheless, adults who have never had scarlet fever are less liable to take it than children similarly circumstanced. This is not attributable to differences of age, but to feeble individual susceptibility, which probably held as well during the childhood of these persons. It is certain that a not very small percentage of persons successfully resist exposure to the scarlet-fever contagion throughout life. While, then, it is not difficult to understand why adults seldom take scarlet fever, it is more difficult to account for feeble predisposition observed during the early months of life. Infants less than a year old are rarely attacked, and often escape even when exposed directly and frequently. According to J. Lewis Smith, infants less than four months of age almost possess immunity. Murchison tabulated the ages of 148,829 fatal cases of scarlatina occurring in England and Wales, as follows, viz.:

Deaths under 1 year	6.7 per cent.
" between 1 year and 2 years	14.09 "
" " 2 " " 3 "	16. "
" " 3 " " 4 "	15.13 "
" " 4 " " 5 "	11.9 "

Fleischmann's figures give 8 deaths of children under one year of age; 304 from one to four years of age; and 206 from five to twelve years of age. J. Lewis Smith[15] added 58 cases reported by Octerlony to 145 of his own, a total of 203 cases, from which he framed the subjoined table:

3 cases were under	1 year of age.
25 " " from	1 to 2 years of age.

Children less than one year of age, therefore, possess no absolute immunity; indeed, scarlatina during fœtal life has been reported. Leale observed such a case, as did also Tourtual. Thomas records several cases occurring in the practice of others. Veit noted scarlet fever in a child fourteen days of age. Numerous similar observations, more or less trustworthy, have been recorded. On the other hand, Murchison saw two new-born infants remain healthy while their mothers suffered from scarlet fever. New-born children are so subject to cutaneous and other disorders that may readily be mistaken for scarlatina, that we may well demand the most definite testimony. Scientific exactness should require that a new-born child must be proven either to have served as the medium of contagion for others, or to have developed characteristic symptoms in the midst of predisposing surroundings. The third year is the one during which the most cases are probably encountered. Nearly ninety *per centum* of all cases of scarlet fever occur before the completion of the tenth year. Although the disease is rare in advanced life, it sometimes occurs. In Murchison's tables there are recorded ten deaths of persons over eighty-five years of age.

Barthez and Rilliet thought that boys were more often affected than girls. They were probably correct, though the difference is not great. Of 472 cases in St. Joseph's Hospital, in Vienna, Fleischmann states that 263 were boys and 209 girls. Barthez and Rilliet observed that scarlet fever rarely attacks tuberculous children. (Grisolle believed the same rule to prevail for the adult.)

The predisposition to scarlet fever is much less universal than that to measles and small-pox. While the two latter diseases will almost certainly attack all unprotected persons exposed to their contagion, scarlet fever often leaves unscathed persons who have been brought into the most intimate personal relations with it. It is consequently much easier to practise isolation with the hope of success. However, the immunity possessed by an individual, as shown by repeated exposures, may not prove perpetual, and well-marked, even fatal, scarlatina may follow a final exposure. A degree of immunity from scarlatina is sometimes exhibited in families, the members of which escape altogether, or have only light attacks. Unfortunately, on the other hand, a decided family predisposition to the disease is occasionally encountered, one member after another falling a victim to its virulence.

Careful observation has failed to show that predisposition to scarlet fever is especially favored by the nature of the soil or the state of the weather; neither can it be proven that the type of the disease is especially influenced by any ordinary surroundings, further than that conditions of life prejudicial to the maintenance of good health diminish the powers of resistance to the onset of the disease. It is important to remember that in the absence of the contagious principle no degree of filth, deprivation, dampness, bad ventilation or drainage, or exposure, no matter how injurious to general healthfulness, can serve as the starting-point for scarlet fever. Indeed, it is remarkable, considering the bad hygienic environment of the poorer classes, that between them and the rich there should be so small a difference in the degree of predisposition to, and in the relative mortality from, scarlatina.

To develop scarlatina an individual must, of necessity,

receive into his body the *materies morbi* derived from one who has, or who has had, the disease. In all cases the contagion must be communicated by the air, or in solids or fluids received into the body. It is probable that physical contact occurs but rarely between infected and unprotected persons, and that when it does occur, the danger of infection is due rather to the increased liability of intercepting emanations from the body. Scarlet fever appears to be not contagious at the very beginning. In this respect it differs markedly from small-pox and measles. In the prodromal stage the contagion is probably not set free as readily as at a later period. Girard, however, has asserted that it is contagious only on the first day. This hardly needs a refutation. Longhurst[16] also claims that it is most contagious during the pre-eruptive stage, and not at all during desquamation. These and similar opinions of individuals are negatived by the almost universal experience of observers. Scarlet fever develops its highest properties of contagion during its period of eruption, and, still unlike measles, retains its contagiousness until desquamation is far advanced. Two children, at the Netherfields Institution at Liverpool, were believed to have been centres of contagion six and a half weeks after the beginning of their illness.[17] Cameron[18] reports a case in which, nearly nine weeks after the beginning of her own attack, a child communicated the disease to her sister by contact. It seems probable that the power of communicating scarlet fever is retained, gradually diminishing in intensity, until the end of desquamation, which may not be completed for six, eight, even ten weeks. Thomas mentions cases where children, even after the completion of desquamation, while suffering from scarlatinal dropsy, probably served as centres of contagion. The agency of the atmosphere as a contagion-bearer does not seem to extend beyond a few yards. Thus, it often happens that the disease does not spread beyond the sick-room, provided mediate contact can be avoided. Possibly the contagion is of too great gravity to be wafted for any distance. Yet it is certainly, under certain conditions, very tenacious of life, and may be conveyed long distances and preserve its properties for prolonged periods. It has often been carried by a healthy person, who has been exposed to the malady, to persons at a distance. There are authentic accounts of physicians, nurses, attendants, and visitors serving thus to carry infection. Such unfortunate occurrences are not very common, and probably only happen when the carrier of contagion passes directly from the sick-bed to the unprotected person, without due regard to the proper disinfection of the person and clothing. A pernicious custom is the habit of putting on over-clothing and wraps over the dress in which the patient has been visited, without proper exposure to the free circulation of fresh air. The tenacity with which the contagion clings to inanimate substances is most remarkable. Articles of clothing, bed-linen, furniture, wall-paper, hangings, and the like, frequently serve to communicate the disease, and often after almost incredibly long intervals. Richardson gives an example of this. Four children lived with their parents in a thatched cottage. One child was taken with scarlet fever, and the others were sent away. After three weeks one of these was permitted to return. It took the disease on the first day and died. The walls of the cottage were now cleaned and whitewashed; everything was thoroughly scrubbed, and all wearing apparel was washed or destroyed. After four months another child returned. The next day he was seized with the disease and died. Here the thatch was thought to have retained the contagion. The germs of the disease may be shut up in a letter and conveyed a long distance. Woollen clothing, put away and brought out after many months, pillows, cushions, toys, books, have all been known to preserve the contagion in full vigor. The dissemination of the virus in the atmosphere has been stated to be very limited, but the same cannot be said so confidently concerning the agency of fluids. The spread of scarlet fever has never been directly traced to the water-supply, but there is abundant reason to attribute its occasional extension to the medium of milk. Thomas quotes two examples of this. One, reported by Bell, leaves it an open question whether the milk, its receptacle, or the boy who carried it, was the medium. The other came under the observation of Taylor, who noticed "that one of the first severe cases which initiated an epidemic occurred in the house of a milkman whose wife milked the cows, the milk being supplied to about twelve families in the city. In six of these scarlatina occurred in rapid succession, at a time when the disease was not epidemic, and without any communication having taken place between those who were affected and the person who brought the milk. It is very probable that in this instance the milk was the carrier of the contagion, as, previous to its distribution, it had stood in a kitchen which had been used as a hospital for scarlatina patients." More recently, Airy, in eighteen families, consisting of thirty-five persons, reported twenty-four of these sick with scarlatina within thirty-six hours. Every one of these patients received milk from the same source. Neighbors who had milk from other sources were not attacked. It was found that a person who milked the cows lived with a child in full desquamation from scarlatina. Several observations of this kind make it hardly doubtful that milk may serve as the vehicle for the scarlatina virus, and that it, indeed, may be considered a favorable culture-fluid for it. But until recently it has not appeared that the virus-bearing milk received its contamination otherwise than through human sources. Later investigations seem to throw much light upon the possible origin of scarlatina in man, and upon one of the paths for its dissemination previously unrecognized. A recent outbreak of scarlatina among persons who received their milk-supply from a dairy in Hendon, in England, seemed to be traceable directly to a disease of the cow. The cows of this farm were affected with a peculiar affection, among the symptoms of which were a shedding of the hair and the formation of vesicles and ulcers upon the teats and udders. This is an inoculable disease among cows.* In this connection it is an important fact that inoculation of cows, especially when in milk, with the virus of scarlatina, results in the production of definite symptoms. The reports upon these observations by Mr. Power, Dr. Cameron, and Dr. Klein will go far toward establishing the prevalence of a scarlatina in cows, and its fruitfulness as a cause of the spread of scarlatina to mankind. Further information upon this most important subject will, doubtless, be soon forthcoming.

The scarlatinal virus gains access to the blood through the respiratory tract, and is also conveyed in solid and liquid food to the stomach, whence it is absorbed. Though it is unlikely that absorption can occur through the sound skin, the disease is said to have been inoculated by artificial deposition of contagion-bearing material upon the abraded cutis. Miguel d'Amobise claimed to have inoculated children successfully with blood taken from scarlatinous patches. Stoel and Harwood have been reported as having conducted successful inoculations. On the other hand, Petit-Radel failed in his experiments. New observations upon this point are required. The contagion probably resides in the epidermis, and becomes diffused as this is exfoliated; also in the buccal and faucial mucous membranes, and probably in the secretions, in the lymph, and in the blood. In the absence of reliable inoculation experiments we have no fixed knowledge upon these points. Some writers deny that the exfoliated epidermis contains any virus whatever.

Clinical History.—*Incubation.*—Scarlet fever has a shorter and much less definite period of incubation than the other eruptive fevers. In determining the interval between infection and the outbreak of symptoms, it is much easier to reach correct conclusions when the fever has followed a single exposure than when the exposures have been repeated or prolonged. There is abundant evidence to show that the period of incubation may be less than twenty-four hours. On the other hand, it has been

* The existence of scarlatina among animals has been ably upheld. Salmon's and Peters' papers upon equine scarlatina are very important.

claimed that four or five weeks may elapse before the disease manifests itself. Most cases of scarlatina have an incubation period of from four to seven days. Even this wide limit, differing markedly from that of the other eruptive fevers, is subject to very many exceptions, and the literature teems with examples of scarlet fever developing a few hours after exposure, or only after many days, even weeks. Murchison believed the incubation period to be more often less than forty-eight hours in duration. The shortest authentic stage of incubation was in the case of Richardson, who after auscultating a scarlet-fever patient immediately became nauseated and chilly. He was conveyed home in the carriage of a friend, and dated an attack of scarlatina from that hour. Incubative periods of not more than twenty-four hours have been reported by many writers.[19] In 20 cases Dukes found the duration to vary from one to nine days, in 10 cases it was less than five days. Murchison reported, in the "Transactions of the Clinical Society,"[20] the incubative periods of 75 cases, none of which exceeded ten days. He considered a person safe from contagion who is not attacked within a week after exposure. Thomas[21] thinks that from four to seven days is the most frequent interval; Kaposi considers it to be about eight days; Gee thinks that seven days are rarely exceeded; Lewis Smith, that it is ordinarily less than six days. Longer intervals, however, are not infrequently noted. In one case Hagenbach[22] determined it to be eleven days; in another, fourteen days. Intervals of twelve days or more have been recorded by Veit, Paasch, Böning, Lewis Smith, and others. From the rather untrustworthy results of inoculation, seven days would seem to have been the incubative period. Barthez and Rilliet, Gee, and others thought they had observed cases where the incubative period covered several weeks, and, indeed, in delicate children, especially those with rickets or other neuroses, it may be much prolonged (Mayr). There is, however, a growing belief that the incubation of scarlet fever lasts less than six days, and, without attempting to be more accurate, we accept that as the common duration. It is very often less than this, and but very seldom more. In this, as in most other features, scarlet fever shows great variability, and, if the term be allowable, a capriciousness contrasting strongly with the other specific fevers.

Period of Invasion.—For convenience of description it will be proper to describe scarlatina as following an *ordinary* or *mild*, and a *graver*, course. The course is very often irregular, from the absence of characteristic symptoms, or from the undue prominence of one or several of them, or from the presence of complications. In fact, scarlet fever may vary from an insignificant, even an unappreciable, disturbance of health, to a malady pursuing its fatal course with lightning-like rapidity; and although the type of the prevailing epidemic may be mild, severe, or malignant, individual cases can only in a measure conform to the standard, from which they will invariably differ to a greater or less extent.

Milder Forms.—Ordinary Course.—Prodromal Period. At the end of incubation the active symptoms of scarlet fever usually develop suddenly; rarely they appear more gradually. In most cases fever is the first symptom observed. In larger children and adults an initiatory chill is often noted. Convulsions may occur at the outset; usually, however, they usher in graver forms of the affection. The fever develops during the night, or during the day the child loses its playfulness and in a few hours is found to have a high temperature, in most cases not exceeding 103° F. (39.5° C.), but occasionally reaching 104° to 105° F. (40° to 40.8° C.). At the same time the pulse will be full and frequent, beating from 120 to 140 times in the minute very commonly. The rapidly rising temperature and great acceleration of pulse are characteristic, and under favoring conditions should excite suspicions of scarlatina. The face becomes flushed, the eyes bright and injected. There is much thirst, but almost complete anorexia. Nausea and vomiting are so frequent that J. Lewis Smith attaches some diagnostic importance to the symptom. Of 214 patients it was present in 162. Jenner thought that severe vomiting is apt to precede severe throat symptoms. Diarrhœa sometimes occurs, especially in graver cases. The tongue may be only slightly coated; frequently it is covered with a white, creamy fur, but remains red at the edges. Already the little patient complains of sore throat (indeed this may be the first symptom to attract attention), and upon inspection the mucous membrane of the pharynx will be found to be swollen and dry, and of a bright or dusky-red hue, and often spotted with small areas of duskier redness. At this stage no curdy nor diphtheritic deposit will be observed. The nasal mucous membrane sometimes participates in the hyperæmia, and a nasal catarrh is induced. There will now be difficulty in deglutition, and already there may be some enlargement of the submaxillary and cervical glands. There is often headache and also delirium, sometimes of an active kind. As the fever increases in severity the patient becomes dull, listless, and drowsy, and various symptoms of cerebral disorder are common in graver cases. In very many cases, however, all the symptoms will be mild. There may be little fever, no noticeable disturbance of the various functions, not even sore throat. Beyond slight peevishness and irritability the child may not seem to be unwell. In not a few cases there may be no prodromal period at all, the eruption first attracting notice. During the prodromal stage the urine is rather scanty, acid, and high-colored. According to Gee, the urine is diminished in quantity; urea is not necessarily increased; chloride of sodium is diminished, sometimes decidedly, the diminution generally ceasing suddenly on the fourth, fifth, or sixth day; phosphoric acid, at first normal, is notably diminished on the fourth or fifth day, remaining for four days from one-third to one-half the normal quantity, and then returning to the healthy standard; uric acid is greatly diminished on the second and third days, becoming excessive on the fifth day, and then normal. Even at the earliest observation albuminuria may be observed. Böning, who denies a prodromal stage, and always encounters the eruption on the first day simultaneously with the chill, has found blood-corpuscles, renal epithelium, and albumen in the urine from the very start. The respiratory movements quicken in proportion to the rapidity of the pulse. Nearly all cases will begin to show the eruption within twenty-four hours, many within twelve hours, a few during the second day. When the eruption appears later, an abnormal or unusually severe form of the disease often follows.

Stage of Eruption.—The eruption first appears upon the sides of the face, upon the neck and submaxillary region, and on the front of the chest, in the clavicular region, as small, pale-red points, closely aggregated although at first discrete, and very slightly elevated. It rapidly extends over the chest (where it becomes most intense), upper and lower extremities, and attains its full distribution by the end of the second day, acquiring a bright red or scarlet color. It occasionally happens that the eruption begins on other parts than those mentioned, or may never become general. Rarely it spreads more slowly, even fading in some localities before the lower extremities are invaded. It is especially apt to affect the flexures of the joints. In mild cases the spots remain discrete over most of the body, and may resemble a fine "prickly heat," densely arranged and of minute size. At times the eruption consists of dark-red points, surrounding hair-follicles, separated from each other by less intensely red areas (Henoch). In cases of greater intensity it is coalescent almost universally, and presents a continuous brilliant scarlet surface, like the shell of a boiled crab or lobster. The intensity of coloration varies somewhat, even in the same patient, depending much upon the degree of heat; becoming paler when the surface is cooled, more scarlet when this is protected by heavy covering, etc. It is, however, not perfectly smooth, but shows the tiny papules upon the reddened base, and communicates to the hand passed over it a sensation of roughness and of dry and pungent heat. Upon the legs and arms the eruption very often becomes more scattered, assuming the form of separate tiny points; rarely it is distributed over distinct

areas of the trunk and extremities, with intervals of faintly erythematous redness (scarlatina variegata). This form, however, is apt to appear in severe complicated cases. It must be remembered, however, that, unlike measles, scarlet fever affects the face less than other parts. Never very intensely developed over the forehead, temples, or chin, the eruption entirely spares an area around the mouth, including the upper and lower lips and some distance beyond the angles of the mouth, and often extending upward to include the nose. This area contrasts with the surrounding parts by its remarkable pallor. It has been asserted that the cheeks are also spared by the eruption. This is not true. The cheeks do not show the pointed redness of the early eruption elsewhere, but at once assume a scarlet or crimson redness that is deeper than the color induced by fever. The lips are often dry and cracked, and may bleed. The face becomes considerably swollen, especially in the loose tissue about the orbits. The ears are also swollen and of a bright red color. The eruption does not spare the scalp. Upon the backs of the hands and feet the eruption is discrete, and is arranged in groups the size of a lentil, while upon the palmar surfaces of the hands and fingers, and upon the soles of the feet, a bright, diffused redness, with swelling, is seen. At times the eruption will be partial, developing upon the trunk alone, or on the extremities, or in isolated patches about the body. These cases may not be abnormal in other respects. The skin over the joints is especially prone to be affected. The lesions may be more or less disseminated spots, varying from the size of a pin-head to that of the finger-nail, or a half-dollar, or even larger. It has been asserted that the eruption constantly consists of a papulated rash upon a reddened base, even when universally diffused. This is not invariably so, and one may encounter a smooth, uniform redness inappreciable to the touch. Where the eruption is very intense, small hæmorrhagic spots, or petechiæ may appear. When thus occurring, their occasional presence is not of serious importance. In warm weather especially, and in children too warmly covered with bedclothes, the surface, particularly of the neck, chest, and belly, is sometimes plentifully sprinkled with an eruption of sudamina. In some epidemics these are more often observed than in others. It is not impossible that the "miliary fevers" that formerly occasionally prevailed in Europe, were, in reality, forms of scarlatina. Mayr has said that the eruption of scarlet fever often spares the skin of paralyzed limbs; but Kaposi asserts that it may be unusually intense upon these parts. In dark-skinned races the eruption undergoes some modifications, which are greatest in those of full negro blood. In mulattoes and negroes it becomes often exceedingly difficult to distinguish the eruption. Of course the scarlet color is absent, a tinge of red will often struggle through the darkly pigmented skin, especially of the cheeks and abdomen. The true character of the eruption may often be revealed by a finely papular condition, the tiny papules of the size of a pin-point being made apparent by their acuminated summits, which give, against the dark background, a resemblance to a sprinkling of the surface with a fine dust. The hand passed over them can perceive the little asperities. These are closely aggregated. In many cases it is impossible to recognize the eruption, and the diagnosis must rest upon the concomitant symptoms, which will not be peculiarly modified.

While the eruption—which attains its height by the end of forty-eight hours in mild cases, later in severe ones—is developing, the other symptoms become pronounced. The faucial mucous membrane is uniformly redder, or, occasionally, shows numerous red macules; the uvula, tonsils, and buccal mucous membrane are reddened and swollen, and pain in deglutition increases. As the eruption reaches its height, the tongue parts with its coating in patches, exposing areas of intense redness. By the third day it acquires a uniformly brilliant red color, with enlarged papillæ scattered numerously over its general surface, and presents the characteristic "strawberry" or "raspberry" appearance. Exceptionally, this exfoliation of the lingual epithelium does not occur, and the creamy deposit persists. In many mild cases there is slight nasal catarrh, with a thin discharge from the nostrils. A muco-purulent discharge from the nostrils is associated with the throat complications of the graver forms.

During this period the fever continues to increase until the completion of the eruption, or the prodromal temperature remains unchanged. In the type of cases we are considering 105° F. (40.5° C.) is not often exceeded. Should the fever continue to increase after the third day, grave solicitude as to the result will be justifiable. The other symptoms continue with undiminished vigor—digestive disorder, nausea, vomiting, complete anorexia, rarely diarrhœa, persist. The skin burns or itches more or less intensely. Nervous symptoms, restlessness, stupor, headache, delirium, usually diminish, but may continue unabated; or active delirium may occur. Convulsions at this time are very ominous. The sore throat becomes distressing, and the cervical and submaxillary glands enlarge and become painful. Bronchial and pulmonary inflammation only occur as complications. After the fourth or fifth day nearly all of these symptoms cease to increase, and it becomes evident, *cæteris paribus*, that the course of the disease is to be favorable. The eruption, after persisting in full development for a day or two, becomes duller and slowly fades, first in the parts earliest affected, latest from the back of the hands. The color, which at first completely faded, now leaves a yellowish stain when the finger compresses the skin. It is not, however, until after four, five, or six days, that the skin loses its scarlet color. This may last longer. Jenner[23] has known it to persist for from fourteen to sixteen days. The fever slowly declines, until it ceases about the sixth, seventh, or eighth day, or later, and not before the eruption has entirely disappeared. Sometimes, from unknown reasons, it persists for days after all local symptoms have ceased to be active. On the other hand, fever, in some very mild cases, will hardly be noticed, or will endure but a few hours. The throat manifestations, or the supervention of complications, may protract the fever for many days. The sore throat, unlike the other symptoms, often fails to show signs of amelioration after the height of the eruption. The swelling and redness may increase, and white or yellowish curdy deposits form upon the tonsils and uvula, or the posterior wall of the pharynx may be bathed in a thick muco-purulent discharge from the posterior nares. True diphtheritic membrane is not apt to form in these cases, but the neighboring lymphatic glands may become highly inflamed and suppurate. It is probable that renal catarrh and nephritis occur more frequently during this period than is commonly supposed. Frerichs, Reinhardt, Eisenschitz, Böning, Begbie, Newbigging, Holder, and others, consider the renal symptoms as essential in scarlatina. This is, however, not true. Thomas[24] practised microscopic examinations of the urine in twenty-five of eighty patients, and in twenty of these daily. In the prodromal and eruptive stages he found slight albuminuria only rarely and transitorily. Decided alterations in the renal tract were most uncommon. Mild catarrh was more often seen. Only the more severe forms he considered to depend upon a specific scarlatinal influence. Fleischmann,[25] in 472 cases of scarlatina, reported dropsy during the first week in 9 cases. Not enough, certainly, to bear out the sweeping assertions just quoted, but sufficient to direct attention constantly to the condition of the kidneys in scarlatina.

Many cases of mild scarlatina fail to exhibit all the symptoms enumerated. The prodromal stage may be absent, sore throat may be insignificant, or absent throughout. The tongue may never assume the "strawberry" appearance. The fever may be of feeble intensity. Finally, the rash may be faint and not widely distributed. It may be limited to a few reddish or pinkish punctate spots upon the neck or chest; or it may only affect the flanks or the flexures of the joints; or it may be so transitory as to escape observation or to be noted only during a few hours; or, finally, it may fail altogether to appear. On the other hand, sore throat may be the only active evidence of the disease. Cases that have been exposed to the contagion sometimes develop sore throat

only. These may subsequently become dropsical from nephritis, or they may desquamate more or less abundantly, or even communicate scarlet fever to others. An interesting feature is a tendency, often shown by those exposed to contagion, to suffer from a mild attack of pharyngitis after every exposure. Many physicians, nurses, etc., experience this. Finally, the eruption may fail to appear, knowledge that scarlatina was present being acquired through the occurrence of desquamation or dropsy. Cases of this kind have been designated "*scarlatina sine exanthemate.*" They are not so very rare. At other times the eruption is so indeterminate in appearance that, in the absence of accompanying symptoms, it is impossible to speak positively of its character.

Stage of Desquamation.—After the fading of the eruption the patient passes into the stage of desquamation. This is an immediate result of the eruption. Desquamation begins usually upon the neck, and continues for from eight to fourteen days, but not infrequently for four, six, or even eight weeks or more. Usually not earlier than the sixth day of the disease it is noticed upon the neck and face, and quickly extends over the whole surface, and may even occur upon parts not visited by the eruption. Upon the face and neck the scales are mostly fine, but coarser than those following measles. From other parts the epidermis peels in great shreds. On the hands and feet the lamellæ are always large, and sometimes from these members the cuticle is removed in masses resembling a glove or slipper. Desquamation endures longest where the epidermis is thickest, often for weeks; that newly formed exfoliating repeatedly. The hair and nails are sometimes shed after scarlet fever. Desquamation is at times observed in those who have had no eruption, or, at least, one of very circumscribed extent. With the completion of desquamation the disease may be said to have run its course. Great care, however, must be exercised for some weeks to protect the patient from the effects of complications and from the sequelæ to which the disease has made him liable. With the fading of the eruption, the cessation of fever, and the beginning of desquamation, general improvement takes place. The tongue gradually resumes its normal appearance, or for a time becomes again coated; the sore throat diminishes; the various functions are properly performed; appetite and strength return. Desquamation may, however, be sometimes delayed. The local use of oils and ointments during the eruption tends to make the desquamation less free. The occurrence of dropsy sometimes defers the beginning of desquamation, and this may not become abundant until after the dropsy has subsided. Contagion has spread from desquamation beginning in this manner, after isolation has been abandoned as no longer necessary. In rare cases desquamation can hardly be said to occur at all. Even in mild cases, in winter, the patient should not be permitted to leave his bed until the end of the third week, or to leave his chamber until the completion of desquamation. In midsummer it is usually not advisable to insist upon confinement to bed for so long a period. Cases which run the apparently mild course just described are by no means free from danger, as they are often accompanied or followed by local pathological processes which, while they may not be essential symptoms of scarlet fever, are especially prone to affect those suffering from it. Such lesions will be considered among the complications and sequelæ of scarlatina.

Graver Forms.—Every case of scarlatina is dangerous. In those following the type just described the peril arises from processes that are not essential to the disease. Such forms pass, by insensible gradations, into those where life is imperilled by the greater or less intensity of characteristic phenomena. The graver forms of scarlatina may not differ in their initiatory symptoms from those already described. In most cases the severity of the disease is in great measure dependent upon lesions in the throat, while, as a rule, the eruption shows a more general distribution and a more intense coloration. The prodromal symptoms do not differ in kind from those of milder types, but are more severe. Vomiting is more apt to occur, and nervous symptoms to become prominent. Headache, jactitation, and delirium become more marked, or the patient grows petulant, drowsy, and stupid. Convulsions also may occur. Fever attains great intensity at the very outset, reaching 40° to 42° C. (104° to 106° F.), the latter temperature always denoting extreme danger. There is already sore throat, with difficult deglutition and with swelling and deep redness of the faucial mucous membrane, which by the third day, in the less severe cases, shows curdy deposits scattered over the tonsils. These deposits do not involve the mucous membrane, and may generally be detached by a mop or a brush. They are quite like the exudation of ordinary catarrhal pharyngitis. After the third or fourth day, under conditions of constantly increasing fever and general distress, in some cases, diphtheritic exudation begins to show itself over the tonsils and soft palate, and posterior wall of the pharynx. It is an interesting point of difference between primary and scarlatinal diphtheria that the latter never begins to appear before the third or fourth day, after which date it is sufficiently common. Fleischmann reported diphtheria 168 times in 472 observations. The diphtheritic deposit is first developed on the lateral portion of the tonsils, except in those rapidly fatal cases where the whole pharynx seems to be simultaneously involved. The patches are of a whitish or grayish-white color, and involve the mucous membrane sometimes to a considerable depth and superficial extent. At times the diphtheritic membrane rapidly spreads in a continuous sheet over the fauces, extending forward into the buccal cavity and into the posterior nares. In the latter case, a fatal termination is almost inevitable. Heubner [25] asserts that those cases in which the entire mucous membrane, from the root of the tongue to the œsophageal and tracheal orifices, is covered with the membrane, die within twenty-four or forty-eight hours, without exception. Here the membrane is sharply margined against the dusky-red mucous membrane, and within a few hours the slough shows signs of separation and develops a gangrenous odor. In these cases the membrane hardly ever travels down into the trachea. Bretonneau has made a positive assertion that this does not occur. It does so occasionally, however. Lewis Smith reports cases, with necroscopic examination, where diphtheritic membranes extended along the trachea into the bronchial tubes. In the most severe cases, however, the deposit does invade the posterior nares, and the ordinary slight catarrhal discharge is supplanted by an offensive sanio-serous or sanio-purulent discharge from the nostrils, which causes excoriation of the upper lip. At the same time the nares become obstructed, and the little patient is driven to breathe almost entirely through the mouth. In many cases of extreme throat involvement the strength rapidly fails, pallor replaces the prematurely receding eruption, except at certain spots where this may persist as circumscribed patches of dusky redness; the temperature remains stationary or falls, the pulse becomes more and more feeble and rapid, and death ensues within a few hours, as if from blood-poisoning. Death either follows slow spread of gangrene to the soft palate and tongue behind the *sinus pyriformis*, and to the walls of the throat, or occurs through diphtheritic inflammation of the lymph-glands and connective tissue of the neck, or through œdema of the glottis. At other times the clinical appearances during the first week may not be alarming, danger becoming imminent about the beginning of the second week. The fever may remain elevated, the eruption brilliant and intense, until a short while before death. In the rapidly fatal cases the throat and neck may not appear very much swollen. At other times the neck and submaxillary region are greatly swollen, principally from the inflammation of the glands and peri-glandular tissue. These parts become hard and brawny, and from the pressure upon the great veins acquire a livid appearance, which may also be communicated to the face and head. The tonsils and soft palate may be swollen until the throat will appear quite closed. The mucous membrane will be deeply congested, and covered here and there with diphtheritic exudation, and with ulcers caused by the separation of sloughs. The

posterior wall of the pharynx may be bathed in muco-pus. Retro-pharyngeal abscess is sometimes formed, and may precede the fatal termination. Dyspnœa may result from swelling of the fauces caused by inflammatory exudation into the parts, from *œdema glottidis*, or from extension of diphtheria to the larynx and trachea, or it may be a result of the imperfect oxidation of the blood. The term "diphtheritic" is here used in a clinical sense, to designate a condition of coagulation-necrosis in the tissues involved, and has no reference to a pathogenetic relationship with true diphtheria. This necrosis occurs simply as a result of the intensity of the accompanying inflammatory changes. There is no evidence that true diphtheria may not co-exist with scarlatina, but that the commonly observed membranous pharyngitis of scarlatina represents this combination is most improbable. J. Lewis Smith has seen four instances where the diphtheria became dissociated from the scarlatina, and attacked other persons as idiopathic diphtheria. Such observations are exceedingly uncommon. The scarlatinal diphtheritic membrane is, indeed, essentially identical with that of idiopathic diphtheria in structure. The differences are etiological. The diphtheritic poison and the scarlatinal poison, differing in their specific natures, possess in common the power to excite such violent inflammatory changes in the tissues that a coagulation-necrosis results. The diphtheritic membrane of scarlatina, then, is purely scarlatinal in its origin. This view has received solid endorsement. It has been adopted by Henoch. Heubner considers scarlatinal diphtheria to differ from primary diphtheria both clinically and histologically. It begins with a simple catarrhal affection, and, following his observations, changes from catarrhal to diphtheritic inflammation on the fourth day. Koven also thinks that the throat affections of more severe grade are necrosis from direct intensity of the scarlatinal process, and not truly diphtheritic. He observes that while two acute diseases rarely co-exist, of 426 cases of scarlatina 125 had *necrosis faucium*, although at the period of observation there was not a single case of primary diphtheria in Christiania. He further declares that diphtheritic paralysis never occurs after scarlatina, and that while true diphtheria shows the membrane at once, the scarlatinal slough usually appears after several days of increasing angina, and does not extend to the larynx.[27] Henoch has never seen a single case of accommodation paralysis of the eye or of the soft palate, nor of the neck, nor of the extremities, after scarlatinal diphtheria. The inflammation may, often does, extend along the Eustachian tube to the middle ear, and excites changes that give scarlet fever one of its principal terrors, resulting often in more or less complete permanent deafness. These changes will be considered with the complications and sequelæ of scarlatina. In a number of these cases cervical adenitis and periadenitis occur, and prolong the fever beyond the eruptive stage indefinitely, frequently resulting in suppuration. Occasionally the pus burrows deeply among the tissues of the neck, and extensive gangrene may follow. Williams has reported a case of extensive sloughing in the left anterior triangle of the neck, with exposure of vessels, followed by recovery. Other similar cases have been recorded. In most cases where death does not speedily occur after suppuration and evacuation of pus recovery will take place, but the patient may ultimately succumb under blood-poisoning and protracted fever. Occasionally, also, parenchymatous tonsillitis may cause rapid and enormous enlargement of the tonsil, with the formation of pus, a condition of extreme gravity, especially if associated with retro-pharyngeal abscess and œdema of the glottis. In favorable cases the sloughs in the fauces will cease to extend, the œdema and dusky redness will slowly subside, and the diphtheritic ulcers begin to granulate.

In many cases the faucial symptoms here described do not appear, only because life is early destroyed by the intensity of the action of the specific poison upon the blood and tissues. In such malignant cases the patients often die with the rapidity of those who succumb to narcotic poisoning; or a series of convulsions inaugurate the disease and terminate life within an hour or two. At other times brief initiatory symptoms have been followed by intense fever (106°–109° F.), with uncontrollable vomiting, diarrhœa, delirium, rapidly deepening coma, and death, before the appearance of the eruption. Or, again, the disease may begin in the ordinary manner, not suggestive of a severe course, and alarming symptoms may not develop until after several days; or it may be intense from the beginning, with severe and repeated convulsions, vomiting, profound nervous depression, and the appearance of the eruption at the usual time, with steadily increasing gravity of all the symptoms, until, after a few days, death results from convulsions or coma. Finally, the malignant symptoms will appear suddenly in the midst of what has seemed a mild attack of scarlatina. An unusually protracted period of invasion is sometimes the forerunner of malignant scarlet fever, and should always be regarded with apprehension. Cases may at times exhibit at the beginning alarming symptoms. A decided apathy, in which no notice of what is passing is taken, with great apparent depression and even delirium, excites the apprehension of the attendants, yet the pulse and temperature will not show marked variation from the normal. After the second or third day such cases will very often pursue a mild course. A high temperature and very quick pulse may even be added to these symptoms and justly excite alarm, and yet the case may assume a favorable character after the development of the eruption. In such cases as these the probability of the issue in life or death seems to vary from hour to hour. All the symptoms show intensity. The fever, accompanied by more or less severe initiatory symptoms, rapidly increases, the eruption is copious and deeply colored, the pulse beats 130, 140, 160 times, or oftener to the minute, the respiration is proportionally accelerated, the throat duly shows more or less extensively the peculiar alterations. This course may be held throughout the first week, and even longer, without mitigation, the result remaining doubtful all the while.

In malignant scarlet fever the usual course is one of intensified general symptoms. Those of the invasion period are indicative of grave perturbation of the economy. By the time the eruption appears it is already evident that the patient is dangerously ill. He is apathetic, or perhaps extremely restless, remaining in one position not an instant. The skin is hot, dry, and pungent, the temperature very high, the features swollen, the conjunctivæ injected, the fauces reddened and dry, the thirst intense, but water and all ingesta are often vomited as soon as swallowed; the urine is scanty, or even suppressed, from acute renal inflammation. Diarrhœa may be present. The nervous phenomena become intensified. The eruption now appears, and may at first develop regularly, but after a while will become duskier and will not completely fade on pressure. The color tardily returns to the part whence it has been pressed. Coma or convulsions may now carry off the patient in full eruption. Often, however, the eruption will recede from certain parts in whole or partially, or it may become paler universally; or in place of the regular eruption hæmorrhagic exudation will appear. Ecchymoses, from the size of a pin-head to that of the palm, or larger, will replace the usual eruption, which will in great measure disappear. Then livid spots, not fading on pressure, are found, generally upon the flanks and back, but may appear anywhere. According to Mayr, the hæmorrhagic eruption may appear over a large part of the surface in children, but in adults is mostly confined to the neck, upper part of the chest, the back, and about the joints of the upper and lower extremities. This hæmorrhagic variety is the most formidable form of scarlet fever, and is probably always fatal. Hæmorrhages from mucous surfaces are exceedingly uncommon. Mayr has described a scarlatinal dissolution of the blood, in the gravest form of which death occurs in from twelve hours to five days. "Extreme muscular depression, with slight headache and a remarkably rapid pulse, are present from the very commencement. . . The patient lies on his back with his eyes half open, but in an unconscious state. . . . Quivering movements of the

muscles of the face and of the fingers are also commonly observed in these cases, and in children general convulsions often occur. The pupils are moderately dilated; the lips and tongue are dry, the latter being usually of a bright-red color. As the disease goes on, mucous râles are heard in the large bronchial tubes; the abdomen becomes distended, but there is seldom any enlargement of the spleen; the urine becomes scanty and of a dark-red color; the pulse continually increases in frequency, reaching as many as 200 beats a minute; the features become shrunken and the extremities cold." Death speedily follows. This form resembles the so-called typhoid scarlatina, in which drowsiness, stupor, delirium, and subsultus precede the fatal issue. The life-destroying symptoms are often connected with impairment of the heart's action, attributable to crippling of the vagus, when death occurs from heart-paralysis, without widespread molecular disintegration. This failure is shown by increasing weakness, frequency and inequality of the pulse, with quickened and shallow breathing, and coldness of the hands and feet. Allbut has classified the modes of death in scarlet fever as follows: 1, Hyperpyrexia (this Jenner denies positively); 2, specific blood-poisoning; 3, special malignity of the case; 4, asthenia. In the rather uncommon event of recovery from any of the most severe forms of scarlet fever, the progress is slow, the essential symptoms, complications, and sequelæ proving all very obstinate. In those cases where extensive diphtheritic exudation precedes a rapidly fatal course, the eruption undergoes many modifications, the integument remaining pale except for some few splotches about the joints, at other times showing only a few dark-red patches irregularly distributed, and again entirely disappearing before death. At other times the eruption persists in full efflorescence.

Complications. — *Nephritis.* — Derangements of the kidneys are the most important complications of scarlet fever. Indeed, a number of recent writers assert that these organs are always affected in this disorder. Among these may be mentioned Frerichs, Reinhardt, Begbie, Newbigging, Holder, Böning, and Stevenson Thompson. Steiner states that evidences of kidney disorder are always present in those who die of scarlet fever. Thomas' clinical observations do not bear out this statement, and Friedländer, who examined the bodies of two hundred and twenty-nine persons dead of scarlatina, found kidney disorder in less than one-half. Though renal inflammation is not shown as yet to be a constant accompaniment of scarlet fever, it occurs much more often than is commonly supposed. Renal catarrh, which Eisenschitz declares to be as much a feature of scarlet fever as bronchial catarrh is of measles, is indeed an extremely common complication. It usually escapes detection from the general neglect to duly examine the urine. Thomas, in denying that this catarrh is at all constant, shows that it also occurs in measles, croupous pneumonia, etc., and is often only an expression of the febrile condition. Yet the catarrh is relatively so common in scarlatina that he cannot avoid concluding that the specific influence of the disease is often concerned in its production In many cases, from the very beginning, cylinder-like masses of renal epithelium may be detected. In milder cases the urine will contain mucous casts with increased quantity of mucus, but no albumen. In more severe cases the urinary sediment will contain hyaline masses with epithelium and epithelial *débris*, and red and white blood-corpuscles. Slight albuminuria will also be present. This catarrh is usually insignificant, and but rarely serves as the starting-point for the graver and characteristic forms of nephritis scarlatinosa, though doubtless many milder forms of nephritis and dropsy originate in it. Thomas concluded, however, that the cases of scarlatinal nephritis not developing from preceding catarrh, but arising suddenly, usually end fatally. Scarlatinal nephritis varies greatly in the relative frequency of its occurrence, involving from five to seventy per cent. of cases in different epidemics. In the Children's Hospital, Hillier noted its occurrence in about half of the cases. Dickinson [28] considered this rather below than above the average. Fleischmann [29] noted 95 cases of Bright's disease in 472 observations. During 1861 every third child with scarlatina had dropsy, while in 1862 it affected only one case in ten. Thomas asserts that renal alterations develop in about one-half of all cases of scarlet fever. It has been shown that there are those who assert that the renal alterations are constant. On the other hand, Jaccoud [30] declares that for fifteen years he has never had a case of nephritis among his scarlet-fever patients, a result that he attributes to his treatment. Albuminuria may appear at any time during the attack of scarlatina, though its most common occurrence is during the second and third weeks. Dropsy should not be taken as marking the beginning of the nephritis, the signs of which may be present in the urine sometimes for days before this occurs. In Fleischmann's cases dropsy occurred 9 times during the first week, 30 times during the second week, 23 times during the third week, 20 times during the fourth week, and 5 times after the fourth week. Of 60 cases at the Children's Hospital, 42 began between the end of the first week and the end of the fourth week; 5 became dropsical during the first week.

Nephritis during the first week of scarlatina often escapes detection from the blending of its symptoms with those of the essential disease, and from the attendants' neglect to examine the urine. Dropsy will, of course, attract attention, but this does not often occur so early, and may be confounded with the œdema from the exanthem. Rarely, the fatal issue of what was, apparently, malignant scarlet fever, may really have resulted from uræmic poisoning due to a fulminating nephritis. The symptoms may be identical. Fever, vomiting, headache, delirium, amblyopia, coma, convulsions, may have been present. The convulsions are often very irregular. They may be general, partial, or unilateral, tonic or clonic. The patient may have them in rapid succession, or may pass into a *status epilepticus* from which death alone will release him. The urine will be completely or partially suppressed. If secreted it will be of high specific gravity (1.020 to 1.040), dark and smoky in appearance, loaded with albumen, and forming an abundant sediment of hyaline, granular, epithelial, and blood tube-casts, with renal epithelium and white and red blood-corpuscles in greater or less quantity. If the kidneys become implicated toward the end of the first week, the symptoms may delay the course of what may otherwise appear to be an ordinary case of scarlet fever. Microscopical research will often betray the onset of the changes in advance of chemical analysis; casts of the renal tubules will be observed, with epithelial deposits and detritus, before albuminuria is established. This will shortly appear, and in severe cases the nephritic symptoms will obscure those of the scarlatina. There will be no constant relation between the amount of albumen, the tube-casts, and the general detritus, one variety of sedimentary matter being at one time copious, at another scanty. At this time vomiting may appear with returning headache, the appetite will again fail, and pain in the loins may become annoying; the patient may again become dejected and feeble, and his fever may cease to diminish—may even exceed its original intensity. At other times no apparent influence will be exerted upon the scarlatina, which will follow its usually mild course until dropsy and albuminuria reveal the state of the kidneys. When the renal disorder develops after defervescence, during the second, third, or fourth week, or later, the same series of symptoms may be observed, their severity being in direct ratio with the earliness of their occurrence. Cases developing after the fourth week may be expected to pursue a favorable course. Although it has been asserted that the renal disorder may arise several months after a scarlatinal attack, a patient will almost certainly escape it if he pass the sixth week in safety. The symptoms in cases arising during these weeks are not always gradually developed, and some of the most disastrous results of the disease may be encountered during the second, third, or fourth week, in children apparently convalescing from scarlatina, and often in full desquamation, who, after indisposition for a few hours, with nausea, headache, con-

fusion of ideas or stupor, with return of fever, rapidly pass into coma or convulsions, ending after a short interval in death, before dropsy has developed, but after partial or complete suppression of urine. Scarlatinal nephritis has usually a mild and favorable course. Dropsy is usually the first symptom observed, first appearing in the face and sometimes remaining confined to this locality; at other times becoming general speedily, and giving an appearance of plumpness, but with a wax-like translucency of skin. The face, upper and lower extremities, body-wall, and prepuce, may thus become dropsical. The serous cavities are also implicated, and more or less effusion into the pericardial, pleural, peritoneal, scrotal, and intracranial cavities occurs. Œdema of the lungs and of the glottis may imperil life. Desquamation is often completely arrested upon the supervention of dropsy. The temperature is more commonly but little above the normal (38.3° to 39° C. [101° to 103° F.]). The pulse, sometimes feeble and accelerated, will often become remarkably slow and intermittent, and so remain throughout the attack. The child will grow dull and listless, and extremely feeble. Pain in the belly and in the back may at times prove very distressing, or, again, it may be absent. The tongue, having lost the strawberry aspect of the eruptive stage, will become pale, flabby, and coated. The appetite will fail, and the bowels become sluggish. The urine will rapidly diminish in quantity and may deposit urates abundantly, or may present a smoky and oily appearance, due to the abundant presence of epithelial cells, white and red blood-corpuscles, and tube-casts. The total amount may now be reduced to a few ounces. The blood-corpuscles often form a thick red layer at the bottom of the test-tube. This free admixture of blood may amount to pronounced hæmaturia. Such hæmaturia is generally post-scarlatinal, and, according to Schütz, occurs most frequently during the third or fourth week. Of itself it adds but little to the gravity of the case. The patient often feels fairly well, and may eat and sleep with comfort. While the pallor and œdema may be very decided, the temperature and pulse may vary but little from the normal, or may show the variations of ordinary nephritis. With the gradual improvement of the general symptoms the hæmaturia disappears. Heubner has reported a case of nephritis after scarlatina in which hæmoglobinuria was present. The urine was brownish-black; no blood-corpuscles were found. Death resulted from asthenia on the fifth day after both albumen and hæmoglobin had disappeared from the urine.

The amount of albumen in the urine in scarlatinal nephritis is usually very great. The urinary sediment is abundant, and is largely composed of tube-casts, the hyaline character predominating; finely and coarsely granular, epithelial, and blood casts are, however, numerous. Later coarse fatty granules stud the casts plentifully. These casts are often almost diffluent, and differ strikingly from the firm and sharply outlined ones of more chronic nephritis. Crystalline deposits are scanty, and are mostly of uric acid and urates; on the other hand, the amorphous urates are often very abundant. The degree of albuminuria present is of less importance than the total quantity of urine secreted, rapid and pronounced diminution of this indicating the accumulation of nitrogenous waste in the blood, and consequently the danger of uræmia. According to Glax, a lessening of the proportion of urine secreted to the fluid ingested (2 : 3), not infrequently foreshadows the approach of uræmic symptoms, even though the urine contain no albumen. Whether the temperature remain normal throughout the attack, or whether, after an initial chill, it become elevated, and all the symptoms of acute nephritis develop, complete recovery may reasonably be expected if the patient pass safely through the earlier phases of the disorder. But although nephritis may be mild, the dropsy lasting only a few days, and, perhaps, being limited to slight puffiness about the eyes, the disorder does not usually entirely subside in less than a month. It may endure as long as three, four, or even five months; and there is good reason to believe that chronic nephritis in young people may, in rare instances, have had its beginning in antecedent scarlatinal inflammation of the kidneys. Such a result is, however, exceedingly uncommon.

The dropsy indicates the degree of renal derangement, except in the most acute cases, and sometimes attains enormous proportions. As the urine increases in quantity the albuminuria proportionately diminishes, and the dropsy disappears. The skin, which until now has been dry and inactive, becomes softer, more elastic, and resumes its proper functions. The appetite improves, the spirits, strength, and mental activity return, and good health becomes gradually restored. Just as the microscope reveals the earliest evidence of renal derangement, so does it continue to expose the results of pathological action after chemical tests fail to do so. Tube-casts continue to appear in the urinary sediment, sometimes for weeks after the cessation of albuminuria, the blood-casts, epithelial, coarsely granular, and fatty casts gradually giving place to finely granular, hyaline, and mucous ones, which, in turn, finally disappear. When the disorder terminates fatally, the symptoms will be those of acute nephritis; suppression of urine may be followed by cerebral disturbance, headache of violent character, during which blindness may occur, with or without dilatation of the pupil, vomiting, and convulsions, partial or general, coma, and sometimes paralysis; or the fatal termination may be slowly reached through constantly increasing asthenia; or, what is more frequent, complications may arise which cannot always be definitely ascribed to the nephritis or to the scarlatina itself. Such are inflammations of the pleuræ, of the pericardium and endocardium, the peritoneum, the cerebral meninges, etc. Pneumonia, acute articular rheumatism, or enteritis, may also hasten the fatal issue.

Cases are occasionally observed in which dropsy follows scarlatina, but without albuminuria. Indeed, a tendency toward non-albuminuric dropsy after scarlatina has been associated with certain epidemics. Scarlatinal dropsy without albuminuria has been observed by Guersaut, Rilliet and Barthez, Noirot, Bouchut, Löschner, Duckworth, and others. Quincke [31] tries to explain such cases of non-albuminuric dropsy as not depending upon nephritis, but as a consequence of the scarlatinal irritation exerting some peculiar influence upon the connective tissue. Cases occur probably in the experience of most practitioners. One should be cautious, however, in deciding against a nephritic origin of these dropsies, except where they can be definitely attributed to anæmia and debility. Henoch [32] has asserted that nephritis may occur without albuminuria up to the time of death. He reports a case in which anasarca was present for three weeks after scarlatina, without tube-casts or albuminuria, until convulsions occurred, death resulting from œdema of the lungs. The necropsy revealed the presence of acute nephritis. He also reports the case of a child, dead on the thirteenth day, of malignant scarlet fever, in whom repeated tests during life had not shown albuminuria, and yet whose kidneys showed indubitable evidence of hæmorrhagic nephritis. Steiner has seen nephritis without dropsy, but never dropsy without nephritis, after scarlatina. It is altogether probable, however, that in many cases the dropsy following scarlatina without albuminuria is secondary to concomitant anæmia. This is the view adopted by Henoch. Whatever be their explanation, such cases usually run no remarkable course. The general health is not much reduced. The urine is in normal amount, the various functions are fairly performed. With the disappearance of dropsy convalescence is established.

Scarlatinal nephritis is not associated with any especial phase or type of scarlatina. It is as frequent after mild as after severe attacks; indeed, it is possible that the care exercised over those who have grave attacks of the fever, in proper nursing and surroundings, may furnish a safeguard against renal complications. At all events, there is a widespread belief that the milder cases are more apt to be followed by nephritis and dropsy. Violent nephritis may certainly follow a scarlatina so mild as to have escaped observation. Individual predisposition and epidemic type are probably the most important etiological

factors, though at present enough is not known to justify dogmatic statement. The nephritis and dropsy may occur without antecedent symptoms of scarlatina. Instances of this are not uncommon. Several members of a family or of a school or asylum in which scarlatina has been known to prevail, may exhibit dropsy and albuminuria characteristic of scarlatina, without having manifested any other symptom of the disease. Such cases pursue an ordinary course generally, but at times develop a severity altogether unexpected.

INFLAMMATION OF THE GLANDS AND CONNECTIVE TISSUE OF THE NECK.—Although Barthez and Rilliet, and others have observed cases of scarlatina in which there was no angina, in one form or another it is nearly always present. More or less hyperplasia of the neighboring lymphatic glands also constitutes part of the ordinary phenomena of scarlatina. It has already been shown that the inflammation sometimes leads to suppuration and even gangrene of the glandular and peri-glandular structures. This especially occurs in scrofulous and rachitic children, but is probably a result of septic absorption. The active symptoms become prolonged beyond those of simple scarlatina into the second, third, or fourth week, and even later, and merit some especial notice. They may not develop until as late as the third or fourth week, thus constituting true sequelæ rather than complications. Usually the fever continues after the subsidence of the eruption, the pain and stiffness of the neck increase, and deglutition continues painful and difficult, or even almost impossible. The mouth may be held open and saliva constantly dribble from it. The neck becomes hard, brawny, and swollen; the integument tense, smooth, and shining. The outline of the neck sometimes stands in line with that of the head and underjaw, and it becomes impossible to distinguish the enlarged glands in the mass of inflammatory exudation. The patient is unable to find repose, or to swallow food or fluids, unless in small quantities and with great pain. Rest is broken and unrefreshing. Suppuration reveals itself by dark-red, livid spots which soon fluctuate; or, it may be deep-seated and difficult to detect, or may point and discharge internally. The parotid gland and peri-glandular tissue often become involved. At times more or less widespread necrosis may lay bare important muscles, vessels, and nerves, and involve large areas of tissue. These diphtheritic and gangrenous inflammations may give rise to phlebitis or arteritis with thrombosis, and embolism with metastatic inflammation. Compression of the larynx, of the trachea, or of the jugular veins may also result. At times pus may burrow into the deeper cervical structures. Hæmorrhage may also occur from exposed vessels. Baader [33] reported two cases of death from hæmorrhage thus occurring. The extent of these phlegmonous inflammations of the neck varies greatly. In most cases, after the evacuation of pus, recovery follows, though slowly. In more severe cases death may result from exhaustion or from blood-poisoning. In healing, the scars may be insignificant, or, where granulation involves a large surface and is protracted, the resulting cicatrix may occasion deformity by its contraction. Retro-pharyngeal abscess, which has already been described, is not common. Schmitz, in the Child's Hospital, in St. Petersburg, did not observe it once in 450 cases of scarlatina. Cases, however, have been reported. Bokai reported it as occurring 7 times in 664 cases. Of these two died. Lewandowsky [34] reported two cases, both resulting in recovery.

DISORDERS OF THE AUDITORY APPARATUS.—These are very important complications of scarlatina. Probably most cases of deafness acquired in early life are results of scarlatina. Of 85 cases of affection of the middle ear following this disorder, 18 had lost the sense of hearing in one or both ears, and 3 were deaf-mutes.[35] Milder degrees of middle-ear inflammation arise by extension from the throat, and are simply catarrhal; but the severer forms are preceded by croupous-diphtheritic inflammation of the fauces. The milder form of otitis media will cause the patient some earache, of which, if he is old enough, he will bitterly complain. Infants will indicate their sufferings by cries, by raising their hands to the ears, by rolling the head toward the affected side. If the Eustachian canal remain pervious, all inflammatory exudation may escape, and no symptoms, other than those mentioned, and slight and transitory deafness, may occur. This latter symptom may result from the pressure of an enlarged parotid gland upon the external auditory canal. But in the severer forms the pain may be excruciating, deafness more or less complete, and fever high. The Eustachian canal becomes occluded from inflammatory swelling, and exudation accumulates in the cavity of the tympanum. Headache may be violent. The drum membrane will be bulged outward from internal pressure, and will be reddened and swollen. The pent-up fluid, unless released by puncture of the drum membrane, finds an exit for itself by perforation. Extreme pain is often produced by pressure upon the tragus and over the mastoid process. Rarely, delirium may be followed by signs of meningitis from extension of the inflammation from the middle ear to the *dura mater*, along the course of the middle meningeal artery. In mild cases the inflammation will subside, with or without perforation of the drum, and hearing may be perfectly restored. In severer cases, timely tapping of this membrane may yet preserve the sense of hearing, but, unfortunately, it but too often happens that the ossicles of the ear, and the tympanic membrane are destroyed; the bony walls, even of the middle ear, become carious, and irreparable damage is done. The severer inflammations involve a croupous diphtheritic process that often entails wholesale destruction. According to Green, disease of the labyrinth, involving absolute deafness, may occur within a day or two. In such cases the watch held to the skull, the ear or between the teeth, may not be heard. Green [36] thinks that when loud "clashing," "ringing of small bells," or "musical notes," are heard during scarlet fever or cerebro-spinal meningitis, these are apt to be immediate premonitions of labyrinthine disease; whereas, the subjective sounds always accompanying acute purulent inflammation of the tympanum are described as "hissing," "singing," "buzzing," or "throbbing." He also suspects that the fluid secreted in immense quantity—a clear, limpid serum—differing from the wine-yellow serum of tympanic inflammation, may be labyrinthine peri- and endo-lymph. Pus may form in the mastoid cells. These changes may occur either as complications or as sequelæ. Caries sometimes appears quite early, and the chronic otorrhœa thus set up may last for years, occasioning widespread disorder of both soft parts and bone.[37] Fatal hæmorrhage from the ear may occur after scarlatina, from exposure of vessels from the diphtheritic processes.[38]

Chronic posterior nasal catarrh, and necrosis of the bones of the nasal cavity, constituting various degrees of ozæna, sometimes follow the extension of the pharyngeal inflammation to the naso-pharynx. The eye may likewise be implicated in scarlet fever. Conjunctivitis may develop as a complication, or diphtheritic inflammation may extend along the lachrymal canal and involve the conjunctivæ. It may produce keratomalachia, and even destruction of the eyeball. Retinitis after scarlatinal nephritis has been observed by Schröter. Its course is favorable. Temporary blindness may be due to uræmia. Acute amaurosis after scarlatinal nephritis has been noted.[39] Transitory blindness, lasting from twenty to sixty hours, has been observed by Ebert,[40] Henoch,[41] Tolmachew.[42] In a case of Förster's it endured eighteen days.

INFLAMMATION OF JOINTS.—Not very infrequently inflammation of the synovial membrane of the joints appears as a complication or as a sequel of scarlet fever. The usual date of its occurrence is during the second week or later. It is often only indicated by pain without swelling, and may be limited to a single joint. In other cases a number of joints are involved, usually the ankles and wrists, knees and elbows. The hip-joints may be affected, and also the smaller joints of the extremities. The inflammation may betray all the features of acute rheumatism—the fugitive character of the inflammation, the metastases, the sweating, the fever, even the tendency to implicate

the other serous surfaces, the pleuræ, the endo- and pericardium, and the meninges. Mahomed's[43] studies showed that, as the urine increases in quantity from the seventh to the fourteenth day, it loses its deposit of lithates, and often its albumen (if this has been present). It is highly acid, and uric acid is abundantly thrown down by the nitric-acid floating test. It was at this period that he found the rheumatism most apt to occur. This rheumatism seems identical with ordinary acute rheumatism, but follows a less protracted course. Cheadle[44] quotes fifteen cases from West, in which endo- or pericarditis, or both, supervened upon scarlatina. These did not occur during the acute stage, but during desquamation. He, however, considered them rather the result of uræmia and nephritis than of rheumatism. Henoch[45] relates two cases in which acute arthritis appeared during the first week of scarlatina, followed by severe chorea and loud mitral murmur. As to the cardiac symptoms, Cheadle concludes that they occur in scarlatina as results both of scarlatina and of nephritis. He also thought that "scarlatina would appear to have a special influence in causing dilatation and hypertrophy without accompanying valvular disease." Endocarditis, which rarely arises, may be very insidious, and may even pass undetected if not looked for. Probably not a few old valvular affections have originated in attacks of scarlet fever. Acute pleuritis or pericarditis may accompany joint inflammation, or may occur independently. In severe cases they may result in purulent exudation and ultimately terminate fatally. Sometimes the serous inflammations are pyæmic. Endocarditis ulcerosa may begin in this manner. Numerous writers have seen purulent arthritis as a sequel of scarlatina. It commonly occurs during the second or third week, and in most instances is mono-articular. Pyæmic arthritis usually results in suppuration, erosion, and destruction of the cartilage of the joint. According to Spender,[46] the wrist-joint is most often attacked, next in frequency the knee and hip. Recovery may take place, but usually death follows the discharge of pus and the formation of fistulous openings, from exhaustion, or from the further progress of the pyæmia. The approach of these complications, which are fortunately rare, may be recognized through the thermometer. Peritonitis occurs most rarely, and is usually purulent.

In the most severe and malignant cases of scarlatina the heart-muscle undergoes, first, cloudy swelling, and later, fatty degeneration, especially on the right side. This is the occasion of death from heart failure in many malignant cases. Inflammation of the respiratory tract is decidedly uncommon in milder scarlatina Bronchial catarrh is apt to complicate serious cases. Pneumonia is seen sometimes as a secondary complication following nephritis, diphtheria, etc. Disorders of the intestines are also uncommon. Diarrhœa, when present, is usually associated with severer forms. Diphtheritic enteritis was the most frequent sequel in the cases observed by Fleischmann. Henoch has seen bed-sores complicate scarlatina.

SEQUELÆ.—The affections that constitute true sequelæ usually are disorders that persist after scarlet fever has completed its course, having begun as complications. Thus are encountered chronic buccal, pharyngeal, nasal, and aural inflammations, nephritis (which, as a rule, ultimately entirely disappears), or inflammation of the various serous membranes. In some cases, marked by severe eclamptic seizures, there results contraction of different groups of muscles, giving rise to permanent deformity. Mania has been known to follow scarlatina.[47] Gangrene, apart from that resulting from diphtheria of the throat, is infrequent. Noma has been observed by a number of writers (Barthez and Rilliet, Heyfelder, Böning, and others), but it is notably less common than after measles. Necrosis of the nasal cartilage was observed by Henoch during convalescence.

CONCURRENCE WITH OTHER SPECIFIC AFFECTIONS.—Scarlet fever may be complicated by, or may complicate, other acute exanthemata, not to the extent, however, that many writers believe. Mayr and Hebra, indeed, taught that scarlatina never coexists with measles or small-pox. This question is involved in much obscurity. Scarlatina may be simulated by a variety of affections that may in fact co-exist with the exanthemata, by various erythematous eruptions, by the roseola that often precedes and accompanies the eruption of small-pox, by certain anomalous forms of measles, and by various medicinal rashes —those caused by belladonna, copaiba, chloral, and especially cinchona and its preparations. These considerations and faulty methods of observation and recording, lead to the rejection of much of the evidence adduced in favor of these coexistences. After all faulty observations are thrown out, however, there still remains strong proof that scarlet fever may coexist with other exanthems. It will be everywhere admitted that one exanthem may follow close upon the heel of another. Prior[48] noted a case in which scarlatina developed on November 18th, varicella on December 2d, and measles on December 13th. When the two exanthems develop simultaneously, there will often remain much doubt, in the absence of evidence of the double exposure of the unprotected individual and of his subsequent double protection. Where one precedes the other by a few days, the difficulties are not so great. Scarlet fever has been observed as complicating, or complicated by, other exanthemata by Steiner,[49] Monti,[50] Thomas,[51] Fleischmann,[52] Fabore,[53] Stillen,[54] Zechmeister,[55] Backer,[56] Dornig,[57] Lewis Smith,[58] Murchison,[59] and many others. The combinations and the order of occurrence have been noted as follows, viz.:

Scarlatina and measles.
Measles and scarlatina.
Scarlatina and small-pox.
Small-pox and scarlatina.
Scarlatina and vaccinia.
Scarlatina and varicella.
Varicella and scarlatina.
Scarlatina and typhoid fever.

Concurrence of scarlatina and Rötheln has not been reported. A probable source of fallacy is the scarlatiniform rash that is often observed in small-pox, and occasionally in typhoid fever; indeed, Simon asserts that Fleischmann has even made this very error. The possibility of these rashes should always be held in mind when questions of concurrence are under consideration. When scarlet fever develops after small-pox the eruption involves the parts of the skin left free by the lesions of small-pox, more especially about the chest and abdomen. When the two exanthems appear simultaneously, their course is shortened; "the second mitigates the first and becomes shortened itself," excepting, according to Fleischmann, when severe small-pox occurs in connection with scarlatina, when death usually results. The same author asserts that if scarlatina appear at the period of maturation of small-pox, the latter, in mild cases, is shortened and mitigated. When scarlatina complicates measles, the latter is shortened, but the scarlatina thus occurring may be mild or severe. Barthez and Rilliet noted that in scarlatina-measles, when the former malady predominates, bronchitis is more marked; but when measles is most severe, faucial angina is worse. All of these statements lack such evidence as would entitle them to unqualified acceptation. Very often neither disease is well developed, and the true condition may be very difficult of recognition. In America these concurrences are more uncommon than they seem to be abroad.

Whooping-cough has been known to complicate scarlatina, and a number of non-specific affections may occur simultaneously with it. These coincidences are purely accidental and present no peculiar interest. Biart[60] has reported psoriasis as following scarlatina. Barthez and Rilliet assert that tuberculous children very rarely have scarlatina. Some chronic affections partially or entirely disappear during an attack of scarlatina. Among these may be especially mentioned certain cutaneous affections, eczema, psoriasis, etc., but they usually reappear upon the establishment of convalescence.

SURGICAL SCARLATINA.—Sir James Paget, in 1864, and again in 1875,[61] declared that patients who have undergone surgical operations are peculiarly susceptible to the

action of the scarlet-fever poison. This question has attracted a great deal of attention. In France, Trelat was the first to accept this view, though scarlatinoid rashes had been observed by Civiale, Germain Sée, Tremblay, and others. Similar rashes were reported by Hutchinson. Hilton, Bryant, Lee, Moore, Stirling, and others. They had generally been considered as of septicæmic origin. In 1879 Paley and Goodhart[62] and House[63] reported observations of endemics of scarlatina in the Evelina Hospital for Sick Children and in Guy's Hospital. The first-named authors based their report upon twenty-five cases of scarlatina occurring in surgical patients. Of these nineteen were known to have been exposed to scarlatina, and all the rest, save one, were known to have had possible sources of infection. House's paper was based upon four cases of surgical scarlatina. The epidemic tendencies ceased upon the establishment of isolation, and one cannot doubt their scarlatinal origin. These writers were careful not to assert that *all* such red rashes should be attributed to scarlatina, or that there is *not* "such a thing as a rose rash in a typical case of septicæmia;" but they believe that when occurring in groups they may nearly always rightly be attributed to scarlatina. Riedinger and Howard Marsh also agreed that there exists in wounded persons a predisposition to scarlatina. While Holmes coincided with these views, he, however, declared that many cases of "surgical scarlet fever" are really due to pyæmia and other causes. Most recent writers incline to the opinion that these eruptions are due to true scarlatina. When any epidemic tendency is shown, everyone will agree with such conclusions. This cannot be granted of rashes occurring in isolated cases. Of 25 cases reported in Paley and Goodhart's paper, scarlet fever attacked 17 after operations; 7 were without any wound whatever, and 1 had only an old sinus. In many of the cases reported by other writers there was no open wound. These reporters, unfortunately, most rarely note whether their patients had ever previously had scarlatina. Most children, when first exposed to the contagion of this disease, become infected. Is it remarkable that they are unable to withstand it when it attacks them, weakened by injury or surgical operation? Apart from epidemic influences, it is probable that scarlatiniform eruptions in the wounded may justly, in a large proportion of cases, occur quite independently of scarlatina. Rashes of septicæmic origin are well known to occur. Various fugitive eruptions often result from emotional and nervous irritations, or from the ingestion of certain articles of food or medicines. It must be admitted that scarlatiniform septicæmic rashes are uncommon. But there is excellent evidence that they occur.[64] Attempts have been made to establish a differential diagnosis for the surgical scarlatiniform rash. Cheadle,[65] for example, claimed that it has specific characters in not often being universal, and in being confined to the body and parts covered by the clothing; that it rarely lasts twenty-four hours, and that it never desquamates. He also asserted that there is no tonsillar swelling, nor glandular enlargement, nor the peculiar "strawberry tongue." Such points of differentiation do not appear to be well founded. Scarlatiniform eruptions also occasionally follow the ingestion of certain drugs. They may be evoked by belladonna, copaiba, opium, chloral, mercury, and other drugs, but, above all, by cinchona bark and its derivatives. These eruptions are much more common than is generally supposed. The quinine eruptions are only beginning to receive due attention. The drug is frequently given to those who have been injured or submitted to surgical operations, and beyond question eruptions evoked by it are often attributed to other causes. A number of eruptive forms are observed, but the one of especial moment is the scarlatiniform rash. At the onset it often cannot be distinguished from scarlatina. Beginning with high fever, and often with sore throat, the eruption appears upon the face, chest, and neck, and within twenty-four hours the entire surface may present a bright scarlet aspect. At the end of this period the resemblance may be made perfect by the "strawberry tongue." Up to this point the diagnosis may be impossible. Rarely it remains so throughout the attack, especially when the ingestion of the cinchona preparation is continued. Usually, however, after thirty-six or forty-eight hours the type of normal scarlatina is departed from. The fever rapidly decreases, the angina disappears, and the rash either fades or acquires features unlike those of true scarlatina. It becomes duller, more papular, and often tends to form miliary vesicles. Eventually it may resemble ordinary "prickly heat." Sometimes, however, the scarlatinal features are preserved throughout. In either case a copious desquamation is sure to follow. This is usually lamellar. Even albuminuria has been known to add to the embarrassment of the diagnostician. These medicinal and septicæmic rashes occur in isolated instances, and may at times baffle the keenest diagnostic powers. We may conclude that unprotected persons who have suffered injury, or who have undergone surgical operations, are rather more liable to scarlatina than the unprotected healthy. Scarlet fever is more apt than the other exanthemata to attack such persons, because its symptoms vary within such wide limits that it often escapes the attention of those who readily detect other infectious disorders and provide against them. When an epidemic tendency of the symptoms we have been considering is shown to prevail, it may be confidently concluded that true scarlatina is present. Septicæmia is occasionally accompanied by a scarlatiniform rash which does not depend upon the scarlatinal poison. These rashes are often attributed to scarlatina.

Scarlatina Puerperalis.—While pregnant women seem to enjoy a remarkable immunity from the specific eruptive fevers, it is well known that during the *puerperium* they are especially subject to them after exposure, and that the disease is then apt to pursue a grave and often fatal course. Not only scarlatina, but measles and small-pox may affect the lying-in woman with such malignity that the symptoms may not acquire the features of the maladies to which they belong, but become indistinguishable from those of malignant septicæmia. Scarlatina is especially liable to attack the lying-in woman. It may assume the virulence referred to, or it may pursue a course in which it is difficult to determine whether its symptoms are septic or really scarlatinal, or, finally, it may appear with typical and unmistakable features. Not a few writers have thought that the scarlatinal virus may produce in the puerperal woman septicæmia, pure and simple. This view is maintained by Playfair, Braxton Hicks, Leishman, and others. They assert that in these women, after exposure to the specific contagium, symptoms of acute blood-poisoning may be developed, and not those of scarlatina. On the other hand, just as in septic conditions, independent of puerperal causes, an erythematous rash and other scarlatinal symptoms may be observed in which true scarlatina has no part, so must one guard against assigning to scarlatina every scarlatiniform rash occurring in obstetrical cases. It may be septic in origin, or it may be a medicinal eruption. When a septic, or medicinal, or other form of erythema can be excluded, and when exposure to scarlatinal influence is followed by any degree of the symptoms we are considering, are we in atypical cases to look upon the results of the infection as distinctly scarlatinal? More recent writers regard the scarlatinal nature of the disorder as preserved, and as capable of further dissemination. It has not been determined to what extent women who have already had scarlatina preserve an immunity from further attacks during their lying-in period. It would appear that the intensified predisposition of the childbed carries with it an increased liability to second or third attacks. Busey[66] has related a case in which the patient had already had scarlet fever. Other such cases are upon record.[67]

In all probability the scarlet-fever contagium evokes scarlet fever, and not septic disorder, in the puerperal woman, whose systemic condition affords peculiar susceptibility to its influence, and predisposes her to a virulence of its activity that often leads to disastrous results. The less remote the date of delivery, the graver the course of the malady is apt to be. If the symptoms do not appear before the seventh day, their development is no

longer to be feared. Olshausen[68] collected from the literature 141 cases, of which the scarlatina attacked, during pregnancy, 7; in 8 it immediately followed delivery; in 62 it occurred on the first and second days; in 27 on the third day; in 22 after the third day. After the fifth day none was attacked. While the puerperal woman shows intense susceptibility to scarlatina, the pregnant woman enjoys a marked immunity from it. Olshausen thinks, however, that the period of incubation may last for months during pregnancy, but only a few days during childbed. This opinion he rests upon no solid basis. Primiparæ are more often attacked than multiparæ. The mortality in puerperal scarlatina is high. In the series just alluded to it was forty-eight per cent. (3 cases during pregnancy and 64 in childbed).

In the recorded cases studied by McClintock[69] the mortality was over sixty-six per cent. In 34 cases at the Lying-in Hospital the death-rate was thirty per cent. Of 10 deaths at this hospital, 8 occurred when scarlatina had developed within thirty-six hours after delivery. Of 18 patients attacked on the first or second day, 8 died. Of those attacked on or after the third day (16 in number), all but 2 recovered. McClintock also quotes Dr. Halahan's cases, as follows, viz.: 3 patients, ill of scarlatina at the moment of delivery, died; of 5 attacked during the first twenty-four hours, but 1 recovered; of 10 attacked during the second day, but 1 recovered; of 4 attacked during the third day, but 1 recovered. The remaining 3, attacked on or after the fifth day, recovered. Braxton Hicks'[70] contributions to this subject have been most important. He believed that in one-half of the cases the usual symptoms of scarlatina are manifested, and that the disease almost always commences after the third day after delivery. The death-rate will be greater, the earlier after labor the symptoms develop. Though lying-in women are peculiarly liable to scarlatina, they are frequently exposed to its influence without detriment. Women have not seldom been confined in the room, even in the bed, occupied at the same time by scarlet-fever patients, without experiencing the slightest interruption of their normal convalescence; a result that is not astonishing in protected persons if the scarlatinal virus only transmits scarlatina, but which would not be expected were the virus equally competent to communicate septicæmia in these cases. While a large proportion of cases pursue a grave and anomalous course, there are many others in which a perfectly typical scarlatina is observed, without seriously endangering life. Secondary inflammations are not unknown. Metritis, cellulitis, peritonitis, or pyæmia may be developed, but whether these are direct results of scarlatina or of the puerperal condition is undetermined.

Relapses and Recurrences.—There are recorded numerous instances of relapse of scarlet fever within a short period after the original attack, and second or even third attacks after a more or less prolonged interval are well known to occur. By a relapse is meant a second attack of scarlatina that is evidently due to the persistent activity of the influences that excited the first attack. Within a short period (three days after deflorescence in a case of Woldberg's[71]) after the original attack all the symptoms are repeated; the initial disturbances, the fever, the eruption, the angina, and other phenomena, with ensuing desquamation, are developed. It is held that the second attack is but the completion of the first, that it occurs after an incomplete primary attack, and that it tends to be severe in proportion to the mildness of the first, and often to affect in eruption only those parts which were originally spared,[72] imparting thus to the second eruption the appearance of scarlatina variegata. The relapse may be accompanied by complications of throat, kidney, and other disorders, that were not present in the earlier disorder, and *vice versa*. These relapses are usually very rare, but seem to be more frequent in certain epidemics.

Thomas applies the term pseudo-relapse, or *reversio eruptionis*, to those cases in which the exanthem returns before the disorder has entirely completed its course. Trujawsky found the interval between the two attacks to be from seven to ten days, with an average of eight and five-eighths days. The intermissions are completely afebrile. These relapses have been explained by, (1) a recrudescence of the original contagion, and (2) the action of a newly acquired contagion from a source different from the original one. The prognosis is often graver than in the primary attacks. Recurrences or attacks of scarlet fever occurring after a more or less protracted interval, are more common, and are due to fresh infection. They may occur at almost any period. Trujawsky[73] noted, in 300 cases of scarlatina, 18 patients who had had a former attack. Of these 4 were under ten years of age; 10 were over ten years, and 3 were adults. The interval between the attacks varied from one and a half to seven years. Thomas had personal knowledge of a case in which a second attack occurred. Willan never saw one. Many years may elapse between the two attacks, as when a mother who had the disease during childhood again develops it by contagion from her child. Heyfelder himself had a second attack twenty-seven years after the first one. Trujawsky thought that immunity is greater against contagion originating at the home or in the neighborhood of the patient than when it is brought from a distance. A third attack in the same individual may be observed (as in Richardson's case), and there are reports of repeated attacks of scarlet fever. Bernouilli,[74] for example, mentions the case of a woman, fifty years of age, who experienced in rapid succession six attacks of an exanthem indistinguishable from scarlatina. Other similar cases are on record, but their consideration suggests that they may rather have been forms of medicinal eruption. Acute exfoliative dermatitis may also be mistaken for scarlet fever, and may attack repeatedly the same person. Rashes resembling scarlatina may occur in various other affections, such as typhoid fever, small-pox, etc. Hallopeau and Tuffier[75] saw a scarlatiniform eruption in acute rheumatism, in which there were two relapses with intense erythema, followed by copious desquamation. The possibility of all such cases being mistaken for scarlatina should be remembered. It is a rather singular fact that many persons suffer from angina whenever they are brought into close personal relationship with those who have scarlet fever. This is commonly mild, but may occasion serious discomfort. Those who suffer thus from exposure to the scarlatinal influence do not communicate scarlatina to unprotected persons. Mild desquamation is said to have been noted in some such cases. This, however, would indicate a true scarlatinal infection.

Pathological Anatomy.—In most fatal cases every trace of eruption disappears after death. After a very intense exanthem, more or less redness may remain. After malignant cases blood extravasations may present the only post-mortem discoloration. Remy[76] and Neumann[77] have lately investigated the histology of the skin in scarlatina. Remy found the capillaries of the papillary layer dilated and hyperæmic, and filled with leucocytes which were enlarged and of different sizes, but not so large as in leukæmia. The vascular wall was not altered. The epidermis was thickened by increase of its cylinder-cell layer. The horny layer, sebaceous glands, and hairs were unchanged. The sweat-glands were empty and shrunken. Neumann found the cells of the *rete* swollen. In many specimens the prickle-cells were elongated, and here and there formed interspaces in which exudation-cells were imbedded, and into which small blood extravasations often occurred. Exudation-cells extended abundantly as far as the horny layer, and at the orifices of the follicles they were very numerous. The corium was swollen, the fibres thickened, partly separated by proliferation, partly by enormously dilated vessels that were at times bulbous. It is this exudation into the epidermal layers that causes the loosening of the horny layer from its bed, and the characteristic desquamation. Löschner and Fenwick have also noted this infiltration of the *rete*. The latter writer found the basement membrane of the sweat-glands also thickened, and the lining membrane gone in places, but in other places it was increased so as to occlude the sweat-glands. The deeper layers were normal throughout. The scarlet-fever exanthem, then,

consists of hyperæmia with exudation. Remy found the changes he describes, regularly and uniformly distributed.

The throat symptoms, as constant as are those of the skin, are due to lesions that are always recognizable after death. The milder alterations offer nothing characteristic; they are identical with those of pharyngeal catarrhal inflammation. In more intense degree follicular inflammation, with suppuration and ulceration, is superadded, and œdema becomes more prominent. The inflammatory changes extend beyond the pharynx into the buccal and nasal cavities, while parenchymatous tonsillitis and inflammation of the cellular tissues of the throat and neck develop, with, sometimes, extensive gangrene.

According to Härlin (Thomas), scarlatinous angina is specific, and is marked by "a deep, bluish-red injection of the mucous membrane of the tonsils and neighborhood, of the uvula, of the posterior portion of the tongue in the neighborhood of the highly swollen papillæ, of the posterior portion of the region of the cricoid cartilage, and of that portion of the pharynx which includes these different parts, and measures about two inches in breadth." This coloring is said to be sharply outlined in the direction of its transverse diameter. A point of the highest importance is the nature of the diphtheritic membrane so often formed in scarlatinous angina. By most writers it is assumed to be pathogenetically identical with primary diphtheria. Now, while there can be no doubt that primary diphtheria may and does complicate scarlatina, it is almost equally certain that in many cases the membrane is simply a result of the intensity of the inflammation evoked by the action of the scarlatinous virus. In the one case the scarlatinal, in the other a true diphtheritic, poison acting upon the vascular tissues of the throat, causes a coagulation-necrosis that results in the production of the membrane. The lesions of the two processes are identical. They only differ etiologically and in their results. The membrane sometimes extends to the nasal cavity, the larynx, and the trachea. Lewis Smith has seen, in four cases, the diphtheria become dissociated from scarlet fever, and attack other members of a family as idiopathic diphtheria. On the other hand, there is very satisfactory reason to believe that the diphtheritic membrane is most often without the specific nature of primary idiopathic diphtheria. Heubner concludes that scarlatinal diphtheria differs from primary diphtheria clinically and histologically. It begins with a simple catarrhal affection; the change from catarrhal to diphtheritic commonly occurs on the fourth day. Henoch likewise denies that the affection is primary diphtheria. Koven[78] gives some remarkable figures that go to prove the nonidentity of the two affections. His report includes 426 cases. He shows that while it is most uncommon for two infectious diseases to coexist, of 426 cases 125 had necrosis faucium, while at the very time *there was not a single case of idiopathic diphtheria in Christiania.* Moreover, *diphtheritic paralysis was not once observed.* Scarlatinal diphtheria, also, much more rarely than primary diphtheria, extends to the larynx and trachea.

Kidneys.—Friedländer[79] describes three forms of renal inflammation with scarlatina. These are: 1, Initial catarrhal nephritis, the early form; 2, the big, flabby hæmorrhagic kidney, interstitial septic nephritis; 3, glomerulonephritis, nephritis post-scarlatinosa. The first, he asserts, appears at the beginning of the exanthem, or a few days later, and disappears in a few days or weeks. It rarely excites œdema, and hardly ever kills. It is analogous to the alterations productive of the febrile albuminuria of many infectious diseases. Cloudy swelling and proliferation of the tubular epithelium, and, later fatty degeneration, are shown. Within the tubular lumen are hyaline and granular cylinders, round cells, and desquamated epithelium. In the interstitial tissue are scattered round cells. Bowman's capsule is thickened, and there may be a small quantity of albuminous fluid between the capsule and the glomerule. Micrococci are sometimes found in the capillaries and tubules. The large, flabby hæmorrhagic kidney was found in 12 of the 229 scarlatinal necropsies made by Friedländer. It was found especially where the scarlatina had been complicated with diphtheria, abscess, etc. It is not characteristic of scarlatina, but is also seen in primary idiopathic diphtheria. The kidneys are enlarged and soft, and show pronounced cortical changes. The cortex is invaded by small extravasations and larger blood infiltrations. The epithelium is only slightly altered, but the interstitial tissue is thickened and abundantly infiltrated with round cells. Emboli of micrococci are commonly present. It develops between the first and fourth weeks, and proves fatal so rapidly that œdema does not develop. It is an especially severe form of septic nephritis. Glomerulo-nephritis, Friedländer holds to be the only characteristic scarlatinal nephritis. Here the kidneys are firm, often hyperæmic, and resemble the cyanotic kidney, except that the glomeruli do not appear red upon section, but gray and anæmic. They are enlarged and prominent. Alterations are almost limited to them. Their nuclei are enlarged, their coils empty of blood, their walls thickened, their lumina contracted or obliterated. Bowman's capsule is not much thickened. There are also slight interstitial cell infiltration, fatty degeneration of epithelial cells, and hyaline formation in the arteries. The alterations in the glomeruli account for the anuria and uræmia, as well as the rapid hypertrophy of the left ventricle by the obstruction of the renal arteries, as nearly all of the renal arterial blood has first to pass through the glomeruli. Klein,[80] who has given the subject especial attention, in a series of 23 necropsies did not observe the identical glomerulo-nephritis as described by Klebs.[81] Klein's cases had died at various periods between the second and forty-fourth day. Their ages were between two and thirty-six years, the largest number being under twelve years of age. Changes resembling the glomerulo-nephritis of Klebs were observed, but they were only characteristic of the early stages of scarlet fever. A sharp definition between the early and late changes is not practicable. The first set of changes are chiefly limited to the cortex. They are: 1. Increase of nuclei (probably epithelial) covering the glomeruli. 2. Hyaline degeneration of the elastic intima of minute arteries, especially of the afferent arterioles of the Malpighian tufts. The intima of these vessels is swollen here and there into spindle-shaped hyaline masses, causing narrowness of the lumen. There is similar hyaline degeneration of the capillaries of the glomeruli, rendering them often impermeable. These degenerated parts become fibrous in appearance, and Bowman's capsule becomes thickened. 3. A third change is multiplication of the nuclei of the muscularis of the minute arteries, with increased thickness of their walls. This is greatest at the point of entrance into the glomeruli, but is also distinct in other arteries of the cortex and in the base of the pyramids. There are also swelling of the epithelia of the convoluted tubules and proliferation of their nuclei, especially of the tubules close to the afferent arterioles of the glomeruli. In some cases the epithelium of the large tubules of the pyramids is detached. Klein's observations, 1, that the hyaline changes readily affect the arteries near their point of branching, and, 2, that the hyaline substance is of the nature of elastic tissue, agree with the conclusions of Neilson concerning the arteries in various cerebral disorders and in many infectious diseases. He does not think that the anuria and uræmic poisoning in scarlatina, when the kidney does not show conspicuous change, are due to compression of the vessels of the glomerulus by the nuclear germination, as claimed by Klebs, but rather to the changed state of the arterioles, and suggests that the increased formation of arterial muscular fibres, under the stimulus supplied by the disease, may cause a contractility that obliterates the calibre of the arterioles and shuts out the glomerulus from the circulation, and thus, so far as it operates, suppresses the secretion of urine. The parenchymatous changes found in the early stages are slight and difficult to detect, the cloudy swelling and granular degeneration being limited to small portions of convoluted tubules. The second order of changes begins about the ninth or tenth day. They are interstitial as well as parenchymatous. Round cells are found around the larger vascular trunks, spreading

into the bases of the pyramids and into the cortex. This process begins about the end of the first week, and gradually increases until portions of the cortex, rarely portions of the bases of the pyramids, are converted into pale, firm, round-cell tissue, in which the tubules become compressed and obliterated. The parenchymatous element of the nephritis consists in crowding of urinary tubules with lymphoid cells and various kinds of tube-casts, and fatty degeneration of the epithelium of the tubules. This grows more marked with the advance of interstitial changes. The round-cell infiltration of the cortex begins at the roots of the interlobular vessels, spreading rapidly toward the capsule of the kidney, and laterally among the convoluted tubes around the glomeruli, att first between the medullary rays, later it encroaches upon them. Portions of the cortex may be converted into firm, pale, bloodless cellular masses in which Malpighian tufts and urinary tubules become more or less destroyed. In one case renal embolism was encountered ; both interstitial and parenchymatous inflammation was very intense. The kidney was markedly enlarged. Klein also noted deposition of lime in the epithelium and lumina of the tubules, first of the cortex and then of the pyramids, at an early stage of scarlatina, when only slight changes are otherwise shown. He concludes that cases of scarlatina which die after the ninth or tenth day usually show more or less well-marked interstitial nephritis.

Lymphatic Glands.—Peculiar changes have been noted in the lymphatic glands by Klein. In addition to the ordinary inflammatory infiltrations which he describes as occurring in the lymphatic follicles connected with the organs of the throat and in the glands of the neck, the ordinary uninuclear lymph-cells are greatly diminished in number, and are replaced by large granular cells containing numbers of germinating nuclei.

Liver.—This viscus becomes slightly enlarged from cloudy swelling. In one case Klein noticed, after two days' illness, acute interstitial hepatitis. The middle and internal coats of some arteries show the same alterations as in the kidneys. Wagner observed lymphoid new formations and numerous collections of cells and nuclei, especially in the interacinous connective tissue.

Spleen.—In the spleen the changes are uniform and constant. They are : 1. Enlargement of the Malpighian corpuscles. 2. Hyaline degeneration of the intima of the arteries. 3. Proliferation of the nuclei of the muscular coat of the ultimate arterioles, with increased thickness of their walls. 4. Hyaline swelling and degeneration of the adenoid tissue around the degenerated arteries. 5. In the central parts of the Malpighian corpuscles the ordinary nuclei of the lymph-cells disappear, and in their stead are found large hydropic cells containing pigment (Klein). Other writers assert that there is no uniformity in the splenic changes, beyond a slight enlargement. Biermer has observed enormous enlargement of the Malpighian bodies.

Disorders of the alimentary canal are not frequent in scarlatina, and when they occur it is usually in grave cases. They then not infrequently constitute the principal complicating lesion. In the cases of Fleischmann, diphtheritic enteritis was the most common sequel. The peculiar "shaved-beard appearance" of Peyer's patches has been at times observed, and at times these patches and the solitary glands are prominent, reddened, and inflamed, with associated tumefaction of the mesenteric glands (Harley). Barthez and Rilliet show, however, that in cases where the typhoid-like lesions have been discovered, the symptoms shown during life did not resemble those of typhoid fever ; and conversely, cases of typhoid scarlatina cannot be expected to reveal these lesions after death. Enteritis is more often catarrhal in nature. It has been asserted that in scarlatina the exanthem invades the mucous membrane to the same degree as the skin. Post-mortem evidence of this, however, is by no means constant. The glands throughout the alimentary tract are sometimes swollen, and sometimes form small ulcers and extravasations.

Meningitis is rarely the cause of even the most intense cerebral symptoms. Hyperæmia of the brain and meninges, with great venous engorgement, is often seen, but signs of pronounced change are extremely uncommon.

Periosteitis and osteitis occur in connection with affections of the joints, of the nose, of the pharyngeal and aural cavities, and of other parts, but afford nothing characteristic. Neither do the general serous surfaces show peculiar lesions. The condition of the blood and blood-vessels after certain rapidly fatal cases is important. Sometimes the blood is very fluid and black. At other times clots are abundant and firm ; again, it may have become diffused throughout the tissues. Remy has seen all the vessels of the papillary layer of the skin filled with coagulated blood. Thrombosis of the sinuses has been noted after scarlatinal diphtheria (Thomas). Fatty degeneration of the heart following cloudy swelling, with dilatation, occurring particularly in the walls of the right ventricle, is a frequent result of scarlatina, as it is of other infectious disorders.

Diagnosis.—Scarlet fever must be distinguished from measles, rubella (Rötheln), roseola variolosa, scarlatiniform rashes of septic or medicinal origin, certain idiopathic erythemata, and diphtheria. From measles it differs in its shorter incubative stage, and in the characters of its prodromes. In the former affection there are symptoms of coryza and bronchitis, with photophobia, sneezing, and coughing, while in scarlatina the prodromal symptoms especially involve the throat. In scarlatina the eruption begins to appear during the first or second day; in measles during the third or fourth day. During the course of scarlatina there is an absence of catarrhal symptoms for the most part. There are the characteristic sore throat, the peculiar "strawberry tongue" (after the first two or three days), the well-defined eruption, the more protracted fever, the pronounced desquamation, and the tendency toward renal complications. The eruptions differ both in their development and distribution in the two affections. In scarlatina the face is characteristically invaded by the eruption, which entirely spares the area about the mouth, and is nowhere copiously developed in this region; while in measles the eruption is, probably, most intense upon the face. The macules in measles are large, irregular, and mostly papular. In scarlatina the eruption is punctate and more regularly distributed, not elevated ; it is scarlet in color, and generally coalescent, while in measles it is more discrete, elevated, arranged very extensively in forms of crescents and segments of circles, with greater or smaller areas of healthy skin between the lesions, and is of a darker raspberry color. In measles the stage of eruption lasts from three to four days, and begins to decline as soon as the eruption upon the lower extremities becomes complete. It occupies about thirty-six hours in attaining its acme. In scarlatina this stage lasts from two to six days or more. It attains its acme in about eighteen hours. In measles there is a rapid return to a normal temperature in uncomplicated cases, while in scarlatina both eruption and fever decline more slowly. The conjunctival, nasal, and bronchial catarrh of measles is absent in scarlatina. In measles the tongue remains coated throughout. Sore throat is constant in scarlatina, quite uncommon in measles, and when present is almost invariably only catarrhal. The fever in scarlatina is at once more intense and more protracted. The desquamation of scarlatina is pronounced and lamellar; that of measles insignificant and branny. Scarlatina is frequently complicated by diphtheritic pharyngitis and renal inflammation, measles by inflammations of the respiratory apparatus.

The eruption of rubella (Rötheln) more closely resembles that of scarlatina. It is paler, more discrete, and its lesions are larger and more distinctly papular. It is more transitory, and fades almost without desquamation, which, when present, is branny. Rötheln, moreover, has a longer incubation, almost no prodromal stage, sometimes marked catarrh, and but slight elevation of temperature. It is feebly contagious, of much shorter duration, and is hardly ever followed by nephritis and dropsy. The diagnosis is difficult only when the eruption of rubella becomes confluent. Here, however, the

confluence involves certain areas. It is sharply circumscribed by normal integument, and shows in contrast the outlying characteristic lesions. It is of a pale rose-red, and not of a scarlet color, and is accompanied by the peculiar symptoms of rubella, and rarely lasts more than thirty-six hours. Both measles and rubella may at times closely resemble the milder forms of scarlatina, and from the eruption alone the diagnosis may be difficult; but a consideration of all the symptoms will usually lead to correct conclusions. Roseola variolosa should only excite embarrassment when it occurs before the peculiar eruption of small-pox has appeared. It is less general, is more like a simple diffuse erythema than is scarlatina, and is so speedily followed by the characteristic vesicular eruption that doubt will soon be dissipated. Its coexistence with the essential eruption may excite suspicions of a concurrence of scarlatina and small-pox. Such an error may readily occur. Obstetrical and surgical scarlatina have already received attention. When erythema begins near a wound and becomes scarlatiniform in spreading, a septic origin must usually be allowed, though instances of scarlatina thus beginning have been reported; otherwise, septic erythema is more circumscribed and irregular. Scarlatina in the wounded and in lying-in women may be perfectly typical. Medicinal eruptions have unquestionably been at the bottom of many errors of diagnosis. It has been shown that many drugs may excite eruptions and general symptoms very like those of scarlatina; but for the most part they are simple active hyperæmias, such as are produced by the action of belladonna upon the cutaneous arterioles. Such eruptions differ from that of scarlatina in the absence of prodromes, and, usually, of fever. They are also mostly partial and without the history, course, or results of scarlatina; but at times, and especially when they follow the ingestion of preparations of cinchona, the whole complex of scarlatinal symptoms may be accurately simulated. The conditions for diagnosis have already been pointed out. In second or repeated attacks of so-called scarlatina, due consideration of the possible influence of drugs as an etiological factor will, doubtless, convert some very puzzling cases into very simple ones. Acute exfoliative dermatitis and desquamative scarlatiniform erythema[82] may well be mistaken for scarlatina upon their first appearance. The rash is more protracted than in the essential fever, and is less abrupt in its onset. The local symptoms are very marked, while the constitutional phenomena are usually insignificant. The desquamation may begin while the eruption is in full florescence. These affections are not contagious and have no specific sequelæ. An erysipelatous eruption may be like that of scarlatina. It, however, differs markedly in its distribution, its evolution, and course, being never universal, always progressive, and of indefinite duration. The subjective symptoms are quite different in the two affections; the erysipelatous eruption is painful both spontaneously and on pressure. Much œdema accompanies the latter eruption. Diphtheria may complicate scarlatina, and the intensity of the local inflammation may induce a coagulation-necrosis exactly corresponding to the membranous formations of diphtheria. Idiopathic diphtheria may especially resemble scarlet fever when it is accompanied by the erythematous exanthem that is sometimes developed, either early in the disorder, or later, in cases of blood-poisoning. At first it may not be possible to arrive at a correct diagnosis. According to Robinson,[83] in the early diphtheritic erythema there is no marked elevation of temperature. The rash may begin in any region, and rarely extends to the whole surface. The tongue is not affected, and there may be no special general disturbance. Desquamation does not occur. The late diphtheritic erythema is septic. When the eruption of scarlatina is imperfectly developed, or when it does not appear at all, and when sore throat and fever are the only symptoms to attract attention, the diagnosis must rest upon the history of the patient and his surroundings, and upon the course of his illness. In not a few cases a retrospective diagnosis of scarlatina must be made, after the occurrence of desquamation or the supervention of nephritis and dropsy under condi tions that indicate their scarlatinal origin.

Prognosis.—The mortality from scarlet fever varies widely in different epidemics. From the affection that in Sydenham's time "hardly deserved the name of disease," to a pestilence of intense malignity, all degrees of fatality have been, and continue to be, observed. Epidemics have been recorded in which no deaths have occurred. Recently Whitla[84] has recorded but a single death in 133 cases of scarlatina treated in hospital. Such results are, unhappily, exceptional. The mortality has been known to reach thirty and forty per cent. An excessively high rate of mortality is, in great part, attributable to epidemic tendencies toward grave complications, diphtheria, nephritis, etc. In private practice the death-rate will not often exceed ten per cent. In hospitals the percentage of deaths is usually much higher, the result being due to the fact that milder cases are kept at home for the most part, and not to differences in social condition, except in so far as neglect and exposure previous to admission may have aggravated an attack or have excited a complication. The death-rate will be high or low in accordance with the type of the prevailing epidemic, and the average mortality of the disease should always be considered with reference to this. Neither season nor atmospheric condition appears to exert any influence upon the epidemic type. Likewise, telluric conditions do not modify it. Benign and malignant epidemics follow each other without evident cause. The mortality at the beginning and during the height of an epidemic is greater than during its decline. Barring the effects of extreme poverty and exposure, scarlet fever affects the rich and poor impartially. The sexes are almost equally attacked, but age exerts a striking influence upon the result. Children under one year of age, though less apt to be attacked, are especially liable to fatal forms of the disease. According to Fleischmann, the mortality at St. Joseph's Hospital was: Under one year of age, seventy-five per cent. (8 cases, 6 deaths); from one to four years of age, forty-three per cent.; from five to twelve years of age, 19.6 per cent.; the total mortality being ten per cent. The majority of deaths occur under the sixth year of age; with increasing years the prognosis becomes more favorable. Fleischmann's records show a higher mortality than those of some other writers. For example, Kraus gives 4 deaths in 13 cases less than one year of age; 29 deaths in 113 cases from the close of the first to the close of the fifth year of life; 10 deaths in 106 cases from the end of the fifth to the close of the twelfth year of age; and 2 deaths in 40 cases from the twelfth to the twentieth year of age. Voit reported 1 death in 5 cases less than one year of age; 24 deaths in 166 cases from the first to the close of the sixth year of age; 10 deaths in 109 cases from the sixth to the twelfth year of age. Roset reported 16 deaths in 43 cases less than one year of age; 31 deaths in 156 cases from the first to the close of the fifth year of age; and 3 deaths in 88 cases over five years of age.[85] An exception must be noted to the favorableness of the prognosis in persons of maturer years, in the case of puerperal women, in whom scarlatina has already been shown to be especially malignant. No case can appear to be so mild as to justify a prognosis unqualifiedly favorable. From the beginning until the termination in recovery there is no period when a sudden change may not place the life of the patient in jeopardy, whether by an aggravation of the essential symptoms of the disease, or by the supervention of complications. The prognosis, however, is generally favorable if the disease pursue a regular course; if the eruption follows a brief prodromal stage, and is regularly developed; if the fever, more or less intense from the first, does not exceed at the height of the eruption 40° C. (104° F.), and, steadily falling, reaches the normal on the sixth, seventh, or eighth day; if the angina do not assume a diphtheritic character, and is not complicated by parenchymatous tonsillitis, retropharyngeal abscess, or cellulitis of the throat or neck; if the kidneys remain unaffected or show only slight evidences of disorder. On the other hand, the prognosis is more grave when the eruption appears after a prolonged

prodromal stage, or when the attack is ushered in by convulsions or other profound nervous disturbance; or when the temperature reaches a high degree, 40.6° to 41° C. (105° to 106° F.), at once; or when intractable vomiting is present; or when diarrhœa is a prominent feature; or when the pulse beats more than one hundred and twenty times to the minute, and is feeble, unequal, and irregular; or when the throat is ulcerated and develops diphtheritic inflammation; or when suppurative, parenchymatous, or gangrenous inflammation of the tonsils, or retro-pharyngeal abscess supervene; or when the neck becomes swollen, brawny, and livid from glandular, peri-glandular, and diffuse cellular inflammation. Apprehension should always be excited if the eruption come out imperfectly or irregularly while the fever is intense; or if, once fully developed, it suddenly fade; or if the eruption assume a livid color or a distinctly hæmorrhagic character. A coppery hue of the eruption is unfavorable, as is also a livid coloration of parts not invaded by the eruption. Small, scattered petechiæ in the midst of an otherwise normal eruption are unimportant. Miliary vesicles, developing in the ordinary course of the fever are insignificant; occurring later, during an attack of unusual severity, they are often the forerunners of death. Convulsions first occurring after the height of the fever, are more ominous than if occurring earlier. Should the eruption, and especially the fever, continue unabated after the usual period, dangerous complications are to be apprehended. Coma is of grave augury, as indicating uræmia, œdema of the brain, or even meningitis. Nephritis is more serious the earlier it is developed. It occasionally happens that scarlet fever at first shows the symptoms of a mild attack, but before the completion of the eruption assumes a malignant character. If symptoms of malignancy occur after the completion of the eruption, they are usually attributable to complications. On the other hand, all the signs of malignant scarlatina may be present at the outset. High fever, rapid pulse, convulsions or coma, protracted vomiting, intense eruption, may all yield after the second or third day, the disease thenceforward pursuing a mild course; again, symptoms of malignancy may disappear upon the supervention of a delayed eruption. Mayer[86] observed a temperature of 43° C. (109.4° F.) on the evening of the second day. The temperature subsequently varied slightly until the fourth day, when, upon the appearance of the eruption, it subsided. The occurrence of scarlatinal diphtheria always increases the danger of death. Heubner regards its sudden extension to the soft palate and to the portals of the œsophagus and trachea as certainly to be followed by death within from twenty-four to forty-eight hours, the fatal issue occurring either through gradual progress of gangrene, by inflammation of the lymphatic glands and connective tissue of the throat and neck, or by *œdema glottidis*. When circumscribed spots are invaded and the lateral portion of one tonsil shows the first patch, from which the membrane gradually spreads, recovery may occur. Diarrhœa persisting during the attack greatly increases the danger. Nephritis is always a serious complication, though terminating favorably in most cases. The danger is usually proportionate to the earliness of its occurrence. Death may occur as in ordinary nephritic inflammation. Scarlatinal nephritis most rarely becomes chronic. Inflammation of the organs of hearing, while rarely imperilling life, often results in partial or complete deafness. This, according to Burkhardt-Merian,[87] depends upon croupous-diphtheritic inflammation primary in the throat. The prognosis is more unfavorable if the process be allowed to go untreated. Rheumatic and rheumatoid inflammations are not commonly dangerous complications. Endo- and peri-carditis, pleurisy, peritonitis, meningitis, pneumonia, dysentery, parenchymatous degeneration of the heart, etc., are all complications of extreme danger. Purulent inflammations of pyæmic origin usually constitute sequelæ of scarlatina, and are of the gravest importance.

TREATMENT.—Mild cases of scarlatina require little more than good nursing. As soon as the nature of the disease has been recognized, the patient should be removed to a clean, well-ventilated room, supplied with only such furniture as is indispensable. Only the attendants of the patient should be admitted to the sick-room. All superfluous articles of clothing should be discarded. As far as practicable, woollen outer garments should not be worn. In summer the windows should be kept open sufficiently to secure free movement of air and agreeable temperature; in winter an open wood or coal fire should, if possible, be kept constantly burning. The temperature of the room should not exceed 21° C. (70° F.), nor fall below 18° C. (65° F.). The patient, unless an infant, should be kept in bed even during the mildest attack. The bed-covering should be sufficient to secure comfort, nothing more. The diet should consist in easily assimilable food; the nearer this approaches a pure milk diet the better. Cold drinks may be allowed; cold water, lemonade, raspberry vinegar properly diluted, soda-water agreeably flavored, are grateful to the patient and preferable to warm and mucilaginous drinks. Though milk should form the principal article of food, light broths and soups, beef-tea, chicken-jelly, and, especially during convalescence, the various appetizing and wholesome preparations of food now so abundantly supplied, may be given. Clothing and bed-clothing may be frequently changed under precautions providing for appropriate disinfection. In such cases internal medication may be held in reserve, a careful observation of all symptoms being meanwhile maintained; the condition of the kidneys being systematically ascertained by daily observation. For the angina, if this does not exceed a simple hyperæmia, soothing gargles of flaxseed, sage, or chamomile tea, or of decoction of quince-seed, will prove efficacious. Should the throat develop the whitish curdy deposits of follicular inflammation and the erosions that so often accompany acute catarrhal pharyngitis, a mildly antiseptic gargle will act beneficially and will correct fetor of breath, and, to some extent, disinfect the secretions and exhalations. For this purpose one of the subjoined gargles may be employed:

℞.	Acid. carbolic. cryst.	ʒ ss.
	Glycerin	f ʒ j.
	Aq. destil. q. s. ad	f ℥ vj.
M.	Sig.—Gargle.	

Or,

℞.	Tinct. ferri chlorid.	f ʒ j.
	Potass. chlorat.	ʒ ss.
	Glycerin	f ʒ j.
	Aq. destil. q. s. ad	f ℥ viij.
M.	Sig.—Gargle.	

External applications to the throat are often useful. A favorite domestic remedy is a strip of bacon-rind applied to the skin of the throat. It produces a slight vesicular eczema, and is probably of some advantage as a counter-irritant. Obviously, such applications are inadmissible when diphtheritic inflammation is present. Mildly stimulating liniments are more handy and elegant, and quite as efficacious. The itching and burning of the eruption will be greatly alleviated by inunctions with camphorated oil, cold cream, vaseline, or lard. This practice is especially commended as restricting the spread of contagious particles. Tepid bathing or sponging under the bed-covering is refreshing to the skin and nervous system, contributes greatly to bodily comfort, and may be practised several times daily. Although every case demands constant watchfulness, when the temperature does not exceed 39° C. (102.5° F.) medication beyond that mentioned will not be called for, unless complications develop. When the degree indicated is exceeded, marked benefit will be derived from antipyretic remedies. These may be administered internally or externally. Of internal antipyretic remedies, until recently, the most popular was quinine. The sulphate may be prescribed in capsules, in doses of from three to five grains to a child five years of age, at intervals of two hours, for two or three doses. It must be confessed, however, that in scarlatinal hyperpyrexia quinine is at best an uncertain and feeble remedy. In severe cases there is often intractable vomiting, and quinine is

especially apt to be rejected almost as soon as swallowed. It is better, therefore, to give it in solution by the rectum or hypodermically. By the latter method a solution containing four grains of the hydrobromate of quinine in twenty minims of water, or of the muriate of quinine with urea,* may be injected once or twice daily. Other agents occasionally used for the reduction of fever are aconite and veratrum viride. In mild cases, however, they are unnecessary, and in severe ones they are both unsatisfactory and unsafe. Salicylate of sodium possesses positive antipyretic properties, and may be used in scarlatina with frequent benefit. The synthetically prepared alkaloids of the aromatic series of carbon compounds, of which thallin, antipyrin, and antifebrin may be considered the most reliable and safest for the reduction of temperature, are probably the most valuable remedies by the internal administration of which exalted temperature may be reduced. These drugs, which promise to hold a firm position in therapeutics, will most probably serve a very useful purpose in the treatment of scarlatinal hyperpyrexia. At present, however, observation has not been sufficiently extended to justify definite conclusions. Antipyrin acts well with children, and seldom produces objectionable diaphoresis or eruptions. Argutinsky recommends the following minimal doses of this agent: For children under one year of age, three grains thrice daily, at intervals of three hours; for those of from one to three years, five grains; for children between this age and five years, from five to six grains three times daily, at intervals of two hours; for children of from six to eight years, from eight to ten grains daily, at intervals of two hours; and for children of ten or twelve years, from ten to twelve grains thrice daily, at intervals of one hour. Thallin may also be used to effect the same purpose. The dose of thallin is about one-fourth of that of antipyrin. There is a somewhat greater tendency to collapse after thallin than after antipyrin, and, therefore, the earlier doses should be given very cautiously. Antifebrin affords advantages over either of these agents. Vomiting most rarely occurs after its use. The dose is one-half of that of antipyrin, though its full action is produced more slowly. Neither is sweating quite so constantly produced, though a pronounced cyanosis of the cheeks and mucous membrane and of the extremities is often observed. These agents are also active when administered by enema.

During the administration of these drugs the thermometer should be constantly employed, care being taken to avoid collapse. After a few hours the influence of the dose fails and recourse must be had to them repeatedly. By far the safest and surest agent for reducing temperature in scarlatina is cold water. This may be applied in various ways. The simplest method is by frequent spongings with cold or tepid water under cover of the bedclothes. At the same time cold wet-cloths may be applied to the head, and the patient may be permitted to suck small pieces of ice. In most cases it is better that the water be warm. The spongings may be repeated frequently during the day and night. In cases where, with an elevated temperature, the eruption develops incompletely, or is much delayed in appearance, the body may be immersed in water somewhat cooler than its normal temperature. A cool bath (27° C. = 80° F.) has been extolled as of singular virtue in such cases, and at times it is of the highest value. The tepid, even the warm bath, is probably of equal benefit in most cases. Recent writers have denied that efforts to "bring out" an imperfect or delayed scarlatinal eruption are of any avail. There can be no doubt, however, that treatment with this object in view is often successful. The hot bath, even with the addition of mustard, by exciting cutaneous hyperæmia, will often relieve the congestion of internal parts. Warm and hot drinks made from various vegetable substances were formerly much employed to "bring out" the eruption. They were given copiously, and often in combination with such diaphoretics as spiritus mindereri, spirits of nitrous ether, etc. This plan of treatment is not much practised to-day. The cold bath, which should be of a temperature not lower than from 24° to 27° C. (75° to 80° F.), should be reserved for cases whose temperature exceeds 40° C. (104° F.). The body should be immersed but for an instant, the benefit of the plunge consisting largely in the dilatation of the vessels of the skin through reaction. The cold pack is also of value in these cases. When the temperature steadily rises to an alarming degree, or when hyperpyrexia is developed almost at the outset; when, with or without well-developed exanthem, stupor or coma, or other grave nervous disorder, arises, and when the pulse becomes very rapid, feeble, and irregular, the maintenance of life depends upon the reduction of temperature. Here it is impossible to give hard and fast rules for conduct. Water below the normal temperature of the body still remains our most efficient means of reducing the excessive heat. The lower the temperature of the bath, the more rapidly is this result attained, but the shock of the sudden contact with the cold water may exert a depressing effect that may not speedily pass off. The body cannot remain in very cold water longer than a minute or so without exciting chattering of the teeth, lividity about the mouth, and a pinched appearance of the features and of the surface. Cold affusions may often be most profitably employed. They were strongly commended by Currie. The affusion may be practised by pouring from a pitcher, from a moderate height, cold water upon the head of the patient, until the necessary fall of the temperature has been achieved. The warm bath (32° to 35° C. = 90° to 95° F.) has been highly extolled as favorably influencing the course of scarlet fever when used at the very beginning. Thompson employed it thus constantly, and never lost a case treated in this manner. In a bath of from 27° to 30° C. (80° to 85° F.) the patient may remain for five or ten minutes. These baths should be repeated as often as the temperature of the body becomes as high as 39.5° to 40° C. (103° to 104° F.). To avoid alarming the little patient, the bath-tub may be covered with a sheet or blanket. Placing him upon this, he may slowly be lowered into the water. Upon removal from the bath the patient should be wrapped in a dry blanket. As the body soon dries under the protection afforded, rubbing with towels may be avoided. The skin should now be anointed with oil or other agreeable fatty substance. Refreshing quiet and sleep often follow this bath. In using the wet pack, a blanket may be spread upon a hard couch or bed covered with oil-cloth; upon this a sheet wrung out in cold water is laid. The naked patient is stretched upon this sheet, which along with the blanket is wrapped about him snugly. The brief sensation of chilliness is soon replaced by one of warmth, and after a few moments the body breaks out into copious perspiration. This may be encouraged by hot drinks, and hot bottles to the surface. The patient should not remain too long in the pack, otherwise hyperpyrexia may rather be increased than diminished. In the intervals of the baths, in extreme cases, an ice-cap may be worn, and cloths wrung out in iced water may be applied to the epigastrium. Nothing can exceed the efficacy of the above-described method of treating scarlet fever with high temperature; but to secure its full influence, it must be pursued systematically and intelligently. The thermometer must constantly direct the actions of the physician. The prejudices of friends and attendants against the immersion of the fevered body in ice-cold water will not extend to the use of tepid and cool baths, from which, indeed, equally good results may be obtained. The baths may have to be repeated at intervals of two or three hours for days before the fever begins to yield; or they

* This salt, which is also called "quinia bimuriatica carbamidata," is prepared by Andrews & Thompson, of Baltimore, as follows: Muriate of quinine, 793 grains; muriatic acid (specific gravity 1.070), 500 grains; pure urea, 120 grains. Mix the muriate of quinine in the Hcl in a porcelain capsule, and when it is dissolved add the urea and heat carefully over a water-bath until sufficiently concentrated to form crystals (evaporation to dryness under a low temperature may be practised). To prepare the solution for hypodermic use, take of muriate of quinine and urea, ʒ ij.; of distilled water, f ℥ j. Dissolve and filter. Twenty minims of this solution contain five grains of muriate of quinine. For hypodermic use this solution leaves nothing to be desired.

may unhappily altogether fail to control the irresistible intensity of the disease. On the other hand, they frequently exert a most gratifying influence upon the course of the malady, the temperature becoming permanently reduced, the pulse quieter, fuller, and regular; jactitation, delirium, and coma being replaced by composure, consciousness, or natural sleep. Often an attack that appeared about to pursue a malignant course, under the influence of the bath becomes benign and terminates favorably. While exalted temperature that threatens to destroy life can, in the manner indicated, often be reduced, the course of the disease itself cannot be aborted. No remedy is known that can be said to exert a specific influence over it. Vaunted specifics have not withstood the test of experience. Bennett claimed to have never lost a case of malignant scarlet fever, a result that he attributed to the administration of fresh yeast, in one or two tablespoonful doses, several times daily. One no longer hears of Schneemann's plan of rubbing the surface with bacon, and of Deline's oil inunctions as curative, though the value of such adjuvant treatment is universally recognized. Recently Hayward [88] reported several cases of malignant scarlatina successfully treated with crotalus. The agent was applied to the denuded surface of the throat, and was also given internally. The mineral acids, though highly extolled by authors, do not confer any signal advantage in the treatment of scarlatina. Acetic acid has been supposed to exert a favorable influence over the disease, and is a favorite remedy. Probably the most popular routine treatment of ordinary scarlet fever is that of carbonate of ammonia. By many it is considered to have a specific influence. When in cases of very elevated temperature the heart-action flags, the pulse becoming rapid, feeble, and unequal, when delirium or stupor appears, the preparations of ammonia are demanded. The carbonate, in doses of one to three grains to a child five years of age, may be given every third hour in aqueous solution with milk, which in a great measure destroys the pungent, disagreeable taste; or it may be given in solution of the acetate of ammonia, a most commendable combination. The aromatic spirits of ammonia may be employed for the same purpose. Hoffman's anodyne, whiskey, or brandy is especially indicated when the nervous system shows alarming signs of perturbation, delirium, jactitation, stupor, etc. Purgation, which should usually be avoided, may at times become necessary. Small doses of calomel (one-sixth to one-fourth grain) repeated every hour, until the bowels are moved, generally act well. Castor-oil is a harmless and safe, but nauseous, agent. Rhubarb and scammony are also efficient cathartics. Either may be given in doses of five grains to a child six years of age. The taste of scammony resin is not unpleasant, but its difficult miscibility with water is an objection to its use. Ringer recommends as a purgative for children a few drops of a solution of one grain of podophyllin in a fluid drachm of alcohol given in syrup. When depression is profound, reliance should be placed on enemata in preference to active cathartics. During the progress of the disease the expectant plan of treatment is most to be recommended. The daily bath or sponging should be continued. It is probable that renal complications are thus frequently avoided. As the fever and eruption decline, a more liberal, but always easily assimilable, diet should be allowed. The patient should be jealously guarded from draughts and dampness, and even the mildest cases should be kept in bed for at least ten days after the cessation of fever; nor should the patient be allowed to leave his room before the expiration of the third week. Out-of-door exercise cannot be resumed in disregard of season, or of barometric and thermometric variations. In midsummer, when windows and doors must remain open, the question of out-of-door exercise is rather one of danger to others than of personal risk; while in spring, autumn, and winter the risks of exposure are especially great. During these seasons the patient should not venture into the open air before the sixth or seventh week of perfectly normal scarlatina. During convalescence the daily baths should be continued until desquamation is completed, and daily inunctions with oil both expedite this process and minimize the dangers of contagion. No further medication, or at most a ferruginous tonic, will be required.

Unfortunately, during the course of scarlatina there constantly arise complications frequently demanding more energetic treatment than the original malady. Of these the most common (indeed, in its milder degrees it is essential) is pharyngeal inflammation. The milder grades of this will require no more active treatment than that already described. Where the inflammation is more severe, and accompanied by more or less superficial ulceration, applications should be made with a probang or camel's-hair pencil, or by means of the spray. When the surface is foul and covered with offensive exudation, an excellent application is the following, first recommended by J. Lewis Smith:

℞. Acid. carbolic .... gr. iij.–vj.
Liquor ferri subsulphat............ f ʒ ij.
Glycerin........................ f ʒ vj.
S.—Apply with a brush three or four times daily.

Or the following:

℞. Tinct. iodinii .... f ʒ j.
Glycerin........................ f ʒ vij.
M.

Or,

℞. Acid. boracic .... ʒ ss.–ʒ ij.
Aq. destil........................ f ℥ vj.
M. S.—Apply with a brush. This may also be used with the atomizer.

Most therapeutic agents may be profitably given through the hand-atomizers in the case of children intelligent enough to assist by inhalation. Subjoined are suitable formulæ:

℞. Tinct. ferri chloridi................ f ʒ j.
Potass. chlorat .... ʒ j.
Acid. sulphuros.................. f ʒ ij.
Spts. vin. gallic .... f ℥ j.
Glycerin.......................... f ℥ ss.
Aq. destil ....q. s. ad f ℥ vj.
M.

℞. Aq. chlori.......................... f ℥ ss.
Aq. destil .... f ℥ vss.
M.

The various carbolized sprays are most extensively employed. Diphtheritic inflammation calls for the same treatment as idiopathic inflammation.* Cauterization with silver nitrate, acid nitrate of mercury, chromic acid, or other agent, should not be practised. As a gargle in diphtheritis faucium permanganate of potash is valuable.

℞. Potass. permanganat .... f ʒ j.
Aq. destil .... f ℥ iv.
M.

Tracheotomy should never be performed. A case of scarlatinal diphtheria which presents the symptoms that demand this operation, in the idiopathic disorder, is beyond the resources of surgical art. Inflammation of the lymphatic glands of the neck and of the adjacent connective tissue may be treated first by inunction of oil or cerate. In severer forms, cold wet applications, and where suppuration threatens, flaxseed, or cornmeal, or hop poultices should be applied. Suppurating points should be incised early and freely to prevent burrowing. Gangrenous inflammation may sometimes be arrested by strong caustics. Iron, quinine, stimulants, and nourishing and supporting food should be administered in these conditions with a free hand. Nasal catarrh will not usually require treatment. When diphtheria extends to the nasal passages, similar applications to those made in throat

* Dusting powders of subnitrate of bismuth and salicylic acid, and, under proper precautions, of iodoform, is often most useful.

diphtheria should be made through a nasal syringe. Scarlatinal aural inflammation calls for more special treatment; the nasal douche should be used and the diphtheritic pharyngeal and nasal cavities should be repeatedly syringed with antiseptic solutions, for it is by the extension of the inflammation along the Eustachian tube, that the severer forms originate. When the aural inflammation is established, inunctions of mercurial ointment, or of the oleate of mercury, or of iodoform ointment, should be made about the ear several times daily. When the tympanic membrane becomes strongly injected and bulges outward, paracentesis for the release of the pent-up exudation should be performed. Timely tapping of this membrane will often preserve the imperilled sense of hearing. This operation is especially commended by Buck and Olshausen. It is simple and very easily performed. The sensitiveness of the membrane may be obtunded by the instillation of a four per cent. solution of muriate of cocaine. Pomeroy's directions for performing the operation are as follows: "A good-sized speculum is introduced into the meatus. Then an ordinary broad needle, about one line in diameter, with a shank of about two inches, such as oculists use for puncturing the cornea, should be held between the thumb and fingers, lightly pressed so as not to dull delicate tactile sensibility. The part being well under light, the most bulging portion of the membrane should be lightly and quickly punctured with a very slight amount of force. The posterior and superior portion of the membrane is most likely to bulge. The chorda tympani nerve usually lies too high up to be wounded. The ossicles are avoided by selecting a posterior portion of the membrane. After puncture the ear should be inflated by an ear-bag whose nozzle is inserted into a nostril, both nostrils being closed, so as to force the fluid from the tympanum. The puncture may need to be repeated at intervals of a day or two, provided that the pain and bulging return."[69] When pain and tenderness only are present, hot fomentations to the external ear, and to the parotid and mastoid regions, are very soothing. Laudanum and sweet oil, or a two to four per cent. solution of sulphate of atropia instilled warm into the external meatus, often give relief. Frequently renewed solutions of cocaine are very efficacious. Bags of hot table salt, or of heated flowers of hops, are well-known domestic remedies. When perforation occurs spontaneously the hearing may be preserved, but partial deafness is often permanently established, and sometimes the sense of hearing is totally abolished. In such cases the ear should be frequently syringed with warm water, or warm solutions of boracic acid. Iodoform, however, is by far the most effective application in chronic aural inflammation with perforation, with or without necrosis of the bones of the aural cavity. Its disagreeable odor may be masked by adding to the phial a drop or two of some essential oil (cloves, citronella, cinnamon, etc.). Granulations and polypi developing in the course of chronic otitis may be benefited and even cured by astringent powders and washes. Surgical interference will at times be necessary.

When nephritis arises in the course of scarlet fever, or as a sequel, prompt measures for its relief must be adopted. Where it forms a feature of rapidly fatal malignant scarlatina, it may have no time to develop symptoms, or these may escape detection, or the virulence of the disease may throw the renal disorder into the background, or render attempts to treat it futile. In milder cases, and later, during the latter part of the first or during the second or third week, especial attention may be devoted to the treatment of nephritis. Slight albuminuria will occur, according to Mahomed, during convalescence, associated with constipation and a hard pulse, indicative of high arterial tension, without subjective symptoms, and remediable by a brisk purge. This author also asserts that a slight chilling of the surface is sufficient to cause transitory albuminuria. The patient should therefore be carefully protected, in the manner already indicated. Dietary management will go far toward preventing renal complications. A rigid milk diet, in all cases of scarlatina, is regarded by Jaccoud as absolutely preventive of nephritis. Though this may be an extravagant statement, it is certain that in scarlatina there is no better diet than one of milk. Should nephritis arise, it is the more important that the milk diet should be continued. From two to three or four pints may be given during the twenty-four hours, in small quantities, at brief intervals, the latter amount being sufficient for an adult without other food. If there are reasons why milk cannot be taken, light broths and soups and chicken jelly may be substituted, together with light farinaceous food. Buttermilk may, at times, be preferred, and bonny-clabber and slip or junket (milk sweetened and flavored and coagulated with liquid rennet) are often relished, and are excellent articles of food. Proper regard having been paid to the hygienic surroundings and nutrition of the patient, a brisk hydragogue cathartic should be administered, unless diarrhœa be already present. For this purpose there is nothing better than the compound jalap powder. For a child, from five to twenty grains of this should be ordered every night, as required, the object being to secure several watery actions of the bowels every twenty-four hours. The proper dose for an adult is one drachm. The desired watery stools may also be readily secured by the saline cathartics if given in concentrated watery solution, as has been shown by the researches of Dr. Matthew Hay. The more drastic purgatives will rarely be required, except in uræmic intoxication and in extreme dropsy, when podophyllin, croton-oil, elaterin, etc., may occasionally be employed with benefit. When dropsy is but slightly pronounced, purgation may not be required.

The action of the skin should next demand attention. Frequently during the day the body may be wrapped in flannels, wet or dry, as hot as can be borne; or the wet pack may be applied. When available, the steam bath or hot-air bath is to be strongly recommended. The hot-plunge bath may also be employed most advantageously. Pilz has especially lauded this treatment. It should be used after the method of Liebermeister, by gradually increasing the temperature of the bath from 36° C. to 40° C. (96° to 104° F.), in a half-hour. Under its daily use dropsy speedily disappears. Diseases of the heart and lungs, while not positively contraindicating this plan of treatment, necessitate great caution in its application. Sudden chilling of the surface after the bath should be avoided. The imminence of the danger is usually proportionate to the degree of impairment of the function of the kidneys. In giving remedies to modify their action, none calculated to increase their hyperæmia should be employed. Exception can hardly be made in favor of juniper, which enjoys with some writers considerable reputation in scarlatinal nephritis; but digitalis, the pharmacological position of which is not as yet definitely determined, has received very general approval as a most useful diuretic in acute nephritis. From one fluidrachm to a half fluidounce of the infusion (which is much the best preparation for the production of diuresis) may be given three or four times daily, the dose varying with the age of the patient. Its effects, however, are hardly as happy as when dropsy is associated with, or dependent upon, cardiac weakness. Diuretics that act specifically upon the secreting cells of the urinary tubules, the sedative or refrigerating diuretics, are to be preferred, as a rule, in the treatment of scarlatinal nephritis, and will often achieve most astonishing results. Of these the salts of potash are most efficacious—the citrate, the acetate, the bitartrate, and the bicarbonate. For slight nephritis and anasarca a lemonade made with bitartrate of potash will be taken with avidity, and will often almost magically increase the quantity of urine, reduce the dropsy, rapidly diminish the albuminuria, and cause a radical change for the better. This lemonade may be made by adding one drachm of cream of tartar to a pint of boiling water, into which a sliced lemon has been dropped. This quantity, properly sweetened, may be drunk during the day by a child five years of age. Water may be allowed freely, or any of the mild domestic infusions may be substituted for it, their virtue residing principally in the amount of fluid. Dickinson especially recommends the free use of

water as unirritating, and tending to wash out of the tubules the exudate choking up their lumina. In more severe cases, where life is threatened through one or another form of uræmia, very energetic treatment will be required. Jaborandi may now prove useful. J. Lewis Smith, Hirschfeld, and others have commended its action highly. For a child two years of age, one-twentieth of a grain of pilocarpin may be given by the mouth every fourth or sixth hour, or the same amount may be injected hypodermically. Both diuresis and diaphoresis will be promptly increased, and in favorable cases the uræmic symptoms will disappear. Uræmic coma and convulsions, developing suddenly or after progressive renal embarrassment, should be treated without reference to the scarlatina and upon general principles. A remedy of most undoubted value, at least for the control of convulsions, is chloral, which, if the patient be unable to swallow, may be injected in full doses under the skin or into the rectum. After the more acute nephritis has subsided and convalescence promises to become established, iron becomes one of our main reliances, in virtue of its combined hæmatic and diuretic properties. The mistura ferri et ammoniæ acetatis will generally be found to be the best preparation. Quinine is also a remedy of great value in the treatment of convalescence from scarlatinal nephritis. During the height of the inflammation, local treatment is often of great importance. If fever is intense, the pulse full and strong, and if pain and tenderness in the back are pronounced, the abstraction of blood, by leeches or cups, from the loins will often prove beneficial. Large sinapisms and poultices may be applied over the kidneys. Besides assuaging the irritation they tend to promote diuresis and diaphoresis. For obvious reasons, turpentine should not be employed as a counterirritant in these cases. Ascites may occasionally be so excessive that the pressure exerted upon the kidneys interferes with the action of therapeutic agents, and impedes the functional activity of these organs. Paracentesis abdominis, by relieving this compression, will often be followed by copious diuresis and the rapid disappearance of general anasarca. Cases of scarlatinal nephritis which pass into chronic Bright's disease, as rarely happens, will require the treatment appropriate for this condition. During convalescence the usual precautions will be necessary. The treatment of other complications and sequelæ of scarlet fever is not peculiar, and will require no special notice here.

Prophylactic Treatment.—When scarlet fever attacks one member of a household, intelligent prophylaxis can be more successfully practised than is the case with the other specific fevers. All unprotected persons should be rigidly excluded from the part of the house in which the patient is confined. Those entering the sick-room should have no communication with the healthy. Soiled clothing, utensils, excreta should be removed, under cover, by passages and stairways that are not used by others. Soiled linen should not be washed with articles belonging to the unprotected. It should be boiled in separate vessels. As the contagion is especially prone to cling to woollen fabrics, the garments of the attendants should not be of this material. During the fever, daily inunctions will greatly restrict the dissemination of the *contagium* particles. The patient should not put on his regular apparel until the end of the third week. Daily warm baths should, after this, be practised until the sixth week and the completion of desquamation. This usually marks the limit of contagiousness. A number of instances are on record, however, where the disease seemed to spread from cases of scarlatinal nephritis, but it should be remembered that in such cases desquamation is occasionally suspended. Very wide differences of opinion still prevail upon this point. Thompson, who enforces warm bathing, has never known the disease to spread from his patients. Not a few writers consider that protracted isolation of the patient is unnecessary, and that the completion of desquamation need not be waited for, if proper disinfectant inunction and systematic warm bathing be practised. Contagion, however, sometimes occurs after very prolonged intervals, and generally it is better to observe the rule that isolation should be practised until the completion of desquamation. Ashby[90] noted the spread of scarlatina in a ward where an operation had been performed for the removal of pus from the chest of a patient on the forty-ninth day from the beginning of his scarlatina. He concludes: 1. If desquamation is complete, scarlet-fever patients may be discharged at the end of the sixth week, though, in order to secure absolute immunity, it is wiser to delay until the end of the eighth. 2. Cases complicated with nephritis, empyema, otitis, or glandular abscess, should be detained until the cure is complete. 3. While it is important that desquamation should be as complete as possible, the detention of patients beyond the eighth week, in order that the epidermis should be removed from the soles of the feet, etc., is unnecessary. When the patient is prepared to leave the sick-room, he should be bathed and should put on no article of clothing that has in any manner been exposed to the contagion. The sick-room should be dismantled; carpets and hangings should be removed after thorough fumigation of the apartment has been practised; the bedding should be destroyed or steamed; paint and furniture should be washed; the wall-paper should be removed or the walls whitewashed. All articles of wearing apparel or of furniture that cannot be washed should be submitted to the steaming process now available in most large cities, and which is thoroughly effective. Some persons fail to become infected, though unquestionably exposed to the contagion.

Several drugs have been supposed to possess the property, when rightly administered, of protecting from scarlatinal infection those who have been exposed to its influence. Hahnemann attributed such influence to belladonna. The supposed action of this drug was based upon an untenable hypothesis, but remarkable results have been reported as following its administration (Schulte, Massius, Hufeland *et al.*). As, however, scarlatina often fails to spread even when a number of persons have been exposed, the disease exerting its contagious properties most capriciously, the dangers of drawing incorrect conclusions are very great. The most careful observers have about reached the conclusion that belladonna is absolutely without prophylactic value in scarlatina. Nevertheless, there are those who have faith in its efficacy and who always have recourse to it. If it is concluded to try the merits of this drug, the sulphate of atropia may be given in doses of $\frac{1}{200}$ to $\frac{1}{100}$ of a grain daily; or the tincture of belladonna (which is usually employed) may be given. The dose of the tincture should be one drop for each year of the child, administered once or twice daily. It has been claimed that to obtain the desired protection the characteristic effects of belladonna should be produced in the throat and upon the skin. J. Lewis Smith believes that boracic acid, regularly administered, exerts a favorable influence over the course of the disease, and in great measure confers immunity upon those who take it for purposes of prophylaxis. Fordyce Barker[91] claims that salicylic acid possesses prophylactic properties. A few drops of a weak solution in alcohol and warm glycerin should be given once or twice daily.

At one time it was hoped that inoculation with scarlatinous virus might afford a protection from scarlatina similar to that derived from small-pox by inoculation. In the few rather questionable cases in which this has been attempted, the resultant scarlatina appeared to be unmodified. The asserted prevalence of scarlet fever among dogs and cats,[92] and in horses[93] (Peters), has recently again stimulated the hope that protection to the human family may be obtained by a process similar to vaccination. Stickler[94] made a very interesting set of observations, which, however, have not as yet received confirmation. He inoculated rabbits with the nasal secretions of a horse supposed to be suffering from scarlatina. Symptoms of what Stickler considered to be modified scarlatina followed. Later these animals were inoculated with scarlatinal human blood without noticeable result. Again, he inoculated twelve children with matter from "scarlatinous" horses. This was followed

by light eruption, etc. Subsequently these children were inoculated with human scarlatinous blood without effect. Stickler concluded: 1. The subcutaneous injection of scarlatinous virus from horses is without danger. 2. After its injection under the human skin a circumscribed eruption like mild scarlatina appears. 3. After horse-virus inoculation the organism remains resistant to inoculation with scarlatinous virus. It is to be hoped that further investigation will confirm these observations.

SCHINZNACH is a Swiss spa, in Canton Aargau, or Argovie, lying at an elevation of 1,150 feet above the level of the sea. It is protected against the cold winds, yet the climate is somewhat changeable; the average temperature of the summer months is 62.6° F. An analysis of the spring here situated, made by Bolley and Schweizer, gives the following results (Rotureau). A litre of water contains:

	Grammes.
Sodium sulphate	1.2863
Calcium sulphate	0.1571
Potassium sulphate	0.0805
Calcium chloride	0.7144
Magnesium chloride	0.0836
Calcium carbonate	0.1426
Magnesium carbonate	0.0042
Ferrous oxide	0.0011
Silica	0 0128
Aluminium	0.0103
Total	2.4929

The temperature of the water is 86° F. The gases are carbonic acid and sulphuretted hydrogen.

The waters are employed for both drinking and bathing purposes. They are prescribed in the treatment of osteitis and periosteitis, chronic rheumatism, scrofulous affections of the glands, skin, and joints, mercurial and lead poisoning, and various forms of moist and scaly skin eruptions. The season extends from the middle of June to the middle of October. A course of treatment lasts about one month.

T. L. S.

SCHIZOMYCETES AND OTHER VEGETABLE MICRO-PARASITES. Micro-organisms have been found to bear a most important relation to hygiene and to pathology, and the class of organisms most concerned are the *schizomycetes* or *bacteria*. But the *mould fungi*, the *yeast fungi*, and the *protozoa* are also concerned, and have, therefore, been given a place in the following description.

Micro-organisms are present everywhere, in our food and water, in the air, and in the upper layers of the ground. Some of them are of great value, causing putrefaction of dead animals and plants; others cause various fermentations, such as the alcoholic, the acetic acid, etc.; still others cause infectious diseases of animals and plants.

HISTORICAL.*—Although the connection between bacteria on the one hand, and disease, fermentation, and putrefaction on the other hand, has been established only in comparatively recent years, the germ theory had its advocates more than two centuries and a quarter ago. The idea prevalent at that time was that diseases are caused by the putrefaction of humors in the secret recesses of the body. A learned ecclesiastic of the "Society of Jesus," named Athanasius Kircher, found living organisms, invisible to the naked eye, in all sorts of foul matter, in blood, air, water, etc., so that he concluded that if putrefaction is caused by microscopic organisms outside of the body, and if these organisms are found in the blood, etc., they must necessarily cause putrefaction there also. Of course, Kircher was unable to see bacteria with the microscopes in use in his day.† And it matters not what he did see, his observations seemed to substantiate the view that infectious diseases are caused by substances which, introduced into the body, give rise at first to no symptoms, but increase till they bring about disease. The only substances capable of so increasing at the expense of the tissues are living beings, *i.e.*, plants or animals.

First actual observation of micro-organisms.

The first observer who really saw micro-organisms was Anthony van Leeuwenhoek, a private citizen of Delft, in Holland. He spent the latter part of his life in grinding and polishing lenses, and examining surrounding objects of all sorts. Leeuwenhoek (1675) described minute round bodies, rods, threads, and spirals, and spoke of their motion. He examined various sorts of water, the intestines of flies, frogs, doves, chickens, etc., and his own diarrhœal fæces, and found numbers of animalcula, as he called them, varying in form and size and in the character of their motion. In 1683 he observed several different kinds, but one kind was especially abundant in

* Authorities: Löffler, Flügge, and others (see Bibliography at end of article).
† 1657.

the scrapings from between his teeth, notwithstanding previous cleansing, and he made drawings of them. These observations were communicated to the Royal Society of England in a number of letters. Leeuwenhoek made no attempt to assign any importance to these organisms as to any rôle they might play in the economy of nature. He considered it impossible for them to be taken up in the blood, because he imagined that the absorbent vessels were too narrow to allow of the entrance of any such particles, even if they were a thousand times smaller than they really are, and he considered them a thousand times smaller than a grain of sand.

Revival of the vitalistic theory.

But Leeuwenhoek's contemporaries, and those who immediately followed, seized upon the idea of these little worms causing a great number of diseases; even in cases where they were not found they reasoned from analogy that they must be present. Then followed a reaction, and the idea was ridiculed out of existence (1726).

A few men of science, however, still retained the idea of a contagium vivum. Linné held to the idea, as did Plenciz, and the latter deduced logically the connection between Leeuwenhoek's discoveries and contagious diseases, as well as putrefaction. Still all of this was a matter of speculation, and not proven by direct experiment, so that the theory won very few disciples, and was regarded as a vagary till well into the present century.

Thus the rôle that micro-organisms play was often asserted and as often denied; but as matters of curiosity,

First efforts at a classification.

their forms were studied with the microscope with great interest and zeal. The twenty-one different forms that Baron von Gleichen-Russworm observed and pictured in 1778, and the contributions of the many observers from the year 1734 for the next half century, bear evidence of the lively interest, but they led to no important results and may be passed over without further mention. F. O. Müller made an exhaustive study of the various forms of micro-organisms in 1786, and pictured many of those known to us at the present day. The question, however, as to the origin of these micro-organisms seems to have been of greater interest in those days than the question as to what function, if any, they performed. The earlier observers satisfied themselves with studying their morphology and attempting to classify the micro-organisms, but their biology was merely a matter of surmise, which has had to suffer many alterations in the light of the experiments of recent years. Another question, too, which attracted

Generatio aequivoca.

the liveliest interest was as to the source of these minute beings, and the theory of spontaneous generation, which had been overthrown for insects, again occupied the most serious attention of the scientific world. It would be aside from the purpose of this article to enter into a detailed account of the discussion of generatio aequivoca, but the following experiments, which overthrew it, shed a flood of light upon a number of important points.

Charles Bonnet attacked the idea of spontaneous generation, upon theoretical grounds, in 1762, and Lazarus

Beginning of scientific experiments.

Spallanzani showed the correctness of Bonnet's views by experiments in 1769. Spallanzani convinced himself that in infusions exposed to the air there was always a development of animalcula, as they were then supposed to be. He then heated his vessels, and poured boiled infusions into them, and sealed them; but in spite of that some of the infusions became foul. He reasoned correctly from this, that the air contained in the vessels must contain the organisms of putrefaction. So in his following experiments he sealed the vessels containing the infusions and kept them an hour in boiling water, and all of the infusions remained sterile. Franz Schulze showed, in 1836, that the air could have access to sterilized infusions without causing putrefaction, if it were sterilized, *i.e.*, passed through sulphuric acid; and Schwann effected the same thing, in 1837, by passing the air first through molten metal, or by heating it with a spirit-lamp. Schroeder and von Dusch then showed, in 1854, that if the air was filtered through cotton wool, it was incapable of producing putrefaction. H. Hoffmann showed, in 1860, that it was not even necessary to pass the air through cotton, but that, if the neck of the flask were drawn out and bent over, there was no putrefaction in the previously boiled contents. Chevreul and Pasteur made the same observation in 1861, independently of Hoffmann. Van der Broek had shown, in 1857, that if grape-juice, blood, or urine were caught in sterilized vessels, with proper precautions against contamination from the air, they could be preserved indefinitely, and this was substantiated by a number of observers, beginning with Pasteur, in 1863. But a certain percentage of the experiments with infusions which had been boiled and protected from subsequent contamination failed, and a series of experiments of Bastian, in 1873, in which he took an infusion of turnips and added bits of cheese, seemed to indicate that there must be spontaneous generation, for after boiling his mixture ten minutes there was still a growth of organisms after three days' time. But Ferdinand Cohn showed, in 1875, that in infusions of hay, in cheese, and in all fluids which showed a growth of organisms after having been subjected to the boiling temperature and protected from subsequent contamination, there were micro-organisms which possessed the power of assuming a more resistant form. Bonnet had already, in 1762, suggested the possibility of there being organisms capable of such resistance, and Pasteur found he could only sterilize milk at a temperature of 110° C. (230° F.). Schroeder had met with the same difficulty. I shall reserve the discussion of this very important property of micro-organisms, viz., the formation of spores, till later on. The question of spontaneous generation was thus finally settled in the negative.

But, in the meantime, the study of the morphology of micro-organisms was pursued with great energy.

Further efforts at classification.

Christian Gottfried Ehrenberg published a systematic account of bacteria in 1838. His observations were made with the improved microscope of that time, and constitute a new era in the study. Ehrenberg, however, erroneously assigned them a place in the animal kingdom on account of their undoubted independent motion, and also on account of the flagella which he saw on many forms; and finally, he thought he saw eggs and granules, and the process of self-division. Ehrenberg made experiments in feeding bacteria with carmine, and as he found the particles taken up and lodged in various parts of the organisms, he classified them under the polygastrica. Even those organisms which did not take up the carmine granules he regarded as belonging to this group. He called the genus "The Animalcula of Infusion." Ehrenberg was fully aware that his classification was imperfect, and Dujardin's attempted improvement was also equally unreliable. These were, however, steps in the right direction, for, with the exception of Müller's classification, which was made with a microscope greatly inferior to that of Ehrenberg, there was no previous classification. The observations during the next few years of the strong analogy between the algæ and bacteria, led many observers to doubt whether Ehrenberg's idea that the latter belonged to the animal kingdom was correct, and Perty expressed the opinion, in 1852, that a part of them belonged to the animal, and a part to the vegetable, kingdom. The final blow to Ehrenberg's classification was

Cohn's classification.

given, in 1854, by Ferdinand Cohn, in his work on the life-history of the microscopic algæ and fungi. Cohn established the fact that a hopeless confusion existed as to all the forms which had been observed; that the observers had worked with different powers of the microscope, or made their observations loosely; and, finally, had mixed up the young with the matured cells, so that there was the greatest complication. He, therefore, selected the bacterium termo of Dujardin, or the vibrio lineola of Ehrenberg, which is found in all sorts of infusions undergoing putrefaction, and made a thorough, systematic study of this class of organisms. He made a special family out of it, which he called *zooglœa*, and established a very close relationship to the family *oscillaria*, a distinctly vege-

table class belonging to the algæ. The question was thus settled for the vibrio lineola, but Cohn reserved his decision in regard to the other vibrios. Other authors also inclined to the opinion that all these lower forms belonged to the vegetable kingdom. Naegeli had already, in 1849, emphasized the resemblance between the algæ with color and the colorless algæ, and finally made a separate class of the latter, because he observed that they were unable to derive their nourishment from inorganic materials. The former class, algæ with color, are able to subsist upon simple CO_2, NH_3, and H_2O, with certain dissolved salts, just as are the higher plants; the colorless algæ, however, require elaborated pabulum, as is the case with animals, and are not able to liberate oxygen. He consequently considered all the forms which had no chlorophyll as belonging to the fungi, and used the name *schizomycetes* for the whole group of bacteria, vibrios, spirilla, sarcinæ, mother of vinegar, and a specific organism which Cornalia had discovered as causing a disease in silkworms, called *nosema bombycis*. But Naegeli left it an open question whether they belonged to the vegetable or to the animal kingdom. Nevertheless, he showed that they all had certain very distinctive qualities in common, and, as already stated, he and Cohn emphasized the near resemblance through the algæ to the vegetable kingdom.

Naegeli's classification.

As far, however, as the establishment of specific groups of schizomycetes was concerned, there was nothing more determined up to this time (1857) than had been already done by Müller in 1786.

As already stated, the physiological properties of the schizomycetes were also studied in the meantime, with as much success, if not more, than the morphology and classification. Omitting observations which tended more to arouse interest than to advance our knowledge in regard to the rôle played by micro-organisms in various chemical processes and diseases, the first scientific proof that organisms do play such a rôle was made by Cagniard Latour and Schwann, independently, in 1837. These authors observed the growth and reproduction of the organism which had been seen by Leeuwenhoek, and which Turpin had called torula cerevisiæ, in the fermentation of beer and wine, and showed that its growth and reproduction caused the fermentation. Although the belief in the causal connection between organism and disease was strengthened, it was not proved by these experiments. But it was not long before the necessary proof was given, at least for one disease, for in the same year Bassi discovered that a disease of silkworms was due to a fungus, the spores of which covered the bodies of the worms in the form of a white powder, and a trace of this powder produced the disease upon healthy worms.

Study of physiological properties.

Jacob Henle was convinced of the connection between micro-organisms and disease by a careful consideration of the above facts. The plausibility, theoretically, of a belief in a contagium vivum in infectious diseases also forced him to this conviction, and the weight of the opinion of this great authority contributed much to arouse interest in this line of investigation. Henle was not led to change his opinion by not finding organisms in the tissues in various contagious diseases, for he contended rightly that at that time (1840) there were no means known by which it was possible to distinguish between various cells, or cell-nuclei, or nucleoli, and micro-organisms. Nor did he consider the presence of organisms alone sufficient proof of their causal relation, but postulated conditions which we shall presently see have been fulfilled to the letter. The conditions were constant presence, isolation, and proof of the contagiousness of the isolated organisms (by inoculation). When these conditions are fulfilled there can surely be no room for doubt. Similar conclusions were reached by deductive reasoning by J. K. Mitchell, independently, at about the same period.

Henle's deductions.

The next several years were spent in ceaseless activity, by a host of workers, in seeking organisms in various diseases. Bassi's discovery and Henle's deductions inspired the liveliest interest in this line of research; but as the methods at that time employed were very crude as compared with the methods of the present day, much of the work has since been shown to be of little or no worth. The discovery of the sarcina ventriculi by the Goodsir Brothers belongs to this era, and attracted the widest attention.

The epidemic of cholera, which appeared for the second time in 1849–50, in Europe, also awakened great activity in the search for organisms, for it was considered very likely that this disease is caused by a living contagium. The observations on cholera at that time have, however, been found to be erroneous, for the same micro-organisms which were then observed in the excretions of cholera patients were afterward found in a variety of other diseases, and even in fæces from healthy individuals. Bits of food in the cholera stools were also mistaken for micro-organisms. But aside from these results, which were either erroneous or not sufficiently convincing, a great number of diseases of insects, and of the cereals and potatoes, were proven to depend upon micro-parasites, and the same was also shown for favus and several other diseases of the skin. Pollender, too, about this time (1849), observed the anthrax bacilli in blood, and he was followed by Davaine the next year. But there was more zeal than judgment displayed by many workers at this time, and progress was retarded, especially by the writings of Hallier, who thought he had discovered the specific organism for a great many diseases.

Cholera in 1849 and 1850.

The next important epoch was ushered in by Pasteur's discovery of the rôle played by micro-organisms in various sorts of fermentation, in 1857. Cagniard Latour and Schwann, it will be remembered, had already established the relation between organisms and the alcoholic fermentation, but Pasteur deserves the credit of finally establishing that lactic-acid fermentation, butyric-acid fermentation, acetic-acid fermentation, etc., are all caused by micro-organisms, which not only differ in their physiological workings, but are well characterized by morphological and biological peculiarities. In this connection Pasteur also made the discovery of micro-organisms not capable of growth in free oxygen, and assigned to them the names *anaërobic* micro-organisms, to distinguish them from the *aërobic*, or those requiring the presence of free oxygen. Pasteur, moreover, discovered that certain organisms were capable of growing either with or without free oxygen, and these he called *facultative anaërobic* organisms. He considered all the micro-organisms of putrefaction as anaërobic, but offered proof only in a few cases. Pasteur next studied, more exactly than had as yet been done, the products obtained by vinous and acetic-acid fermentation. After having established the important rôle played by micro-organisms in so many processes in the economy of nature, Pasteur rightly concluded that they are necessary for the life of plants and animals, for without their agency the higher plants, incapable of feeding upon the complex molecules of dead animals and plants, would die if dead bodies did not undergo a putrefactive disintegration through the instrumentality of micro-organisms. Thus the germ theory was established; and although there have been, and still are, points about which all authorities do not agree, no one at the present day can have a reasonable doubt of the existence of micro-organisms, nor that they are an important element in nature.

Pasteur's work.

CLASSIFICATION.*—The *mycetes*, or *fungi*, embrace all the vegetable micro-organisms which are known to cause disease, fermentation, and putrefaction. They are *cryptogamic* plants, *i.e.*, they have no blossoms, but many of them reproduce by means of spores, small, highly refractive, oval or spherical cells, which are not as readily killed as the vegetative cells. The *phanerogamic* plants, on the other hand, embrace all the ordinary flowering plants and reproduce by means of seed. The *cryptogamæ*

* Leunis: Synopsis der Pflanzenkunde, 3. Abth. Kryptogamen, bearb. von Frank —— and Flügge, as above.

are divided into *C. vasculares*, or those with leaves and stems, *e.g.*, ferns, etc.; and *C. cellulares*, those without leaves and stems. *C. cellulares* are divided into the *mosses*, *algæ*, *lichens*, and *fungi*. The *algæ*, *lichens*, and *fungi* constitute the *thallophyta*, or plants forming a *thallus*, to be described further on.

The *mycetes*, or *fungi*, are divided into seven orders—*ascomycetes*, *basidiomycetes*, *zygomycetes*, *phycomycetes*, *blastomycetes*, *schizomycetes*, and *myxomycetes*. The first four orders have many points in common, and may be conveniently described under the collective name *mould fungi*, as they cause the moulding of bread, cheese, etc. The *blastomycetes* contain no pathogenic micro-organisms, but the family *saccharomycetes*, belonging to this order, causes alcoholic fermentation. The *schizomycetes*, or *bacteria*, are of more interest than all the others.

Beside the botanical classification it becomes necessary to divide micro-organisms into *parasites*, or those capable of growing upon living plants and animals, and *saprophytes*, or those growing upon dead plant or animal matter. Pathogenic micro-organisms must, of course, be parasites, but many of them grow as saprophytes also, and these are called *facultative parasites*. Therefore, all the pathogenic micro-organisms which are grown in cultures are facultative parasites.

Mould fungi.

A. The *mould fungi* consist of microscopic cells with membrane and cell-contents; the former consisting of a substance resembling cellulose, but differing from it in not giving the violet iodine reaction. The cell-contents consist of protoplasm possessing no demonstrable nucleus, no starch granules, and no chlorophyll, but often having vacuoles, oil-drops, various coloring matters, and, occasionally, crystals of oxalate of calcium. These crystals are very often found upon the outer surface of the cell-membrane. The cells are in the shape of threads called *hyphæ*. The hyphæ generally have transverse cell-walls, and are nearly always branching, the branches growing out from the side of the cell, or each cell sending out two prolongations in the process of growth. The hyphæ are either fruit-bearers or *mycelia*, and whether consisting of one thread or more, or whether they are all mycelia or all fruit-bearers, bear the collective name *thallus*. The mycelia form the vegetative part, the fruit-bearers form the reproductive part of the thallus. The thallus is usually composed of a tangled mass of hyphæ, but occasionally a mycelium assumes, secondarily, a thick fleshy form, the so-called *sclerotium*. The sclerotium has a cortical and a medullary portion, and is only capable of sending out fruit-bearers when exposed for a long time to favorable conditions of temperature and moisture.

The mycelia are capable of penetrating into the cells as well as into the intercellular tissue of dead plant and animal matter. But some of them are not restricted to dead animal and vegetable matter. The mycelia of the latter fungi either penetrate directly the cell-walls of living cells, or they send out short suckers, *haustoria*, which press their way through the cell-membrane. Even bones and teeth are sometimes destroyed by fungi, and their tissues are then found to be crowded with masses of mycelia.

Fructification in the mould fungi.

Reproduction takes place, as already stated, by means of spores, which afterward germinate, sending out one or more hyphæ. Spores are formed in several ways:

(a) Intercalary Spore-formation. Some of the cells of the hyphæ in the process of growth change directly into spores or into mother-cells.

(b) Acrogenic Spore-formation. The ends of the fruit-bearing hyphæ are divided off by a transverse membrane, and perform the function of spores. The thin stems of the fruit-bearers are called *basidia*, and in some cases fine branches connect the spores to the end of a basidium. The fine branches are called *sterigmata*.

Liberation of spores.

There may be one or more spores given off from a basidium. In the latter case the spores form one after another in a row, or in several parallel rows. The spores themselves are usually called *conidia*. They are also known as *basidiospores* or *acrospores*. The separation of the conidia from the basidium takes place in one of three ways:

Ejaculation.

First, the fruit-bearer simply falls to pieces and liberates them; second, the part of the basidium or sterigma immediately behind the spore dies and allows them to fall off; third, the spores may be ejaculated from the end of a tubular basidium as follows: The membrane of the basidium is very elastic, and as the spore approaches maturity this membrane becomes stretched by the absorption of water into the cell to such an extent that it bursts at the weakest spot, which is the zone just where the spore joins the basidium. As soon as the rupture takes place, the elastic cell-membrane contracts and squirts out the contents of the cell. The basidia may grow out from the inner wall of a hollow organ of fructification; in this case they cover the entire inner surface of the capsule, and give off numberless spores.

(c) Endogenic Spore-formation. This takes place in the interior of mother-cells, or *sporangia*. The spores are liberated from the sporangia by the bursting of the latter, or by its membrane becoming dissolved in water, or by ejaculation. The spores have no distinct membrane. Tubular or club-shaped sporangia are called *asci*, and the spores are called *ascospores;* these are generally eight in number to each ascus. The asci are often enclosed in spherical or flask-shaped organs, called *perithecia*. Some of the endogenic spores are liberated under water and have cilia, and are endowed with motion. These are called wandering spores. They finally come to rest and gradually form a cell-membrane, and may then germinate as other spores.

(d) Formation of Zygospores and of Oöspores. Fungus spores often result from copulation. The copulation may be asexual, in which case two mycelia of apparently the same sort send out club-shaped processes which unite. The resulting spores are then called *zygospores*. But in some cases there is a male and a female organ. One mycelium sends out a long, tubular, or club-shaped male organ, called an *antheridium*, to unite with a spherical female organ, or *oögonium*, of a different mycelium. These are called *oöspores*. They are spherical and provided with a membrane of cellulose.

Oöspores and zygospores are generally perennial, requiring a period of rest before they can germinate. They are usually simple, but may be compounded of a number of cells of various shapes. They are either spherical, oval, or occasionally rod-shaped. The cell-membrane is composed of a colored episporium and a delicate, colorless endosporium, which encloses the protoplasm and often contains oil-drops. The spores may develop into sporangia, or they may send out mycelia.

Pleomorphism in the mould fungi.

All these methods of forming spores may take place coincidently or alternately on the same plant. Furthermore, the same fungus may require entirely different nutrition in successive generations. It may act as a parasite to a certain higher organism in one generation, but require an entirely different host in the next. Thus there is quite a wide range of pleomorphism in the broad sense in these fungi.

The *ascomycetes* are the only order that forms asci, and they only do so at the summit of their development. Some of them are parasites, but do not form asci till after the invaded plant or animal is dead. The asci are formed directly on the mycelium only in the lower members of this order. A very large number of fungi belong to this order, but only three of them concern us at present—*Aspergillus*, *Penicillium*, and *Oidium*.

Aspergilli.

The true Aspergilli usually form conidia. The fruit-bearers are long and swollen at the ends into spherical or club-shaped vesicles. The spores are attached to the vesicles by means of a mass of radiating sterigmata (Fig. 3388), which are in some cases branched and in others unbranched. The spores vary from 1 μ to 6 μ in diameter.

Occasionally there is a formation of asci inside of small spherical perithecia, which are about one millimetre in diameter, and have each a separate membrane;

the latter is usually colored and has hair-like projections on the surface. This membrane bursts at maturity. In the *eurotium-aspergillus* the perithecium is preceded by what is possibly a process of sexual copulation, as follows: Several fine branches are first given off from a mycelium; these branches then twist together, forming a sort of corkscrew; this is the so-called *ascogonium*, which represents the female organ. After the formation of the ascogonium several branches grow out from the base, and finally blend together to form the membrane of the perithecium. These secondary branches which form the perithecium are called *pollinodia*, and one of them, while they are still separate, lays itself upon the last turn of the screw-like ascogonium and an intermixture of contents takes place (see Fig. 3389). The pollinodia are looked upon as the male organ.

FIG. 3388.* — Fruit-bearer of a True Aspergillus, showing the Swollen End with Numbers of Spore-bearing Sterigmata. × 180.

The formation of delicate perithecia is met with in the so-called eurotium-aspergillus, as already stated, and this distinguishes the latter from the true aspergilli, which form sclerotia. The thick sclerotium of the true aspergillus remains inert as long as it is dry, but in the presence of moisture it sends out threads which afterward form asci. For the formation of perithecia the very best nutrition is required.

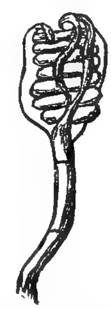

FIG. 3389.—Formation of a Perithecium by Copulation. The Coiled Ascogonium surrounded by the Pollinodia. × 250.

THE PATHOGENIC MOULD FUNGI.—The lesions produced by the pathogenic mould fungi differ from those produced by the pathogenic bacteria. The tendency of the latter is to cause a general infection of all the organs and tissues of the body. Even where the lesion is at first local, the organisms usually get into the blood and are conveyed to all parts of the body. The mould fungi, on the other hand, become lodged in the internal organs, especially in the kidneys, and the mycelia grow out and form distinct foci.

The Pathogenic Aspergilli.—Three species of *aspergilli* have pathogenic properties when injected into the veins of various animals. Inhalations of the spores produce mycosis in the lungs of birds. Animals have been found suffering from an infection without intentional inoculation. The aspergilli are widely distributed, and are found upon mouldy bread, etc.

Aspergillus fumigatus. — Greenish. Conidia-bearers short and swollen into hemispheres, 8–12 μ in diameter, very thickly set with awl-shaped sterigmata. Conidia round, smooth, show no membrane, and are generally colorless, 2.5–3 μ in diameter. Sclerotia are unknown. Grows best at 37°–40° C. Possesses more powerful pathogenic properties than the other two.

Aspergillus niger.—Brownish-black. Fruit-bearers are exactly globular. Sterigmata, 20–100 μ long and branching. Conidia round and brownish-black at maturity, and 3.5–5 μ in diameter. Sclerotia size of rape-seed, and brownish-red. Optimum temperature about 35° C. Does not seem to have any very great malignant power.

Aspergillus flavus or *flavescens.* — Green or greenish-brown. Conidia yellow or brown, with a finely nodular surface, 5–7 μ in diameter. Sclerotia very small and black. Grows best at about 28° C. Stands next to *A. fumigatus* in *pathogenic power*.

The most common of all fungi is the *Penicillium glaucum.* In the family to which this belongs, *penicillium*,

Penicillium.

the conidian fructification is alone met with, except under very extraordinary conditions of nutrition. In the latter case the penicillium occasionally produces a small protuberance, about the size of a grain of sand, upon a mycelium, and this protuberance behaves like a thick-walled sclerotium. Still, as a rule, the fruit-hyphæ are branched, and have a cluster of conidia upon the end of each branch. As is shown in the accompanying cut (Fig. 3390), the conidia are formed in rows upon the finger-like terminal branches of the hyphæ.

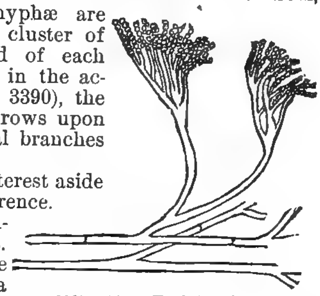

FIG. 3390.—Two Fruit-bearing Hyphæ of a Penicillium. × 170.

Penicillium has no interest aside from its frequent occurrence.

Oidium, Mildew.

The *Oidia* form summer and winter spores. The former are simple conidia separated in a row from the ends of the long, straight mycelia. The winter spores are formed in perithecia, which develop secondarily upon the same mycelia from which the summer spores were given off. The winter spores require a state of rest, *i.e.*, through the winter, before they germinate. The oidia cause the so-called "mildew." A scurf of the comb and gills of poultry, and favus of mice, and perhaps favus and herpes tonsurans in the human being, are caused by the growth of oidia.

FIG. 3391.—Mucor, showing Four Sporangia. × 140.

Some of the members of the Basidiomycetes and Phycomycetes are parasites of plants, but as none of them have been found to cause disease in animals they may be omitted without description.

The Zygomycetes order has among its families the *Mucorineæ*, to which the mucors belong. In the Mucorineæ

Mucors.

the organs of copulation blend to form a zygospore. Spores are also formed without copulation in the interior of sporangia (Fig. 3391), by the division of the protoplasm into small unicellular spores (Fig. 3392), which are liberated by the dissolution of the membrane of the sporangium in water. This membrane is at first colorless, but afterward becomes black. The fruit-bearing hyphæ grow up perpendicularly.

FIG. 3392.—A Sporangium Imagined in Vertical Section, filled with Spores. × 1240.

Pathogenic Mucors.—Two mucors have pathogenic properties when injected into the blood. Rabbits die in forty-eight to seventy-two hours after injections of the spores of *M. rhizopodiformis* and of *M. corymbifer.* The mycelia are found upon post-mortem examination chiefly in the kidneys, but also in the mesenteric glands and Peyer's patches.

B. *The Saccharomycetes*, belonging to the order Blastomycetes, grow by

Yeast fungi.

budding. The parent cell becomes enlarged at some point into a protuberance which grows larger, and either separates or remains attached, and becomes in turn a mother-cell (see Fig. 3393, 6). The formation of ascospores has also been observed.

No pathogenic saccharomycetes have as yet been discovered, but they are of great interest because many of them cause the alcoholic fermentation of sugar. This function, however, is not peculiar to the saccharomycetes, for mucor racemosus also causes the same fermentation. It is even probable that all the saccharomycetes are merely a form of mould fungus, since this same mucor racemosus assumes the budding growth if it is immersed in a solution of sugar. The CO_2 which is liberated in the fermentation buoys the mucor, which has for the time become a budding fungus, up to the surface, where it again sends out hyphæ.

C. *The Schizomycetes*, or *Bacteria*, are very minute uni-

* The accompanying figures were not drawn from actual observation with the microscope, except Figs. 3395 and 3396 (p. 333). Some of them are modified copies from Flügge's Die Micro-organismen (see p. 343).

cellular organisms. They play an exceedingly important rôle in pathology and hygiene. Some members of this group cause many of the most terrible maladies of animals and plants, they constitute the contagium vivum of many infectious diseases; others are of the greatest use in preparing dead vegetable and animal matter for assimilation by the higher plants; others, again, are concerned in fermentation.

Bacteria.

A bacterium consists of protoplasm enveloped in a cell-membrane. The cell is generally colorless; in some rare species it contains chlorophyll or other coloring matter. The protoplasm may also contain minute granules of sulphur, and sometimes refractive oily particles. It is sometimes granular. Some bacteria give the blue iodine reaction, which is especially marked just before the formation of spores. Under unfavorable conditions of growth the protoplasm becomes cloudy and breaks up into granules. The cells have no nuclei. The cell-membrane is sometimes colored, and sometimes is surrounded by a gelatinous envelope or capsule, which can be occasionally brought out by staining.

FIG. 3393.—1, Staphylococci. 2, Streptococci, showing in two places larger forms, to signify arthrospores. 3, Micrococci tetrageni. 4, Sarcinæ. 5, Diplococci. The four diplococci to the right, colored black throughout, are called biscuit-shaped (see Chicken Cholera and Gonorrhœa, below), and are also regarded by many as bacilli. 6, Saccharomycetes.

Classification of bacteria.

It is sufficient for our purpose to divide bacteria into *micrococci*, *bacilli*, and *spirilla*. Micrococci are spherical or slightly oval, and bacilli are rod-shaped. It is evident that the individual bacteria may lie separated from one another after cell division, or they may hang together and form chains, threads, irregular clumps, etc. Now, an organism which grows so as to form chains always retains this tendency; it does not form chains in one generation and clumps in another. This property of organisms has been used as an important means of diagnosis, especially of the cocci. Micrococci which always tend to form chains are called *streptococci;* those forming irregular clumps *staphylococci.* Micrococci which grow so as to form tetrads are called *tetragoni.* If they hang together in all three dimensions of space, they resemble packets bound tightly around with two cords at right angles, and are called *sarcinæ.*

Although bacilli also form chains and clumps, no such distinction is made as in the micrococci, except that bacilli in chains are sometimes called leptothrix. Very short bacilli were formerly called bacteria, but the latter name has come to be universally adopted for the schizomycetes in general. Some of the distinctions of the varieties of bacteria are very slight, and are only apparent to the practised eye. Thus, *clostridia* (Fig. 3394, 1) are bacilli of a spindle shape, and bacilli with a constriction in the middle are called dumb-bell or figure-of-8 shaped (Fig. 3394, 3), and rods with parallel sides may have rounded, square, or even concave, ends. Bacilli that are curved on the long axis are called *commas*, or *comma-bacilli* (Fig. 3394, 4), and a chain of them constitutes a *spirobacterium* or *spirillum.* But there are also spirilla, or long spiral threads, which show no division into commas (Fig. 3394, 4). The bacteria never branch as do the mycelia of the mould fungi.

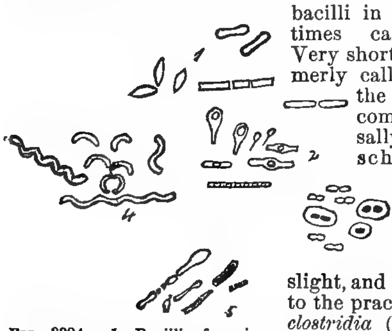

FIG. 3394.—1, Bacilli of various shapes. 2, Bacilli in the process of forming spores. 3, Bacilli enclosed in capsules and figure-of-8 bacilli. 4, Comma bacilli and spirilla. 5, Forms of involution. × 700.

The schizomycetes multiply by fission, the cells simply grow larger and divide, and afterward separate or hang together as already explained. Micrococci show no variation, they simply form micrococci from one generation to the next, but the other members of this order are subject to quite decided changes of form, owing to various conditions.

Involution.

Under favorable conditions bacteria continue to reproduce vegetative cells indefinitely, and under unfavorable conditions they either form spores or undergo a retrograde metamorphosis. In the latter case they degenerate into what is known as forms of involution (Fig. 3394, 5). The cells become swollen and have irregular protuberances on them, and are often so distorted as to bear no resemblance to the normal cells.

Formation of spores in bacilli.

The formation of spores of bacteria may be properly regarded as a metamorphosis; it is a simple transformation of a vegetative into a germinative cell under conditions unfavorable to growth. It is a provision for the perpetuation of the species, and occurs when the organism has nearly exhausted its supply of nutrition, or poisoned it with products of its growth, etc. It takes place whenever the organism is threatened with extinction. The fungi, on the other hand, form spores under the most favorable conditions, even requiring an abundant supply of nutrition, etc., for their production. Indeed, the life-history of the fungi is incomplete without the formation of spores. But it is comparatively rare in the bacteria, and all the conditions which tend to bring it about are not yet known. It is not the result of copulation.

Characteristics of spores.

Bacteria are said to form two kinds of spores, *endogenic* spores and *arthrospores.* Both kinds survive the action of agents which would kill vegetative cells, but endogenic spores are more resistant than arthrospores. The latter have been but little studied. They possibly are present in all sorts of bacteria, and are generally not distinguishable in appearance from the other cells, though sometimes they are larger and have a higher refractive index, etc. (see Fig. 3393, 2). The term, therefore, merely means that certain individual bacteria have a higher resisting power than the ordinary vegetative cells, but are not as resistant as endogenic spores, and may or may not be distinguishable under the microscope. But the endogenic spores have very marked characteristics. They are very highly refractive, and appear as round or oval bodies lying in and among the vegetative cells (see Fig. 3394, 2). Their resisting power is very great; the endogenic spores of some bacteria survive even the temperature of boiling water several minutes (see p. 325). As we shall see presently, the vegetative cells are readily stained with aniline dyes, but the endogenic spores are not stained under ordinary circumstances. They are only found in bacilli, and possibly in spiro-bacteria. Micrococci are restricted to the formation of arthrospores. In the following the word spore is meant to refer to endogenic spores.

Germination of the spores of bacilli.

Spores represent a state of suspended activity, and they may remain inactive for months and years, till they are removed from the medium in which they have been formed and are placed under proper conditions for germination. Under suitable conditions of temperature, moisture, etc., the clear globular mass in which each spore is embedded becomes ovoid and gradually elongates into a rod, the spore in the meantime becoming less and less refractive, and finally disappearing (Koch). Or, the spore swells and loses its refractive power, its dark contour, and its transparent capsule. Germination then takes place, either in the direction of the long axis of the spore or at right angles to it. In the latter case there appears a dark crescentic shadow at each pole of the spore, and a papilla grows out from one side and increases in length till it becomes a rod. In the other case, the cell-membrane of the spore becomes uniformly thickened, and the bacillus is liberated by growing out and breaking through at one of the poles (Prazmowski and Brefeld). The membrane

of the spore which has been thus abandoned by the bacillus remains for some time lying near the latter.

Independent motion of bacilli and spiro-bacteria, and the formation of zoöglœa.

Many of the bacilli and spiro-bacteria are endowed with the power of independent motion; the micrococci have no motion of their own. If bacteria are examined in water, there is always more or less agitation, due to unintentional movement of the microscope, and currents caused by evaporation, etc., but this is the so-called Brunonian molecular motion, and has nothing to do with the indepeudent motion of some bacteria. Bacilli thus endowed dart about in all directions, with a wriggling motion, always end foremost, never sideways. The spirilla have also a twisting motion. The motion in some cases is due to the vibration of a flagellum or fine thread at the ends of the rods. When bacteria accumulate into masses they cease to move, and the masses are called *zoöglœa.*

Colonies of bacteria.

Although the individual bacteria are so minute, their multiplication is so rapid that, starting from an invisible number, they may form macroscopic masses in one or two days in solid media. These masses, whether they are macroscopic or microscopic, are called *colonies*, and we shall see farther on that they are characterized in each species by color, contour, etc.

CONDITIONS OF THE GROWTH OF ORGANISMS.—Some of the conditions of growth have been already mentioned, but in order to understand the laws of nutrition more clearly, the following chemical analysis is not without value. The analyses of the mould fungi and saccharomycetes have been reserved for this place, in order to compare them with that of the schizomycetes.

	UNDRIED.	WATER DRIVEN OFF.			
	Water.	Albumen.	Cellulose.	Fat.	Ash.
	Per cent.	Per cent.	Per cent.		
Mould Fungi	88	29	50	Appreciable.	Appreciable.
Saccharomycetes	40–80	47	37	Appreciable.	Appreciable.
Schizomycetes	83–85	84–87	None.	Appreciable.	Appreciable.

The composition of the ash is as follows:

	Potash.	Soda.	Lime.	Magnesia.	Oxide of iron.	Phosphoric acid.	Silicic acid.	Hydrochloric acid.	Sulphuric acid.
	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.			
Mould Fungi	50	1.5	1	2	1	30	Small amount.	Small amount.	Variable.
Saccharomycetes	28–39	....	1–4	6–8	....	53–59	Sometimes a trace.	....	....
Schizomycetes.*									

* Probably the same as for the Saccharomycetes.

The above analysis of the ash of the mould fungi is really the mean of a number of analyses of the ash of the higher fungi, but is probably approximately correct for the lower fungi.

From the foregoing it will be seen that water enters largely into the composition of all three classes. The schizomycetes contain the largest amount of albumen, and the mould fungi the least. The mould fungi have the largest amount of cellulose, and the schizomycetes none at all. Potassium and phosphoric acid are the principal ingredients of the ash of all three.

It is evident that these organisms require carbon, nitrogen, oxygen, and hydrogen in some form.

Sources of carbon.

As bacteria are, with very rare exceptions, devoid of chlorophyll, they cannot utilize the carbon in the CO_2 of the air, and are therefore compelled to have more elaborate molecules, such as are supplied by plants and animals. Double molecules of carbon, or C in combination with N or O, are unsuited, but C in combination with H (CH_3 and CH_2) are readily assimilated. Thus the sugars constitute a very good source of carbon, whereas cyanogen cannot be used.

Sources of nitrogen.

Nitrogen is, preferably, derived from albuminous matter and peptone, but NH_2 and NH compounds may also serve as a source. Nitrates are also available, but cyanogen is not.

Sources of hydrogen and oxygen.

The hydrogen and oxygen are supplied by the nitrogen and carbon compounds, and also by water.

The above is true for the mould fungi, and saccharomycetes as well, except that the latter are not capable of assimilating the ammonium salts or the nitrates. Furthermore, the mould fungi require free oxygen for their normal growth. The saccharomycetes are capable of growing without it, they are facultative anaërobic organisms. The schizomycetes, as we have seen, vary in their behavior toward oxygen; some of them are aërobic, some anaërobic, some both. The mould fungi grow best in slightly acid media, whereas the other two classes prefer neutral or slightly alkaline substances; some of the latter refuse to grow in the presence of even a trace of free acid.

Very striking behavior of bacteria derived from water.

The water organisms seem to defy all the laws of nutrition above laid down. Other bacteria require at least an appreciable amount of nitrogen and carbon compounds and salts, whereas the aquatic cocci and bacilli find nutrition enough for active growth in freshly distilled water. Distilled water has been used, in fact, to cultivate them through many successive generations.

Influence of temperature, etc.

Of physical conditions temperature plays the most important part. Roughly speaking, temperatures of 30° to 35° C. (86° to 95° F.) are most favorable to active cell multiplication, and also for the formation of spores. Below 18° C. (64.4° F.) growth is retarded. Some organisms refuse to grow at the lower temperatures, and others refuse to grow at the higher; others, again, vegetate very well at temperatures below 18° C. (64.4° F.), so that a general statement is hardly permissible. The vegetative cells are killed in a few minutes by temperatures above 60° C. (140° F.) (Sternberg *et al.*). The presence or absence of light seems to make no difference, except that direct sunlight kills the spores of anthrax in a few hours (Arloing). Pressure of 600 atmospheres continued for twenty-four hours had no effect upon anthrax bacilli, and yeast stood a pressure of 300 to 400 atmospheres; putrefaction did not cease under a pressure of 350 to 500 atmospheres (Certes). Electricity has no effect except very powerful constant currents, which check the growth of organisms (Cohn and Mendelssohn). Mechanical agitation has been repeatedly tried, but the results of the experiments do not agree. It would seem, however, that rest is conducive to growth, for the peculiar class of aquatic bacteria multiply with enormous rapidity in stagnant water (Cramer), but whether this is due to stagnation alone or to other causes is not known.

A great many chemical substances have been found to kill micro-organisms, but the most valuable one for disinfecting purposes is corrosive sublimate (Koch), when it can be applied. In the laboratory a 0.1 per cent. solution is employed to disinfect cultures when they are to be destroyed, and for similar purposes; but a very much more dilute solution is sufficient, if allowed to act for an hour or so. Aqueous solutions of chlorine, bromine, iodine, carbolic acid, osmic acid, permanganate of potash, and bleaching powder, all act as disinfectants, but the solutions have to be much more con-

centrated than solutions of corrosive sublimate. For a complete discussion of disinfectants and germicides see under the headings Disinfectants and Germicides.

Media Employed for Bacterial Cultures.—From the above consideration of the conditions of growth, it becomes apparent that suitable media must contain soluble albumen and certain salts, and, moreover, abundance of water. Three substances have come into universal acceptance as fulfilling all these conditions: Infusions of flesh, boiled potatoes, and blood-serum. Beef-broth is most generally used, and is prepared as follows:

Preparation of nutrient gelatine and agar.

A half of a kilogramme of lean beef is freed of all tendons, etc., and chopped up fine in a sausage-mill or otherwise. It is then put into a litre of pure water and allowed to stand in the cold eighteen to twenty-four hours. The water, which has by this time dissolved out most of the soluble albumen, salts, etc., from the meat, is now filtered through a cloth. One per cent. (ten grammes) of peptone and a half per cent. (five grammes) of common salt are then added. Gelatine in the proportion of five to ten per cent., or even more, or agar in the proportion of 0.5 to one per cent., are also added for reasons which will become apparent presently. But this mixture is acid, so for the cultivation of bacteria and yeast fungi it is necessary to neutralize with carbonate of soda. Gelatine itself has an acid reaction, so the neutralization must take place after its addition and solution by heat; but agar is neutral, so that where it is used it is immaterial at what point the soda solution is added. In both cases the mixture is now boiled until all the coagulable albumen is precipitated, and poured at once upon a hot paper-filter which has been just before washed with boiling water. If the filtrate is not absolutely clear, a small amount of egg-albumen is added, and it is again boiled and filtered. While it is still hot 5–10 c.c. of the filtrate are poured into test-tubes stopped with cotton wool. Now, it is evident that the cotton will prevent the subsequent entrance of organisms from the air, but the cotton wool itself and the test-tubes all have organisms clinging to them, so that before the nutrient gelatine or agar is poured in they must be sterilized, *i.e.*, freed from adherent germs. This sterilization is effected by plugging the tubes pretty tightly with cotton and heating them up in an air bath to 140°–150° C. (284° to 302° F.) for about an hour. But in the process of filtering and in filling the tubes organisms are likely to find their way in, so that after the tubes have been filled they must be again sterilized.

Koch's steam sterilizer.

This is accomplished by subjecting them to a temperature of 100° C. in a Koch's steam sterilizer. The sterilizer is simply a metallic cylinder set upright upon a boiler, so that all the steam which escapes from the boiler streams through the cylinder. It has been found that all objects placed in the cylinder are brought up to 100° C. (212° F.) in a few minutes after the steam begins to be given off. The sterilization in the steam apparatus has to be repeated upon three successive days for the following reason: The first sterilization kills all the vegetative cells, but we have seen that spores resist the boiling temperature for several minutes. The spores which were not killed in the first sterilization will have germinated by the second or third. It would simplify the process to steam the tubes for a half or three-quarters of an hour at once, for this would kill vegetative cells and spores as well, and agar may be treated in this way. But if gelatine is boiled too long at a time it turns to paragelatine, so that the sterilization has to be effected as above described.

Potatoes for bacterial cultures.

The method of preparing potatoes is very simple. Pieces of potatoes, with the skin removed, are put into some convenient vessel and steamed in the sterilizer for an hour or more. For reasons readily understood, the vessels containing the bits of potatoes must have an arrangement for excluding the micro-organisms of the air. Small glass dishes with perpendicular sides, and tops to fit over them, are useful for this purpose (Esmarch). The dishes should be of such a size that a thick round slice of potato will about fill one of them, and the flange of the top should come well down around the sides of the dish. Wide test-tubes plugged with cotton serve also equally as well. In this case the potatoes are cut in the shape of cylinders and fitted nicely into the tubes. The cylinders should have one side cut away obliquely, so as to afford a greater surface. Of course, the dishes and test-tubes may be first sterilized in the hot-air bath, but it is hardly necessary.

Blood-serum.

Blood-serum is prepared by allowing a quantity of blood to stand until the serum separates from the clot. It is then drawn off with a pipette and distributed into sterilized test-tubes as for agar and gelatine. It is desirable to catch the blood, in the first place, with all possible aseptic precautions, in a sterilized vessel. The carotid artery of a dog or other animal affords a convenient source. The instruments used in opening the artery, and the cannula which is inserted, should be first heated, *i.e.*, sterilized, in the Bunsen flame and then allowed to cool. The blood is allowed to flow into a wide-mouthed vessel, which has been sterilized by heat and has a cotton stopper; after the serum separates it is drawn off as already indicated. If the process has been successfully accomplished it is unnecessary to sterilize the serum. It can be at once coagulated by placing the test-tubes containing it in a slanting position in a special apparatus, and subjecting them to a temperature of not above 70° C. (158° F.) for three hours. If desired, the serum may be first sterilized by Tyndall's method, which consists in keeping the tubes at a temperature of 60° to 65° C. (140° to 149° F.) an hour or more at a time, for five or six successive days. The principle of this is readily understood from what has gone before.

Other media.

Other media, such as chicken-broth, veal-broth, and so forth, have been employed, but the three media above described are more employed than any other. They are sometimes varied, for special purposes, by the addition of sugar, glycerine, etc.

Applicability of the various media.

The most useful of them all is nutrient gelatine, but its use is limited to comparatively low temperatures, for it becomes liquid at about 22° or 23° C. (71.6° to 73.4° F.). The other media may be used at all temperatures. Gelatine is liquefied by many organisms, and Sternberg has shown that this liquefaction is not necessarily dependent upon the growth of organisms, for cultures of liquefying organisms, in which the latter had all been killed by heat, were capable of liquefying a second tube of solid gelatine, even when introduced in small amounts. Only one or two organisms as yet known liquefy agar. Where it is not specially mentioned in the following, it is understood that it is not liquefied. Most organisms have a very characteristic growth upon gelatine and potatoes; their growth is less characteristic upon agar.

The French school use bouillon without the addition of gelatine or agar, but the growth of organisms is not as characteristic in liquid media; and for purposes of isolating various species of organisms, and for the study of pure cultures, the solid media possess very great advantages.

Methods of Obtaining Pure Cultures.—Various methods of obtaining pure cultures have been suggested, and more or less successfully employed. Lister suggested a method which is essentially the same as that employed by Miquel and the French school generally. It consists in diluting a suspension of the micro-organisms to be isolated with sterilized water or other liquid, so that in a certain volume, *e.g.*, one drop, it is estimated that only one organism is present. Several flasks of bouillon are inoculated with one drop each of the diluted suspension, so that only one organism is thus introduced and grows out to form a pure culture. But this and the other methods now employed by some of the French school are so far inferior to those which we owe to Robert Koch, that I shall restrict myself to a description of the latter.

Solid media.

Solid media had been already employed by Klebs and others, but Koch's adaptation was so original that it may almost be said that he was the first to use them. Koch's methods are very readily understood, and their advantages are manifest.

It is plain that a number of different species may grow

for a longer or shorter time, side by side, on the surface of a potato or upon a layer of gelatine, without coming in contact, at least until the colonies grow so large that they touch; or, in the case of nutrient gelatine, until the latter becomes liquefied. If, on the other hand, liquid media are used, all the species which happen to be present are mixed together by the currents in the liquid, by their power of independent motion, etc. If, now, a trace of any of the isolated colonies on the potato or gelatine be inoculated into any proper medium, and the culture thus made protected from subsequent contamination, it is evident that it will be a pure culture. It is also equally evident that a pure culture cannot be obtained by inoculating directly from any liquid containing more than one species, for every trace of the liquid will almost certainly contain representatives of each of the species present.

Advantages of the same.

To illustrate the actual process, suppose it is desired to separate the various organisms in any substance which contains them. A tube of nutrient gelatine, as above described, is liquefied at a temperature not exceeding 40° C. (104° F.), and a small quantity of the substance under examination is introduced and thoroughly disseminated through the gelatine. The contents of the tube are then poured out upon a cold glass plate which has been previously sterilized in the hot-air bath. The plate is allowed to stand under a cover till the gelatine is solidified, and it is then transferred to a glass dish with a cover, and placed at a temperature of 18° to 22° C. (64.4 to 71.6° F.). In a few days there will be a number of dots apparent in and upon the gelatine, and a microscopic examination shows that these dots are little masses of micro-organisms. Each one of these masses, or *colonies*, is composed of micro-organisms of the same sort; for while the gelatine was fluid the various organisms were distributed through it, and when the gelatine became solid each separate organism, or zoöglœa, was fixed in the place where it happened to be, and had to remain there and grow without interfering with any neighboring organisms. If a trace of one of these colonies is introduced into a tube of solid gelatine, it grows and constitutes a pure culture.

Process for isolating bacteria.

If agar is used the process is essentially the same. Agar does not become liquid at any temperature below the boiling-point of water, and becomes solid again at 40° C. (104° F.). So it becomes necessary to liquefy it and allow it to cool down nearly to the solidifying-point before introducing the substance under examination. In practice there are always a number of dilutions made from this first or "original tube," by inoculating a second from it, and a third from the second, and so on. The reason for this is, that usually there are so many organisms in the first tube that when they grow out they may come in contact with each other, and thus one colony may contaminate another. But if several diluted plates are made, one or more of them will have the colonies well isolated, and they may be studied and used for inoculations.

When the plates are examined there is always danger of contamination from the air, or contact with the fingers, etc., so that Esmarch's modification of the Koch-plate method has great advantages. According to Esmarch's method, the original tube and dilutions are made just as in the other, but instead of pouring the gelatine or agar upon sterilized plates, a rubber cap is fitted over the tubes and they are held horizontally and twirled in ice-water till there is a film of the nutrient medium covering the inside of the tube. Dr. Booker, in the Johns Hopkins Pathological Laboratory, instead of using ice-water, rolls the tubes in a groove melted in a block of ice. This avoids the use of rubber caps, which sometimes permit the ice-water to run into the tubes. After the colonies have grown out, they may be examined, under the lower powers of the microscope, through the walls of the tube. They are thus not exposed, for the cotton remains in; but even when it is removed for purposes of transplanting, etc., the danger of contamination is reduced to a minimum. The Esmarch tube is, therefore, a most valuable contribution to our technique.

The inoculation of the gelatine and the transplanting from colonies are effected by means of a platinum wire melted into the end of a long glass rod. Each time before it is used the wire is glowed in the Bunsen flame, and the glass handle is also passed a few times through the flame. Cultures may be made either with a straight platinum wire, by taking a trace of a colony, or culture, upon the end of it and simply thrusting it into a tube of gelatine or agar; or the surface of any of the media may be inoculated by means of a platinum loop. The latter cultures might be called smear-cultures, and the former stick- or stab-cultures. Agar and gelatine for smear-cultures are allowed to solidify with the tubes in an oblique position, so as to afford a greater surface.

Pure cultures.

Several methods have been recommended for the cultivation of anaërobic organisms. The air may be excluded from the colonies upon plates by covering the gelatine or agar with a thin sheet of isinglass, applied directly to the surface. Another method is to place the plates under a bell-glass and displace the air with hydrogen or CO_2. Test-tubes of peculiar construction have also been used.[1] These test-tubes have a narrow glass tube opening in the side, about 5 ctm. from the bottom, just above the gelatine or agar. The tubing projects for about 3 ctm. at right angles to the test-tube, and it then bends downward and is plugged with cotton. The air in the test-tube is displaced by connecting the narrow tubing with a CO_2, or, preferably, with a H generator, and allowing the gas to stream through. As soon as the air has been displaced the upper end of the test-tube and the narrow tubing are melted off. A modification of these tubes consists in having the narrow tubing to project down into the bottom of the test-tube, so that the gas bubbles through the gelatine, or agar, which in both cases is kept liquid till after the gas has been allowed to stream through. Still another way is to make Esmarch tubes and fill them afterward with gelatine or agar, as the case may be. Flasks with narrow necks and a tube projecting from the side have also been used as follows (Hüfner, Rosenbach): The agar is boiled in one of these flasks till all the air is replaced by the gases from it, and the narrow neck and projecting tube are sealed. This projecting tube has had some of the material containing the anaërobic organism previously introduced, and after the agar has cooled down to 40° C. this material, which must be fluid, is driven into the flask by gently heating the end of the tube. Anaërobic organisms only grow at the bottom of the tube in a stab-culture, but if the air is excluded by a layer of oil they grow nearer the upper part. They grow at the bottom of the vessel in liquid media.

Cultivation of anaërobic micro-organisms.

The methods are all simple and readily understood, but require great care in manipulation.

METHODS OF EXAMINATION.—The difficulty of distinguishing between bacteria and cell-nuclei, and so forth, which Henle met with, was overcome in the most satisfactory way by Weigert's brilliant discovery of the tenacity with which bacteria retain watery solutions of the aniline dyes. Nearly all parts of a tissue are readily decolorized, after staining with various aniline colors, by treatment with acids, etc.; but to effect a decolorization of the bacteria, the decolorizing agent has to be allowed to act for a much longer time. This is a perfectly decisive, sharp reaction, and renders the detection of bacteria in most cases very simple.

The limits of the present paper will not allow a full account of the various methods of staining, and I can merely give a few general principles and one or two special applications.

Methods of staining bacteria.

Ehrlich distinguishes two classes of aniline dyes, acid and basic. The acid dyes need not necessarily have an acid reaction, but they include all the dyes which form salts with the bases, and whose coloring property is consequently due to an acid radical. The basic colors are generally not found as free bases in the market, but are sold as salts; thus fuchsine is a chloride or acetate of rosaniline. The basic dyes are almost exclusively used as stains for the bacteria. The cell-nuclei also show an affinity for this class of dyes, and in order to get rid of the

diffuse stain in other parts of the tissues the latter are decolorized in very dilute acetic acid or in alcohol. This treatment leaves the bacteria and nuclei stained, and the rest of the tissues unstained. If sections treated in this way are afterward slightly stained with some contrasting color, the bacteria and nuclei often show to better advantage. The most usual colors are methylene blue, gentian violet, fuchsine, and methyl violet, all in watery solutions. These solutions are conveniently prepared by having saturated alcoholic solutions and adding a few drops to water as required. Saturated alcoholic solutions may be kept indefinitely.

FIG. 3395.—From a Section of the Kidney of a Mouse, showing the Capillary Spaces filled with Anthrax Bacilli.

Bacteria in sections of tissues are stained by allowing the latter to remain from twenty minutes to several hours in a watery solution of any of the above dyes. They are then put for a very few seconds into very dilute acetic acid, about 1 drop acid to 20 c.c. water, and are afterward thoroughly washed in water, dehydrated in alcohol, cleared up, preferably, in origanum oil, and mounted in balsam dissolved in xylol.

Most bacteria stain very well in this way, but tubercle bacilli require special staining as follows: 11 c.c. of a saturated alcoholic solution of fuchsine or gentian violet, 100 c.c. of a saturated aqueous solution of aniline oil, and 10 c.c. of alcohol, are mixed. The aqueous solution of aniline oil is prepared by thoroughly shaking 6 or 7 c.c. of the oil in 100 c.c. of water, and after fifteen minutes filtering. Sections must be left in the staining fluid twenty-four to forty-eight hours, and are then decolorized in twenty to thirty per cent. nitric acid, or, better, in dilute hydrochloric acid and alcohol mixed as follows: 100 c.c. of alcohol, 20 c.c. water, and 1 c.c. concentrated hydrochloric acid.

Staining of tubercle bacilli.

Tissues are embedded and cut in the usual way. Celloidine and paraffine are used for embedding. A mixture of glycerine and gelatine, in such proportions as to be of a firm consistence at ordinary temperatures, is a convenient embedding medium for bacteriological purposes. A piece of tissue to be embedded in this way, after it is thoroughly hardened in alcohol, is placed on a bit of cork and the gelatine-glycerine is heated till it melts, and is then poured over it. As soon as the gelatine-glycerine becomes hard, which takes place in a few minutes, the cork, with the tissue thus attached, should remain about a day in alcohol, when the tissue will be ready for cutting. The sections must be cut as thin as possible, and can be stained as above described.

Embedding.

The so-called cover-glass preparation (Fig. 3396) is of especial value in the examination of bacteria. They are prepared by spreading a very small quantity of the material to be examined on a thin cover-glass. If the material is too dry it is well to have a very small drop of sterilized water or salt solution on the cover-glass. After the cover-glass is thoroughly air-dried, it is passed once or twice rapidly through the Bunsen flame and then colored in the same way that sections are. They need not be treated afterward with alcohol and oil, but can be mounted in balsam as soon as they are dry. Tubercle cover-glass preparations are stained in the way already described for the tissues. Tuberculous sputum and preparations from cultures may be rapidly stained by heating the coloring fluid till it gives off visible vapor. There are, besides these, many methods for staining tubercle bacilli, but I must refer the reader to some one of the special works on the staining methods for a description of them.[2]

Cover-glass preparations.

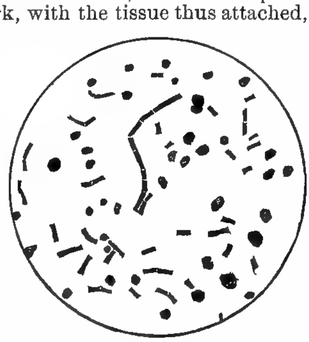

FIG. 3396.—Cover-glass Preparation from the Blood of a Mouse, showing Anthrax Bacilli. × 400.

Many bacteria are very beautifully stained in tissues and on the cover-glass by Gram's method, which consists in staining with the gentian violet solution, which has already been described, for tubercle bacilli, and decolorizing in dilute Lugol's solution and absolute alcohol. The dilute Lugol's solution consists of 2 grammes of iodide of potassium, 300 c.c. water, and 1 gramme of iodine.

Gram's method.

It is often desirable to examine micro-organisms while they are alive to determine whether they have independent motion, their method of forming spores, etc., and this is done in so-called drop-cultures. A very small drop of beef-broth, prepared as above, without the addition of gelatine or agar, is put on a very thin cover-glass and inoculated with a trace of a pure culture of the micro-organism to be examined. The slides used for this purpose have an excavation in the middle so constructed that a cover-glass will fit over it and close it. The cover-glass with the inoculated drop of sterilized beef-broth is put on one of these slides, so that the drop hangs down into the excavation. A small amount of vaseline is smeared around the edges of the excavation in the slide, so that when the cover-glass is put on it adheres all around and prevents the broth from evaporating. The cover-glass and slide are first sterilized by passing them several times through the flame. After the drop-culture is prepared it is put at a temperature of 35° to 37° C. (95° to 98.6° F.), and examined with the oil immersion-lens from time to time. It is always well to prepare a number of drop-cultures at a time, for it often happens that they become contaminated in their preparation. Such cultures may be afterward allowed to dry, and stained and mounted for preservation.

Drop-cultures.

INOCULATION OF ANIMALS, AND DESCRIPTION OF THE PATHOGENIC PROPERTIES OF ORGANISMS.—Guinea-pigs, rabbits, and mice afford the best material for testing the pathogenic properties of micro-organisms. They are more susceptible to infectious diseases, as a rule, than other animals, and are easier to handle. But dogs, cats, sheep, etc., are sometimes used. In some cases even human beings have been used.

The material for inoculation is either simply inserted under the skin, or suspended in sterilized water, three-fourths per cent. salt solution, bouillon, or other convenient liquid, and injected into a vein. The outer vein of the ear of a rabbit is generally selected for this purpose, and the injection is made with a previously sterilized Pravaz' or Koch's hypodermic syringe. In subcutaneous inoculations a pouch is made under the skin with a sterilized instrument and the material introduced, or a suspension is injected with a hypodermic syringe. The root of the tail is generally selected in inoculating mice, and the abdomen of other animals. These points are merely selected for convenience, the object being to introduce the organisms so that they may be taken up by the circulation.

If animals are so inoculated with a substance containing organisms of a disease to which they are susceptible, they sooner or later show all the symptoms peculiar to the disease. Cover-glass preparations from the blood, spleen, liver, etc., show the characteristic organisms in greater or less abundance, and the organisms can be cultivated in most cases. Pure cultures can generally be made, with proper precautions, directly from the blood, etc., but it is preferable to make plates or Esmarch tubes first.

If an organism is cultivated through a number of generations outside of the living body, and is always followed by typical symptoms when inoculated in minute quantities, the evidence of its pathogenic power is complete. If it is not cultivated through several generations before it

is inoculated, the objection can be raised that some poisonous substance from the original material may have been transferred; but, of course, this objection falls to the ground if the culture which has been used is the last of a long series of transplantations, for traces of the original material could not possibly be transferred so often. Such a culture represents simply the organisms which have descended from the original culture. In this case the proof is perfectly conclusive; but suppose the organism is only pathogenic for man? In this case a most important point in the proof fails, and before bacteriology was as firmly established as it now is, it seemed that it was a necessary point in the proof. But authorities are now agreed that, although the actual production of the disease in the lower animals may be wanting, still, in such cases, bacteria have been shown, beyond reasonable doubt, to be the cause of the disease. Before our methods of diagnosing bacteria were as perfect as they are now, we were unable to say positively that a certain bacterium was found in every case of a given disease; we could only say that morphologically similar bacteria were constantly present. At present, however, it is only necessary to find an organism constantly present, with characteristics sufficiently marked to recognize it in all cases. It must be absent in all other diseases and in healthy individuals. Among other examples, Bumm's failure to produce gonorrhœa in the lower animals with his cultures was no proof that the organism was not the cause of the disease in man, because the lower animals have an immunity from gonorrhœa. Bumm found his organism in all cases, and it was so well marked that it could be readily recognized. It was absent in all other cases, and the production of typical gonorrhœa in man (see below) was hardly necessary, though, of course, it strengthened the proof.

Under what circumstances is an organism said to be pathogenic?

Grounds for Accepting Specific Differences in Bacteria.—In the foregoing discussion I have assumed that there are distinct species, reserving this hotly contested point for special consideration. Hallier has been already quoted incidentally as having claimed that all infectious diseases are caused by an organism which he had discovered. His idea was that all organisms of disease are simply various forms which a certain fungus assumed under various circumstances. He thought that he had in his coccus found the cause of the infectious diseases, and that this coccus was derived from a mould fungus. It is easy to understand how Hallier was led into his error, for, as everyone acquainted with the subject knows, micrococci can be found in all sorts of diseases, and if the cocci are not cultivated with great precaution mould fungi invariably take possession of the culture. His theory was very plausible, and it fitted in exactly, even in the minutest details, with all the observed facts; but it disregarded all of Henle's postulates, and was consequently wanting in proof. Cocci were constantly found by Hallier; this would satisfy Henle's first demand if the cocci found at one time were of the same species as those found at another in the same disease; but supposing they were the same, they would have to be isolated, and with the methods known in Hallier's day this was impossible. Even starting from a pure culture, there was no guarantee that it remained pure; on the contrary, there was almost an absolute certainty that it would become contaminated, and that the contaminations would finally crowd out the original species, *i.e.*, that mould fungi would at length occupy the field, for these fungi are specially apt to contaminate our cultures. It is by no means so easy to reconcile many recent observations with the classification of organisms into distinct species. Pasteur has observed that certain micro-organisms lose their pathogenic properties under special conditions. Thus chicken cholera, rabies, etc., lose their virulence when inoculated into certain animals, and this loss of virulence is transmitted. Anthrax virus loses its power also under certain circumstances. Thus Pasteur was able to get cultures of anthrax and other organisms of various strengths, one strength capable of killing mice, but not fatal to larger animals, a still weaker sort incapable of killing even mice. But if the virus which is capable of killing mice, and is incapable of killing larger animals, be once passed through a mouse it resumes its virulence for larger animals. This is mentioned to show that organisms are subject to most important changes of properties, and under the head of morphology we have seen that they may suffer quite marked changes of form, so that every characteristic seems more or less variable, at least in a number of cases. In spite of all this, however, the weight of evidence is in favor of a classification into distinct species, for the changes just spoken of are brought about by definite, controllable causes, and had best be regarded as mere expressions, in each case, of wide but nevertheless limited power of variation. We may transplant various cultures with absolute certainty that we shall obtain similar cultures, generation after generation, if we use the proper precautions as to the avoidance of contamination. The transplanted cultures will have the same characteristics as the cultures from which they are transplanted. The modification of the physiological function already alluded to is more decided than that observed in the higher plants. The latter are subject to decided modifications of form and function under varying conditions of nutrition, etc., but such modifications are not subject to inheritance, except when they are purposely cultivated through many generations, or result from the law of natural selection; and even then there appears a tendency on the part of the plant or animal to return to the normal type. The micro-organisms, on the other hand, as we have seen, may be stamped in one culture representing many generations, it is true, with a modification from the normal which they retain tenaciously, and such modified cultures can be cultivated under circumstances which we would suppose to be favorable to a return to the normal type, and still remain modified, generation after generation. This is a peculiarity which shows that analogical reasoning from the higher plants is misleading, and that the utmost care should be used in the observation of each experiment. Especially in the study of bacteria is the greatest possible objectivity of prime importance; every preconceived idea is a hindrance, and only results which have been obtained repeatedly under every variation of circumstances can be of any value. For this reason all observations which have as yet been made in favor of pleomorphism of bacteria are not convincing. Until it is proven by actual observation of experiments, in which every source of error is excluded, that there is a metamorphosis of species, we are forced to accept specific differences. Direct argument for the existence of species may be deduced from what has gone before.

Some of the forms known to us at the present day have existed for a very long time, for some of them have been detected in fossils. The tartar from the teeth of Egyptian mummies has been found to contain forms identical with those found as constant inhabitants of the mouth at the present day (Zopf and Miller).

The Pathogenic Bacteria.—Although there are many saprophytic bacteria which are of great scientific interest, the limits of this article will not permit a description of individual species of saprophytes. It is, therefore, thought best to restrict the description of species to the pathogenic bacteria, in view of their immediate bearing upon medicine.

The Pathogenic Cocci.—*Cocci of Pus.*—All ordinary suppuration, as met with in every-day practice, is caused by micrococci. It is true that certain chemical agents cause it also, but such cases are rare, and when they occur micrococci are usually secondarily involved.

Staphylococcus pyogenes aureus (Ogston, Rosenbach, Krause, and Passet), *S. p. albus* (Rosenbach, Passet), and *S. p. citreus* (Passet), are the most common pus-producers. One or more of them are found in acute abscesses, in empyema, and in ordinary boils. They are often present in pyæmia, ulcerative endocarditis, and osteomyelitis. They therefore cause many diseases which differ clinically. S. p. aureus is perhaps the most common, and albus next.

These organisms are round, and about 0.87 μ in diameter. They usually form into clumps, but isolated cocci

and short chains are also met with. They are readily stained with the ordinary watery solutions of the aniline dyes.

They grow upon all the different media at low and high temperatures. Colonies in gelatine are visible in a few days in the form of little white dots sunken down into the substance of the gelatine, owing to a little zone of liquefaction around each colony. These little funnel-shaped depressions are very apparent when the plate is seen at a very acute angle. The liquefaction gradually spreads, and the colonies at the bottom of the liquefied zones become orange-colored if the organism is the aureus, lemon-yellow if it is citreus, and remain white if it is albus. They show a similar difference of color when cultivated upon the other media. Their growth coagulates milk in from one to eight days, with the production of lactic (and other ?) acids.

Under the lower powers of the microscope the colonies are light brown, with a dark centre. They are perfectly circular, and have a sharp, smooth edge. Subcutaneous inoculations of traces of the cultures have no effect upon mice, guinea-pigs, or rabbits. Inoculation upon the cornea of the last-named animal causes an inflammation and a grayish-white infiltration which passes away in a few days. Larger amounts rubbed up in bouillon, etc., and injected subcutaneously, cause local abscesses, which either remain local and heal, or lead to general infection and pyæmia. Injections into the peritoneum or into a vein generally prove fatal in from two to nine days. The most characteristic lesions are found in the kidneys, which are filled with yellowish-white foci varying from microscopic points to the size of a pea. The foci occasionally form wedge-shaped masses.

Staphylococcus pyogenes salivarius was obtained from saliva by Biondi, in Koch's laboratory. It differs from the albus and aureus in cultures by liquefying gelatine much more slowly and having a whitish color, which afterward turns gold-yellow. It often forms a skin over the surface of liquefied gelatine.[3]

Staphylococcus of the Clou de Biskra. The Clou de Biskra is an endemic disease of Aleppo, Bagdad, Biskra, and Tunis. It is characterized by nodules which appear upon the face and extremities, and which break after a year or more. The cocci have been found in the blood of individuals affected with the disease, and have been cultivated in calf-broth. They lose their pathogenic properties after they are cultivated for a time.

Streptococci of Suppuration.—There are also streptococci which produce suppuration. They all resemble each other under the microscope and in culture, and differ essentially only in virulence. They are round and somewhat larger than the staphylococci. Some of the individuals are larger than others, and some of these are probably arthrospores. Colonies on gelatine are sharply marked and raised slightly above the surrounding surface, without spreading over it. They always remain small, and do not cause liquefaction. Under the microscope they are circular, seldom oval, of a yellow color with a granulated surface. Older colonies are almost brown and the edges are irregular. On agar they are of a flat conical shape, sloping off all around in steps from the centre to the periphery. Stick-cultures in gelatine show a number of isolated points of growth upon a part or all of the line of puncture. Growth upon potatoes is not visible to the naked eye for a long time. They grow slowly upon all media, but more rapidly at 35° to 37° C. (95° to 98.6° F.). The varieties are:

Streptococcus pyogenes. This organism is found in a great many cases of suppuration, but does not seem to act as energetically as the staphylococci. It causes chiefly inflammations which follow the lymphatic vessels. It permeates the tissues, but seems to require some little time to cause the death of the latter. It has also been found in progressive gangrene and pyæmia. It is probably identical with Fehleisen's streptococcus of erysipelas. It hangs together in chains of four to ten or more individuals.

Subcutaneous inoculations of small quantities either have no effect upon mice, or produce local abscesses which occasionally lead to death. It produces a transient swelling and reddening of the ear in rabbits. But with this exception, subcutaneous inoculations, and even intravenous injections, are usually without effect unless the animals have been first poisoned, or there is a lesion of the aortic valve. In the latter case there follows an extensive endocarditis in from two to five days.

Streptococcus septo-pyæmicus is probably identical with S. pyogenes. It was obtained by Biondi from two cases of primary erysipelas of the larynx, and once in angina phlegmonosa (loc. cit.).

Coccus salivarius septicus was also found by Biondi in the saliva of a patient suffering from puerperal septicæmia. It was also fully described in the above article, together with the bacillus salivarius septicus, which is probably identical with the M. Pasteuri (see below).

Streptococcus pyogenes malignus (Flügge). This coccus was obtained, in the Göttingen Hygienic Laboratory, from a spleen in a case of leucæmia. As the name implies, it is very virulent. It kills mice and rabbits almost always when inoculated in small quantities under the skin. It produces a somewhat extensive local abscess at the point of inoculation, and diseased foci, filled with the streptococci, are found in the spleen and other organs, as well as in the blood. The animals often have one or more joints filled with the streptococci.

Streptococcus articulorum (Löffler) has been found in a large number of cases of diphtheria, but probably has no causal connection with that disease. It forms very long chains of one hundred or more links. The colonies differ somewhat from the above description in that they are grayish under the microscope and have a wavy margin. Intravenous injections produce marked suppurative changes in the joints as a primary effect, and the animals gradually die. The joint affections with the other streptococci are secondary. Rabbits inoculated under the skin of the ear are affected just as with S. pyogenes.

Streptococcus septicus (Nicolaier, Guarneri) does not form chains under all circumstances, and grows more slowly than the other streptococci. Traces of a culture suffice to kill mice and rabbits with absolute certainty in two or three days. The cocci are found in all the organs and tissues in great abundance.

Micrococcus pyogenes tenuis (Rosenbach) was found in a few cases of closed abscesses. It does not tend to form into masses or chains. It often shows an unstained central portion and deeply stained poles. It forms almost transparent masses upon agar, afterward becoming more opaque. Experiments upon animals have not yet been made.

Micrococcus gonorrhœæ, gonococcus (Neisser, Bumm). This organism causes gonorrhœal inflammation of the urethra, bladder, ureters, pelvis of the kidney, cervix uteri, and conjunctiva. It has also been found in gonorrhœal inflammation of the knee-joint. Its growth is restricted to these localities, as far as observation goes.

It is a diplococcus rarely undivided, and is sometimes seen in groups of four. The apposing surfaces are either straight or slightly concave, so that the intervening space between the two halves of the diplococcus is double convex. The space is usually unstained. The long diameter of the diplococcus is about 1.25 μ, the transverse diameter about 0.6 μ. Watery solutions of methylene blue stain the cocci readily. They do not stain by Gram's method. It only grows upon blood-serum, and poorly at best. It requires a temperature of 32° C. (89.6° F.), and the cultures often die without any apparent cause. Inoculations upon various animals have been followed by negative results, but inoculations upon man have been successful. Its pathogenic power is in inverse proportion to the age of the disease. Secretions from old chronic cases have often to be examined repeatedly before finding the organisms, but cover-glass preparations from fresh cases always show them. It is the only cause of gonorrhœa, and is, therefore, of great diagnostic value. Errors have been made in mistaking the following for it:

Micrococcus subflavus (Bumm) has been found in catarrhal affections of the bladder, in pemphigus neonatorum,

in a mammary abscess, and in colpitis. It resembles the gonococcus in cover-glass preparations, but is readily distinguishable by the fact that it grows readily upon gelatine and serum at ordinary temperatures, and liquefies them both. Colonies are at first white, but afterward run together and form a yellowish mass, which finally becomes of an ochre color. It is not pathogenic for animals, but produces abscesses in human beings.

Micrococcus found in erysipeloid inflammation (Rosenbach) of the hands and fingers of tanners, butchers, and others who handle animals. It grows upon gelatine and agar, making extremely small colonies.

Micrococcus tetragenus (Gaffky) is found in tuberculous and other sputum, and upon the walls of tuberculous cavities of the lungs. It is 1 μ or more in diameter, and there are generally four together, but in many of them the tetrads are not distinctly marked. Each tetrad is surrounded by a gelatinous envelope in preparations from sputum and lungs. Gelatine colonies are white, the superficial ones projecting above the surface. Under the microscope they are yellow, and either round or lemon-shaped, with a nodulated surface like a mulberry; the circumference is consequently regularly scalloped.

Micrococcus Pasteuri (Sternberg) is frequently found in the saliva of healthy persons. It was first observed by Sternberg, who found that it produced septicæmia in rabbits, and could be cultivated at higher temperatures; it very rapidly lost its virulence in cultures. A. Fraenkel regards this organism as the cause of croupous pneumonia.

Micrococci have, furthermore, been found in variola, vaccine-matter, scarlatina, diphtheria, cerebro-spinal meningitis, influenza, ozæna, hæmophilia neonatorum, acute yellow atrophy of the liver, yellow fever, trachoma, porrigo decalvans, and granuloma of the skin. But none of them have been, as yet, sufficiently studied to establish their relation to the processes in which they are found. The same, probably, holds true of the micrococci found in Rinderpest in Russia and pleuro-pneumonia of cattle.

The following micrococci have also been partially studied:

Streptococcus perniciosus psittacorum (Eberth, Wolff) was found in nodules of the lungs, spleen, blood, etc., of parrots which had died of a peculiar disease.

A streptococcus was found by Charrin in the blood and internal organs of rabbits which had died of anthrax. It was called the micro-organism of septicæmia consequent upon anthrax. It produced septicæmia when inoculated, and is, probably, identical with Koch's coccus of septicæmia (see below).

Streptococcus bombycis (Béchamp) produces coma in silkworms. A different disease is caused by *nosema bombycis* (Cornalia, Lebert, Nægeli, Pasteur).

Micrococcus of progressive necrosis of the tissues in mice, destroys all sorts of tissue, even tendons. Animals inoculated with it die in about three days. The blood and internal organs remain free. Koch obtained the organism by inoculations of foul substances upon the ear of mice, but only got it pure by using field mice.

Koch, furthermore, obtained micrococci in cases of progressive abscess caused by injecting putrid blood; also a micrococcus in pyæmia in rabbits, and another in septicæmia of rabbits.

Pathogenic Bacilli.—*Bacillus anthracis** attacks whole herds of cattle and sheep, sometimes producing local boils, but generally it kills by producing septicæmia. Most animals and human beings are usually killed when they become inoculated with the minutest trace of a material containing the bacillus anthracis. Algerian sheep, white rats, adult dogs, and frogs are almost insusceptible. Natural infection takes place by the introduction of the spores into the alimentary canal along with the food, and the disease consequently begins in the intestines. Cattle and sheep are especially sensitive to this mode of infection. The bacilli are formed in every organ and tissue of the body in the diseased animals (Figs. 3395 and 3396). Inoculations of very small quantities always kill mice in about twenty hours, and guinea-pigs and rabbits in twice that length of time.

The rods vary in length from 5 to 20 μ, and in breadth from 1 to 1.25 μ. They often hang together in long threads. The ends are slightly thickened and very sharply cut across, or even somewhat concave. They have no flagella and no independent motion. The forms of involution are often met with, especially in old cultures. Spores are formed in the long threads; they are oval, and each one is embedded in a round gelatinous capsule. The latter becomes oval, and is broken through when the spore germinates. They are very resistant, and are not killed by boiling in water one or two minutes. Direct sunlight kills them in a few hours (see p. 330). Anthrax spores are never found in the blood or other organs.

The bacillus anthracis grows very readily in alkaline urine, alkaline vegetable infusions, and the customary nutrient media at low and high temperatures, in the latter case usually forming spores in a few days. It thrives best in free oxygen.

Gelatine colonies under the microscope are greenish-black, and the surface is marked with parallel, zigzag, or shaggy lines; this is most noticeable around the edges. There are often long threads, twisted like a rope, running off from the colony. It gradually liquefies the gelatine, which becomes syrupy.

Bacillus œdematis maligni (Koch). Before the days of antiseptic surgery this organism often caused progressive gangrenous œdema and emphysema. It is usually present in decaying matter, in dust from dwellings, old rags, hay, etc., and in earth which has been fertilized with foul fæcal matter; in the latter it is often associated with the bacillus of tetanus. It probably plays an important part in putrefaction. It can be obtained by inoculating various animals subcutaneously with rich garden earth, and may then be inoculated from one animal to another. Such inoculations of garden earth sometimes produce tetanus. Malignant œdema is characterized by extensive infiltration around the point of inoculation of an abundant, clear, reddish fluid containing the bacilli in great abundance. There are also gas-bubbles here and there in the fluid. The internal organs are not much altered, but the serous surfaces contain numbers of bacilli. The bacilli are not present in the heart's blood before and immediately after death, but appear very soon post mortem. Mice are an exception to this rule, and as the bacilli are found in their blood, etc., in great abundance just after death, malignant œdema has often been mistaken for anthrax in these animals. Mice die in sixteen to twenty hours after inoculation.

The inoculation requires to be made with larger quantities than is the case with anthrax.

The bacilli of malignant œdema resemble anthrax bacilli. Individual bacilli measure from 3 to 3.5 μ by 1 to 1.1 μ, and have a tendency to form long chains of ten or more. These chains are generally bent and twisted. They often have a granular appearance in stained preparations, and the ends are more or less rounded. They form long threads in the blood, etc., in contrast with the anthrax bacilli. Independent motion is sometimes, but by no means constantly, observed. Spores are found in the isolated bacilli, but not in the long threads. It is an exquisite anaërobic organism. It liquefies gelatine, agar, and blood-serum, with the production of gas-bubbles; the gas has a faint, stale odor.

Bacillus of sympathetic anthrax, black-leg, Rauschbrand, etc. (Arloing, Cornevin, and Thomas), causes an endemic disease of cattle. Animals affected with the disease have hard, tense nodules under the skin and in the muscles, especially in the fleshy portions of the body, such as the rump, breast, etc. They may also have, secondarily, all the symptoms of an acute infectious disease, such as loss of appetite, disinclination to move about, etc.; or the constitutional symptoms may be primary and may be followed by the local. The nodules are at first very painful on pressure, but gradually they become insensitive. The

* Observed first by Rayer in 1850, and in 1855 by Pollender, independently of Rayer; Davaine, in 1863, claimed that the bacillus caused the disease, and this was established by Koch in 1876.

swollen parts present upon pressure an emphysematous crackling; hence the German name Rauschbrand. The nodules are rarely found in the deep muscles. The fever reaches about 43° C. (109.4° F.), but before death the temperature sinks to subnormal. Animals die in thirty-six to forty hours after the fever begins. The stage of incubation is from fourteen to twenty hours. Animals often recover when there are no local symptoms, and are then protected from subsequent infection; but they almost always die if the nodules make their appearance. The sound given out on pressure of the nodules is due to an accumulation of a gas in the cellular tissue; the gas is composed of 13.15 per cent. CO_2, 76.51 per cent. H, and 10.34 per cent. N. The internal organs are covered with a dirty-red fluid, as if red wine had been poured over them. Inoculations of the juice of an affected muscle, or with the gall, are successful with various animals if used in considerable quantities—two or three drops. Guinea-pigs are more susceptible and die from inoculations of much smaller quantities. The organism presents also very remarkable peculiarities. Calves up to five months old show no symptoms when inoculated with as much as six drops. They die from inoculations of larger quantities, and are not protected by inoculations of smaller amounts. Cattle reared in a black-leg district are rarely affected after they are two years old; they have all probably suffered from the disease in a mild form and are consequently protected. Imported cattle are susceptible at all ages over five months. Inoculations with blood of diseased animals are generally not successful till just before or after the death of the latter; the blood contains very few bacilli up to that time. Inoculations with portions of a fœtus, or with the amniotic fluid of a pregnant animal suffering from the disease, have been successful. Bacilli have been found once in the urine. Natural infection rarely takes place from the intestines. Very superficial inoculations, and inoculations far removed from the fleshy portions of the body, are usually followed by insignificant symptoms, but animals so inoculated are thereby rendered insusceptible to subsequent infection. If cattle are inoculated at the extreme end of the tail, they recover, as already said; but if they have a wound in any muscular part, the bacilli lodge there and finally cause death. It is also remarkable that even intravenous and intratracheal injections cause only slight local trouble, unless the tissues are much wounded in injecting, or unless there is a lesion at some other point. All of these methods have been successfully employed for preventive inoculations, but, as will be readily understood, they are attended with risk. The methods for preventive inoculation will be discussed in another place.

Frogs inoculated with sympathetic anthrax bacilli or spores, and kept in water at 22° C. (71.6° F.), suffer apparently no inconvenience; they crepitate in fifteen to twenty hours, just as warm-blooded animals do, and their tissues are equally virulent.

The bacilli are 3 to 5 μ long and 0.5 to 0.6 μ thick, usually with a knob on one end which makes the individual bacillus resemble the tongue of a bell. The spores form in the knob-like enlargement, one to each bacillus. The bacilli are endowed with independent motion. They grow in blood-serum, gelatine, agar, etc., but have probably never been obtained in pure cultures. If a portion of diseased muscle of an animal, which has died of Rauschbrand, be introduced deep down into a tube of blood-serum or gelatine, it liquefies the media and produces gas. This organism is anaërobic.

Bacillus typhi abdominalis, typhoid-fever bacillus (Eberth, Klebs, Koch), is readily obtained in pure cultures from diseased portions of the intestines, the mesenteric glands, and the spleen, often also from the liver and kidneys. They occur in separate clumps in these organs, and are not distributed throughout them. The constant presence of this organism in typhoid fever, and its absence in all other conditions, makes its etiological significance almost certain. Injected in large quantities into the veins of various animals, and under the skin of mice, it causes death with somewhat characteristic symptoms, such as swelling of the Peyer's patches. But the death of the animals is probably due to intoxication, and not to a multiplication of the bacilli.

The bacilli are about 2 or 3 μ long, and 0.6 to 1 μ in thickness. The ends are distinctly rounded. The bacilli in cultures resemble those found in the diseased tissues, etc., but the former tend to hang together in long threads. The aniline dyes stain the bacilli rather slowly, but very satisfactorily, if allowed to act long enough. They do not stain by Gram's method, *i.e.*, they are completely decolorized by Lugol's solution and alcohol. The bacilli often remain unstained at various points, and this gives them the appearance of being notched and of having holes in them.

They grow readily, at high and low temperatures, upon all the various media—potatoes, agar, gelatine, milk, etc. Colonies on gelatine plates appear as small white dots in thirty-six hours, at a temperature of 18° to 20° C. (64.4° to 68° F.). Under lower powers of the microscope they appear light lemon-yellow, are either circular or lemon-shaped, with a sharp contour and indistinctly granular surface. The colonies which lie upon the surface of the gelatine, or which have broken through in the process of growth, are spread out flat, they never project appreciably above the surface of the gelatine. Under the microscope they have an irregular contour, often fissured at various places, and their surface is marked with zigzag parallel lines. To the naked eye they have a very delicate bluish tint. Although the growth is vigorous in all cases, it does not produce such thick masses, either in colonies or in cultures, as do many other organisms.

It grows luxuriantly upon potatoes, but the growth is invisible to the naked eye; this characteristic is not absolutely constant. On touching the surface of a potato-culture with a platinum needle, it seems to be covered with a slightly elastic skin.

At a temperature of 35° C. (95° F.), the typhoid bacillus forms oval refractive bodies much resembling spores, but they do not seem to be very resistant to agents which do not usually affect spores.

Bacillus pneumoniæ, pneumococcus (Friedländer), is found in the alveolar exudate, and in the exudate from the pleura and pericardium in cases of croupous pneumonia. It has been seen in the rusty sputum, and once in the blood. Its value in diagnosis is limited by the fact that there are quite a number of bacilli which resemble it, that it is not constantly present, and that pneumonia is caused by other organisms.

Mice are killed by injections into the thoracic cavity, and by inhalations. Post-mortem pneumonia is sometimes found which is not generally of the typical lobar variety, and the organisms are readily obtained from the diseased lungs and the blood. Rabbits are unaffected. Of 11 guinea-pigs, 6 died after inoculation, and there died one dog out of 5 inoculated.

The bacilli are short and thick, some of them look like cocci. The ends are rounded. In preparations from animal tissues the bacilli are each surrounded with a gelatinous capsule, or it may be that a single capsule envelops two or more bacilli. The bacilli have no independent motion.

They grow very readily upon various media. Gelatine colonies twenty-four hours old are white, and afterward project like little knobs above the surface. Under the microscope they have a dark granulated centre, and a narrow olive-green peripheral zone. In stab-cultures a knob forms on the upper surface of the medium, and the line of inoculation tapers as a whitish line from this knob downward, so as to make the so-called nail-growth. In old cultures the gelatine and agar become dark reddish-brown around the line of inoculation. Gas-bubbles are formed in potato-cultures.

The following five organisms bear resemblance to the bacillus pneumoniæ:

Bacillus of rhinoscleroma causes a hardening and thickening, or it may be a diffuse cellular infiltration, of the mucous and submucous tissues of the nose resembling a lymphomatous growth. The disease may spread to neighboring parts. It is comparatively rare and has

been observed chiefly in Southern and Southeastern Europe and in Central America.

The bacilli are indistinguishable in cultures and under the microscope from the pneumonia bacilli, and inoculations upon animals are followed by the same results with both kinds of bacilli.

Bacillus crassus sputigenus (Kreibohm) is indistinguishable from bacillus pneumoniæ in cultures and under the microscope. It was obtained twice from sputum, and once from the coating of the tongue. Mice die of septicæmia when inoculated with traces of a culture. Rabbits react only when large amounts are injected into a vein, and the same is true for dogs.

Bacillus pseudo-pneumonicus (Passet) is even more inclined to occur in an isodiametric form than is the bacillus pneumoniæ, and Passet called it a micrococcus; but, according to Flügge, it is a bacillus. It was derived from the pus of two abscesses. It is in many respects similar to bacillus pneumoniæ, but in stab-cultures it only forms the head of the "nail," and does not grow along the line of inoculation. Colonies are, moreover, grayish-white.

Bacillus pneumonicus agilis (Schou) was obtained from pneumonia of rabbits in which the vagus nerve had been severed. The bacilli resemble bacillus pneumoniæ, but they liquefy gelatine and blood-serum, and cultures on potatoes are reddish-yellow and spread out. Injections into the trachea and inhalations produce severe pneumonia in rabbits.

Bacillus septicus sputigenus. See Micrococcus Pasteuri.

Bacillus tuberculosis (Koch) is the cause of tuberculosis, including lupus and scrofula. No animals seem to have an absolute immunity from the disease, although they present marked differences in susceptibility. The disease is never brought about in any other way than through infection with the tubercle bacilli or their spores. Infection takes place by inhalation, by swallowing the virus, and by inoculation. The bacilli are most certain to be found at the place where the disease is just beginning to attack a new place, *i.e.*, the early stages of the disease, or the parts just commencing to be affected. At first the separate bacilli are isolated, and are found in the cells close to the nuclei; where the process is older the bacilli occur in thick clumps. In old cheesy masses, unless exposed to the air, the bacilli are not so readily found. The bacilli are almost always found in the giant cells.

The tubercle bacillus can be cultivated upon blood-serum at 35° C. to 37° C., and is said to grow best when glycerine is added. It is best obtained for cultures by inoculating a guinea-pig in the belly with sputum from a phthisical patient. After the animal dies or is killed (in from four to six weeks), a tuberculous nodule is cut out with the greatest possible aseptic precaution and rubbed up in a sterilized glass dish, and introduced into tubes of blood-serum. There is no apparent growth for fourteen days or more, it then becomes especially apparent around any little bits of tissue that have been introduced, in the form of little grayish masses which afterward turn to dry crusts. The tube should be prevented from drying out by warming the mouth of the tube and wrapping the cotton plug with thin rubber sheeting, which adheres nicely. This or some other method to prevent evaporation must be resorted to.

The bacilli are 1.5 μ to 3.5 μ long and about 0.2 μ in thickness. They are generally curved or bent at an angle; they often have from two to six spores, which have a larger diameter than the thickness of the bacilli. The method for staining has already been given on p. 333.

Bacillus lepræ (Armauer Hansen, Neisser) is found exclusively and in great numbers in all organs and tissues affected with leprosy. The bacilli are congregated into characteristic clumps, and the clumps are probably cells filled with bacilli. Some of them are similar to the giant cells containing tubercle bacilli, and are called leprosy cells. These bacilli are also met with lying free in the lymph-spaces. Bordoni-Uffreduzzi[5] claims to have cultivated the bacilli in blood-serum to which glycerine had been added. He obtained his cultures from the marrow of a leprous bone. After cultivation on glycerine blood-serum, he contends that the bacilli will grow upon our ordinary media (except potatoes and bouillon) at 22° C. to 25° C. The bacilli direct from the tissues are more readily stained than tubercle bacilli, but from Bordoni-Uffreduzzi's cultures less readily. To distinguish them from tubercle bacilli in cover-glass preparations, Baumgarten leaves them six to seven minutes in an alcoholic solution of fuchsine; decolorizes fifteen seconds in acidulated alcohol, washes in water, and colors afterward with methylene blue. Leprosy bacilli are colored red in this way, but tubercle bacilli are not. Animal experiments have not been very successful. The bacilli resemble tubercle bacilli very closely, and they also have the appearance of containing spores, but Bordoni-Uffreduzzi contends that these are not spores, but that the bacilli form arthrospores.

Bacillus mallei, B. of glanders (Löffler, Schütz), is the cause of the disease from which it derives its name. It attacks human beings, horses, asses, young dogs, guinea-pigs, and field mice. House mice are not affected, rabbits sometimes, and in one case a sheep was successfully inoculated. After inoculation the wound ulcerates, and the neighboring lymphatic glands enlarge. If the amount inoculated is small, the animal may live several weeks, and one or more joints of the feet may ulcerate. There is also swelling of the testes or of the ovaries and vulva, and ulceration of the nasal cavities.

This organism grows readily upon various media, preferably at temperatures above 25° C., producing a reddish-brown, slimy coating upon potatoes. The bacilli are not unlike tubercle bacilli, but are more uniform in length and thicker. In stained preparations they often look like chains of cocci. They are not easily stained in sections.

Bacillus of Rothlauf, microbe du rouget du porc, etc. (Thuillier, Pasteur, Löffler). Hogs affected with Rothlauf become sick quite suddenly. The temperature rises to 43° C. (109.4°F.), and they have bloody mucous passages. Sooner or later the skin of the abdomen, neck, etc., becomes red, and finally reddish-brown. They die on about the fourth day with paralysis or cramps. Chiefly young hogs from three months to three years are subject to it. The disease is believed by some to start in the intestines from the hogs eating mice or other animals, and fæces containing the micro-organism. On post-mortem examination the mucous membrane of the small intestine is found to be red and swollen, the Peyer's patches and solitary follicles are prominent, and are here and there ulcerated, especially in the neighborhood of the ileo-cæcal valve. The liver and spleen are somewhat enlarged. The lymph-glands, especially of the mesentery, are enlarged and dark red with punctiform ecchymoses; these are also found upon the epicardium of the auricles. The lungs are also filled with blood. The muscles are soft, and of a dirty reddish color. The kidneys are the seat of a hæmorrhagic parenchymatous nephritis.

House mice and pigeons die of septicæmia in forty to sixty hours after inoculations of traces of diseased tissues or cultures. The bacilli are found in all the organs and tissues lying in and among the white blood-corpuscles; the latter are sometimes filled with the bacilli. Guinea-pigs, field-mice, and, to a certain extent, rabbits, are not susceptible, but the latter sometimes have a local inflammation at the point of inoculation, and are then thoroughly protected.

The bacilli are 0.2 μ thick and 0.6 to 1.8 μ long, and probably form spores. They are readily cultivated at various temperatures and upon different media. They stain readily in the ordinary way, and also by Gram's method.

The colonies in gelatine are characterized by a delicate bluish-gray cloud which surrounds the thicker central portion. This cloudy zone is seen under the microscope to consist of a very fine network of delicate threads. Colonies never lie on the surface of the gelatine, but are always found to be in the substance. In stab-cultures the cloud appears all around the line of inoculation;

the most vigorous growth is in the lower parts of the tube.

Bacillus murisepticus was obtained by Koch from mice which had died after inoculations of fluids just beginning to putrefy. It behaves in cultures and inoculations upon animals precisely like the Rothlauf bacillus. It is said to be shorter than the latter.

Bacillus diphtheriæ. Löffler, who discovered this organism, was at first cautious in assigning to it its full importance, because it could not be detected in some typical cases of diphtheria, and because it was always necessary to produce some lesion of the mucous membrane in inoculations upon animals. It is possible, however, that in those cases where it was not found it might have been present in the form of spores or retrograde forms; and as to the latter objection, it may be that in the human being also minute lesions are necessary. Löffler also found the bacilli once in a number of examinations of persons not affected with diphtheria. Still, it is very probable that this organism causes at least one group of diphtheritic diseases.

Rats and mice show no reaction after inoculation. Guinea-pigs and small birds die after subcutaneous inoculation with extensive œdema in the subcutaneous connective tissue around the wound. A very characteristic pseudo-membrane was formed in the trachea of rabbits, chickens, and pigeons, where cultures were applied to the wounded mucous membrane; beside the pseudo-membrane there were also bloody œdema and hæmorrhage in the tissues of the lymphatic glands, and effusion in the pleural cavity. Similar symptoms have been also noticed after inoculations upon the conjunctiva of rabbits, and the vulva of guinea-pigs. Young animals seem to be more readily affected than older ones.

The rods are of very different lengths, and about as thick as tubercle bacilli. They are often curved, with one or both ends enlarged; in the latter case they are dumb-bell shaped; they have no independent motion. In uncolored preparations the poles, and occasionally other parts of the bacilli, are refractive, and these portions are more intensely colored in stained preparations, so that many of the bacilli seem to be composed of a chain of irregularly shaped pieces. Forms of involution are often met with.

Young colonies under the surface are round or oval; under the microscope they are dark-brown, coarsely granular, and their contour is not sharply marked. Superficial colonies are grayish-yellow, with a rough granular surface, and a fine undulating margin. The bacillus grows slowly upon gelatine at 22° C. (71.6° F.). The best nutrient medium for it is a mixture of three parts calf's or sheep's blood-serum, with one part of neutralized veal bouillon containing one per cent. peptone, one per cent. grape-sugar, and 0.5 per cent. common salt.

Bacillus of Syphilis. Lustgarten discovered bacilli resembling tubercle bacilli in sections from syphilitic tissues, by using the following method of staining: Sections remain from twelve to twenty-four hours in the gentian violet stain for tubercle, and are then dipped several times alternately in a 7.5 per cent. watery solution of permanganate of potassium and in dilute sulphuric acid. A bacillus found in smegma preputialis and labialis may be stained in the same way, so that there is as yet no reliable method of applying bacteriology in the diagnosis of syphilis. It does not grow upon any of our media, and is not very abundant in the tissues. The bacilli resemble tubercle bacilli. They are usually embedded in peculiar cells which are large, and either oval or polygonal. It is often necessary to make a number of sections before finding them.

Bacillus choleræ gallinarum, microbe du choléra des poules, chicken cholera; B. cuniculicida, rabbit septicæmia. I describe rabbit septicæmia and chicken cholera together, because they are probably identical. Several authorities have observed the disease in epidemics and in isolated cases, where the animals had taken the disease through accident. Koch obtained the organism from dirty water, and from a piece of foul salt-meat. The smallest trace suffices to kill rabbits, house mice, chickens, pigeons, sparrows, and pheasants. Field mice and guinea-pigs are not susceptible. Animals that have died of it have the bacilli in all the tissues, etc., but not always in abundance. Animals have also been infected by feeding them with cultures.

The bacilli grow readily upon various media. Gelatine colonies, under the microscope, are finely granular, and have a light-yellow centre surrounded by a brown ring and a light peripheral zone.

The bacilli are short and stain at the poles, so that they resemble diplococci. They are about 1.4 μ long and 0.7 μ broad. They sometimes hang together and form short chains, and are often surrounded by a capsule. They stain readily in the aqueous solutions of various aniline dyes, but are not colored by Gram's method.

Bacillus septicus agrigenus was obtained from manured earth by Nicolaier, in Flügge's laboratory. It is like the foregoing, except that it kills field mice.

Bacillus diphtheriæ columbarum was obtained by Löffler from epidemics of diphtheria in pigeons. The disease attacks, preferably, young birds and fancy breeds. The bacilli resemble those of chicken cholera, but are a little longer. This organism grows upon various media. The surface of the potato where it is grown assumes a grayish color, but is otherwise unchanged. The most characteristic feature is that it produces a very peculiar marbled appearance in the liver of mice which have been inoculated with it. In the centre of the white spaces thus marked off in the liver are found intravascular masses of bacteria. The animals die in about five days after subcutaneous inoculations. According to Löffler, the diphtheria of chickens is not caused by the above bacillus, for they are not susceptible to inoculation. Guinea-pigs, rats, and dogs are also unsusceptible.

Bacillus diphtheriæ vitulorum was found by Löffler in diphtheria of calves. Cultures were not successful, but inoculations from animal to animal were. The bacilli are about 0.5 μ broad and about five or six times as long.

Bacillus alvei was discovered by Watson Cheyne and Chesire in the so-called "foul brood" of bees. It is readily cultivated upon various media. The bacilli vary from 2.54 μ to 5.08 μ in length, and are 0.85 μ thick. Some of them have a sluggish motion. They bulge out to a spindle shape and form spores in the enlarged part.

Bacilli are found in infusions of *jequirity* and in inflammations caused by it, but they are probably not the active principle of the drug.

Bacillus tetani was cultivated from garden earth by Nicolaier, in Flügge's laboratory. It is an exquisite anaërobic organism, and cultures inoculated into various animals produce tetanus; but pure cultures have probably never been obtained. The bacilli constantly present are narrow and bristle-like, with a knob at one end. They have no independent motion, are thicker, and about two or three times as long as tubercle bacilli, and are readily stained with fuchsine (Hochsinger).[6] But these bacilli are always accompanied by others, so that it is possible that the tetanus bacillus will grow only in combination with one or more kinds of bacteria; in other words, it may be an example of symbiosis (Flügge). Inoculations of garden earth are sometimes followed by tetanus and sometimes by malignant œdema (see above). Even white rats are subject to infection from inoculations of earth. Inoculations from the diseased tissues of patients dead of tetanus have also been successful. The bacilli are found in the tissue dividing the healthy from the diseased portions, and in the pus. They are rare or lacking in the blood, in the cerebro-spinal fluid, in the substance of the nerve-centres, in liquid squeezed from nerves, and in the internal organs; but subcutaneous inoculations with parts of the tissues surrounding the wounds, and with the purulent secretions rubbed up in water, have been found to produce tetanus (A. Bonome[7]). Inoculations with blood are occasionally successful (Flügge, Hochsinger).

Brieger[8] has isolated a specific ptomaïne (tetanine), along with other toxines, from impure cultures of tetanus bacilli.

Bacillus parvus ovatus, Bacillus of swine plague (Löffler, Schütz, Salmon), was found in a hog that had died

of a disease similar to rouget du porc. It was present in the œdematous skin, in the liver, etc. Mice, rabbits, and guinea-pigs all died after subcutaneous inoculations with bloody œdema of the subcutaneous connective tissue and red patches in the lungs, etc. A hog was successfully inoculated. Rats were not affected.

The bacilli are readily cultivated upon gelatine, etc. They are found in enormous quantities in the tissues, and are about half as large as rabbit septicæmia bacilli, but resemble the latter sometimes. They are ovoid in shape.

Löffler[9] found that the principal lesions were situated in the intestine and skin. Schütz[10] found in his cases that the respiratory organs were mainly affected, and succeeded in producing the disease by inhalations of cultures. Salmon[11] has described two diseases: One, in which the intestines are principally involved, he calls *hog cholera;* the other, in which the lungs are affected with multiple pneumonia, he calls *swine plague;* in the latter disease the intestines are sometimes unaffected.

Smith has found that cultures from the spleens of hogs which had died of swine plague in Nebraska, differed from those from other sources by forming a skin on the surface of liquid media, by forming a denser mass at the bottom of the test-tube, by not growing in neutral gelatine, and by not being pathogenic for guinea-pigs.

Bacillus necrophorus was obtained by Löffler from inoculations of bits of condylomata into the anterior chamber of rabbits' eyes. The animals died in about eight days with caseous necrosis around the wound, isolated pneumonic foci with hæmorrhage, or necrosis of large portions of the lungs, and foci in the heart. Rabbits inoculated on the ear are similarly affected. Mice are also susceptible to the disease when inoculated.

The bacilli refuse to grow upon ordinary gelatine, etc., and are best cultivated in neutralized rabbit bouillon, though they grow in chicken bouillon and upon blood-serum from the horse. They make a downy, fluffy mass around any bits of tissue which have been introduced into the liquid media above referred to. They are quite narrow and vary in length, but are usually long and wavy. In cultures they often have swollen and refractive spots when examined on a cover-glass unstained, but the latter are probably not spores.

Bacillus cavicida, Brieger's bacillus, was obtained from human fæces. It kills guinea-pigs, when inoculated in traces under the skin, inside of seventy-two hours without exception. Rabbits and mice are for the most part insusceptible. It produces violent inflammation of the small intestine. The individual bacilli are very small; they grow upon gelatine, etc. The surfaces of colonies on gelatine are divided up by fissures running irregularly in all directions, so that they resemble the back of a terrapin.

The four following bacilli, like some of the preceding, produce extensive disturbances of the alimentary tract when injected into the veins of animals. But those which have been already treated of are more or less active in minute quantities. The following group can hardly lay claim to pathogenic power in the sense of multiplying in the body, causing necrosis of tissue, stopping up the capillaries, etc.; they act by intoxication. They possibly multiply in the body if they are introduced in such large quantities that the organs can no longer resist, but the death of the animal is clearly due to poison, either introduced in inoculation or subsequently produced. Injections of smaller quantities produce the same symptoms in a modified form. Furthermore, the same effects are produced by injections of sterilized cultures, *i.e.*, where the bacteria have been killed but the products of growth are not destroyed. This production of intestinal disturbance, vomiting, dysentery, etc., also follows injections of large quantities of various organisms, even of some of those which have come to be regarded as distinctly pathogenic; but some of the pathogenic organisms show no such action, and even in large quantities produce no effect except the characteristic symptoms of the peculiar disease.

Bacillus oxytoxicus perniciosus was obtained from milk by Wyssokowitsch, in Flügge's laboratory. It is a short, thick bacillus, and produces the gastro-enteric disturbances above described. It grows upon various media.

Bacillus Neapolitanus was obtained by Emmerich from the fæces and organs of cholera patients. Emmerich claims that it is the cause of Asiatic cholera, but his proofs are not conclusive, and he has found but few followers. It very much resembles the typhoid-fever bacillus in cultures and under the microscope, except that on potatoes it has a brownish-yellow, oily, slimy growth. The symptoms following inoculations are as above. As Weisser has found "that in human fæces, normal as well as abnormal, in the air, in putrefied fluids, bacteria are present which are identical with the so-called Neapolitan cholera bacteria in their morphological character, biological function, and pathogenic action,"[12] there is every reason to believe that Emmerich was mistaken in claiming that his bacterium is the cause of Asiatic cholera.

Bacterium coli commune and *Bacterium lactis aërogenes*[13] were found constantly in the fæces of milk-fed infants, and these bacteria were found alone as long as the infants were healthy. They constitute, therefore, a most important diagnostic sign. In proportion to the extent and severity of gastro-enteric disturbance the two organisms become more and more displaced by other bacteria. It is advisable to isolate the two bacteria from the fæces of a healthy breast-fed infant a few hours after birth, and use the cultures for comparison in other cases. The fæces should be obtained by introducing a sterilized glass tube into the rectum, and inserting a second smaller tube or a platinum loop inside of the first. Bacterium lactis aërogenes is found in large numbers in the upper part of the intestines, but in the lower part it becomes rare or even absent, and its place is occupied by the colon bacterium. Plates from the fæces seem at first glance to contain colonies of the colon bacterium alone, but there are always some colonies of the other.

Bacterium lactis aërogenes is 0.5 to 1.0 μ in thickness and about twice that in length. Its growth on all the media resembles that of Friedländer's pneumococcus (B. Pneumoniæ), except that in stab-cultures the growth along the line of puncture is more vigorous in the deeper parts, and often consists of a line of large, isolated, round masses. It also forms gas-bubbles on potatoes.

The bacterium coli commune is about 0.4 to 0.6 μ thick, and varies in length up to 3 μ and more. It has independent motion and is not colored by Gram's method. The deeper colonies in gelatine are yellow and granulated, the superficial colonies are spread out and are regularly granulated or folded into radiating lines.

Both coagulate milk, but the B. lactis aërogenes seems to have more energetic power; it produces coagulation and the formation of lactic acid in about twenty-four to forty-eight hours, whereas the colon bacillus requires a longer time. They both cause a fermentation in solutions of grape-sugar; the bacterium lactis aërogenes also causes fermentation in milk-sugar. Experiments upon animals are essentially as above.

THE SPIRO-BACTERIA.—*Comma bacillus, spirillum choleræ asiaticæ,* was discovered by Koch, in 1883. It is always found in Asiatic cholera and never in any other disease, nor in healthy persons. The bacilli are sometimes met with almost unmixed with other bacteria in the intestines, especially in the lower part of the small intestine, where the cholera lesions are greatest. They are found, furthermore, occasionally in the gall-bladder and vomit. They are not present in the tissues, except in the intestinal wall.

A process similar to cholera asiatica has been produced by injecting a few drops of a bouillon culture of the comma bacilli into the duodenum of guinea-pigs. Under ordinary conditions the organisms cannot pass through the stomach, because they are destroyed by the gastric juice; but if the stomach of a guinea-pig is made alkaline with about 5 c.c. of a five per cent. solution of soda, it remains so for several hours, and the organisms are not destroyed. It therefore becomes necessary, in order to infect guinea-pigs per os, to make the stomach alkaline, but it is also requisite to administer opium in some form so as to check intestinal peristalsis. Guinea-

pigs treated either by injections into the duodenum, or by the introduction of cultures into the stomach, prepared as above, generally die with symptoms very much resembling cholera in man. But simple injections into the duodenum are not sufficient, for unless the intestine is somewhat roughly handled it does not react ; it seems necessary that there should be more or less bruising of the tissues.

The bacilli are generally curved in the direction of the long axis, sometimes hanging together, forming a long or short spiral thread. The separate "commas" vary in length from 0.8 μ to 2 μ, and are about one-sixth to one-third as thick. Many of them are straight, especially in stained preparations. They possess independent motion. They may be colored with various dyes, but are not colored by Gram's method.

Colonies on gelatine at 22° C. (71.6° F.) in twenty-four hours are little white points ; at this stage they appear under the microscope round, light-yellow, with an uneven, wavy outline and surface. They soon assume a glistening appearance, so that plate-cultures appear as if sprinkled with pulverized glass. The gelatine around each colony is liquefied to a slight extent. The liquefaction is not very rapid. In stab-cultures it liquefies all along the line of inoculation in two days, forming a funnel-like depression in the upper part of the gelatine. In this funnel-like depression there is generally the appearance as if an air-bubble were shut off in its upper part. The liquefaction finally extends till all the gelatine is liquefied. It only grows at 30° to 35° C. (86° to 95° F.) on potatoes, forming a light-brown, slimy coating, which afterward changes to a grayish-brown.

Spirillum of Finkler and Prior, and spirillum tyrogenum (Deneke). These two organisms are of interest merely because of their resemblance to the cholera organism. Finkler and Prior's organism was first found in the dejecta which had been kept for some time from cases of cholera morbus. Deneke's organism was found in old cheese. The bacilli of the former are longer and thicker than the cholera bacilli, and are somewhat pointed at the ends. Deneke's organism is a trifle smaller than the cholera organism, and the curve is sharper. The spiral threads of cholera are shorter than those of Deneke's organism, and longer than those found in Finkler-Prior's organism. The colonies in gelatine of Finkler and Prior's spirillum, and of Deneke's also, have a sharp, smooth edge, and are dark colored. Finkler and Prior's organism liquefies very rapidly, and Deneke's occupies the middle place in this respect ; it liquefies much more rapidly than cholera, but less so than Finkler and Prior's. Finkler and Prior's organism grows readily at low and high temperatures on potatoes, and Deneke's refuses to grow upon potatoes at any temperature. Neither of them seems to have as marked pathogenic properties as the cholera organism. Cholera bacilli are killed by drying, they require some moisture ; whereas Finkler and Prior's bacilli may be thoroughly dried and retain their vitality for months. The addition of hydrochloric or sulphuric acid to a pure culture of the cholera spirillum produces a bright-red color (Bujwid).

Spirillum Obermeieri. Long spiral threads, 16 to 40 μ in length. They are readily stained. Only found in the blood during the fever in cases of relapsing fever. They have never been cultivated. Apes and human beings have been successfully inoculated subcutaneously with a small quantity of fresh blood from a patient suffering from an attack of the fever. It is only during the fever, when the spirilli are present, that the inoculations are successful.

UNCLASSIFIED MICRO-PARASITES.—*Actinomyces*, or ray parasite, causes the disease from which it derives its name. It is found in diseased foci in the tongue, jaw, lungs, etc., of cattle, producing in these animals the disease known as "swelled head." The parasite is also capable of infecting human beings. Under the microscope the parasite is seen to consist of a mass of club-shaped branches, more or less radiating from a central point. Boström claims to have succeeded in making cultivations by taking a portion of tissue containing the organism, and allowing it to remain a few days in nutrient gelatine. He then took it out, and pressed it between two glass plates, so as to break it up, and inoculated it upon agar and blood-serum. He found that the club-shaped extremities of the branches were not capable of growth, and regards them as forms of involution. The central mass, composed of branching threads, grew well upon gelatine, etc., in the form of reddish-yellow knobs, with finely feathered margins and feathery projections. Old colonies are feathery all over. Cultures were said to be successfully inoculated upon animals.

It is not decided whether this organism belongs to any of the classes described, but it is considered by Boström to belong to the higher form of bacteria.

The *protozoa* are attracting ever-increasing interest from the fact of their occurrence in certain diseases. Since the investigations of Laveran, who first observed *the malarial parasite*, Marchiafava and Celli, Councilman and Osler, have all been able to find protozoic organisms constantly present in the blood from malarial patients.

Protozoa in malaria.

Dr. Councilman's investigations are still in progress, but he has already established the following important facts : He divides the forms in which the organism occurs into two classes, the intracorpuscular forms and the free forms. The former are always found where the symptoms are of an intermittent type. They vary in size and appearance. The smallest of them are simply small hyaline protoplasmic masses in active amœboid motion, contained in the red blood-corpuscles. They are not easy to see, because they differ so slightly from the surrounding protoplasm. They increase in size till they finally fill the blood-corpuscles in which they lie. They also become pigmented at the expense of the hæmoglobin of the latter ; the red corpuscles becoming paler as the pigmentation of the organisms increases. Just before, or during, a chill the latter lose their hyaline appearance, and become coarsely granular ; and the pigment, which up to this time is arranged in fine rod-like masses, becomes collected in the interior of the body. The protoplasm finally breaks up into the small round bodies mentioned at first. These are liberated along with the pigment. The latter is soon taken up by the white blood-corpuscles. This segmentation is so characteristic that a chill may be diagnosed with certainty two or three hours in advance.

The free forms, on the other hand, are met with in malarial cachexia. They vary in shape. Most of them are crescentic, but round and oval forms are also met with. These have highly refractive edges and a mass of pigment in the middle. The crescents are about once and a half as long, and one-third as broad, as the diameter of a blood-corpuscle.

But besides these forms is another, to which Councilman attaches most importance. This is a body about the size of a blood-corpuscle, and containing pigment granules in active motion. Attached to the body are one or more narrow filaments three to six times as long as the diameter of a blood-corpuscle. These filaments are in active motion, and have little nodular swellings at various points ; they also occur detached from the bodies above described. These filamented bodies are not often seen, but may be found in any of the forms of malarial infection.

The blood drawn from the spleen always contains a greater number of organisms, especially the flagellated forms, than the blood drawn from the finger. And it is a very interesting fact that the intracorpuscular forms disappeared from the blood when forty-five grains of quinine were given for two successive days ; whereas the other forms were only slightly, or not at all, affected by the same amount of quinine.

But the protozoa very probably cause *epidemic dysentery* also. After they were observed by Koch in ex-

Protozoa in dysentery.

cretions from the intestines of persons who had died of dysentery in the tropics, Kartulis found that amœbæ were constantly present in this disease in Egypt, and emphasized their pathogenic power. Finally, Uplavici, after holding the opinion for a long time that dysentery is a mycotic disease, convinced himself that it is caused by amœbæ in Europe also.[14]

Modes of Accidental Infection.—The study of micro-organisms has thrown much light upon the way in which infection takes place in nature. Some organisms are capable of causing only diseases of the intestines; another finds conditions favorable to its growth in the animal body only upon the mucous membrane of the urinary organs, etc., of human beings; others produce disease when introduced merely under the skin; and still others require to be deeply inserted, etc.

But in many cases the mere presence of the organism is not sufficient to produce disease, there must be, besides, a predisposition on the part of the animal. It has been already stated that the spores of the anthrax bacilli, when taken in with the food and drink, cause the disease to start from the intestines, whereas the anthrax bacilli, when free from spores, are destroyed by the action of the digestive juices. From these facts it is apparent that, on the one hand, the power of resistance offered by an organism to the action of the gastric juice, and, on the other hand, the condition of this juice—as, for example, the degree of acidity of the gastric juice—are important factors to be considered when infection occurs through the alimentary tract. Vegetative bacterial cells are probably in most instances killed by the action of the normal stomach, so that, before there can be infection beginning in the intestines with non-spore-bearing bacilli, or with cocci, the function of the stomach must become impaired. It follows that all circumstances which impair the digestion are predisposing causes of infection. Experience has shown that what is popularly and vaguely described as a lowering of the tone or vitality of the body, whether by unhygienic modes of life or by disease, is, in the case of many infectious diseases, an undoubted predisposing factor. Furthermore, there are often local predisposing causes of infection, such as abrasions, existing foci of disease, the presence of stagnating blood or other fluids, the existence of so-called dead spaces in wounds, etc. These local predisposing influences are of special importance in favoring infection with organisms which cause suppuration.

Heredity acts in most cases merely as a predisposing cause of disease. In some cases there is a direct transmission of the organisms from the mother to the offspring (see Bacillus of Sympathetic Anthrax), but this is exceptional, and generally, when the influence of heredity is apparent, the offspring inherit a want of resisting power which need not be manifested by any anatomical peculiarities, and they are liable to become infected at an early period of their existence. If such offspring are placed under conditions favorable to their vigorous development, the inherited predisposition may undoubtedly in many cases be overcome.

Although we are able in some instances to point out the nature of the predisposing factors, such as those already mentioned, it must be admitted that our knowledge on this point is very imperfect, and that while we are compelled to recognize the importance of predisposition as an etiological factor, we cannot define the nature of this element. It is a curious fact that many races of animals have immunity from certain infectious diseases as a specific characteristic; thus Algerian sheep, rats, and dogs are scarcely susceptible to anthrax (see also Mouse Septicæmia, Glanders, etc.). Animals may acquire immunity from a disease by having suffered once from an attack of the same. Upon this rests the theory of preventive inoculation. It has already been mentioned that Pasteur was able to modify the virulence of certain organisms to such an extent that their inoculation produced no apparent effect, and by carefully regulating this process of attenuation he—and others after him—have been able to produce such a modification of the virus that it is capable of producing only a mild disease, which is followed by protection of the animal from infection by the virulent organism. It has also been claimed that inoculation with the poisonous products, or ptomaïnes, produced by a virulent micro-organism, may be followed by protection from infection by the organism; although this view has been advocated by Pasteur, as regards the protective inoculations against hydrophobia, it cannot be considered as proven.

Pasteur's anthrax vaccine is obtained by subjecting cultures to temperatures varying from 42° C. to 55° C. for a length of time, varying in inverse proportion to the temperature. According to Toussaint, an exposure to 55° C. for ten minutes; according to Pasteur and Koch, one to 42° C. for twenty-eight to thirty days, suffices to deprive the living bacilli of all pathogenic power. Chicken cholera, sympathetic anthrax, and Rothlauf cultures have all been modified in different ways, so that they could be used for protective inoculations.

The organism of rabies has not been isolated, but Pasteur makes inoculations with parts of the spinal cord of rabbits which have been previously inoculated from the spinal cord of a rabid dog. If pieces of the spinal cord of an animal dead from rabies are kept in dry air, they gradually lose their virulence, till after seven days they can no longer produce the disease in rabbits.

There is no doubt that preventive inoculations are possible, but the methods have not yet been so perfected as to be of much practical use, or to find universal adoption.

In summing up the factors which produce infection, it is seen that natural, or acquired, predisposition is an essential condition. The organisms may gain access to the body in various ways. They may be introduced with the food and water into the alimentary tract, or they may be inhaled, or they may find their way through lesions in the skin, or they may enter the genito-urinary tract.

As milk is not generally boiled, *i.e.*, sterilized, it affords a most dangerous vehicle of infection, along with all those articles of food which we are accustomed to use in an uncooked state, and those, too, which are left standing to be eaten cold. Such articles may easily become contaminated, and serve as an excellent nutrient material for micro-organisms. Water plays an important part, but since the pathogenic micro-organisms which have been tested do not multiply, or do so only to a limited extent, and for a limited time, in this medium, the danger of infection from drinking-water has often been exaggerated. This is less true, however, for sewage-water.

Infection from unintentional contact with pathogenic micro-organisms, and from want of cleanliness, probably occurs much oftener than has been generally supposed. Infection from the air, on the other hand, is probably less frequent than is usually stated, for micro-organisms are specifically heavier than air, and many of them are destroyed by drying. Unless they are dry, it has been shown that they cannot be taken up into the air. Insects may doubtless be carriers of contagion. The wound made by a mosquito, which has a short time before fed upon a diseased animal, would appear to be a most perfect inoculation.

Mode of elimination from the body.

The mode by which pathogenic micro-organisms are eliminated from the body is doubtless of great importance in determining the degree of contagion of infectious diseases. It has been shown by the experiments of Wyssokowitsch that many micro-organisms are destroyed within the body, and that in general they are eliminated only from excretory organs which suffer characteristic lesions from the presence of the organisms. It is apparent that when the specific micro-organisms are eliminated from the body only by the intestinal excreta (cholera, typhoid fever), direct contagion is much less likely to occur than when the organisms are thrown off from the skin (variola, scarlatina, etc.). If the organism is not discharged at all from the body, as seems to be the case with malaria, direct contagion cannot well occur.

Mode of action of pathogenic bacteria.

We possess little positive knowledge as to the mode of action of pathogenic bacteria. Doubtless this action varies with different species of bacteria. In this connection the investigations, particularly those of Brieger, are of interest which have demonstrated the production by bacteria of poisonous substances, obtained as crystallizable alkaloids, and known as ptomaïnes. Thus Brieger has obtained from impure cultures of the tetanus bacillus various alkaloidal sub-

stances which, injected into animals, produce symptoms resembling tetanus (see p. 339). It is believed that the cholera bacteria also act through the agency of ptomaïnes. Other injurious effects attributable to the action of bacteria are various local lesions, such as inflammation, necrosis, hæmorrhages, occlusion of blood-vessels and lymphatics, etc. In certain diseases the bacteria are present in the blood and other tissues in such enormous numbers that there is reason to believe that they may destroy life by the appropriation, at the expense of the body, of nutriment, particularly of oxygen.

On the other hand, much interesting work has been done to determine in what way the animal body reacts against the attack of micro-organisms. Metschnikoff[15] holds that the white blood-corpuscles eat up the bacteria. This view is based upon experiments in which he inoculated frogs and other animals with anthrax bacilli. He found in the warm-blooded animals which were susceptible, that when virulent material was used only a few leucocytes took up the bacilli. But, on the contrary, when attenuated virus was used, or when the animals were insusceptible (white rats, frogs, and a rabbit, which was found to be immune), the leucocytes take up nearly all the bacilli. This may occur at the seat of inoculation, in the blood and in various organs, particularly the spleen and the liver. The time required for the leucocytes to take up the bacilli was found to vary in different cases. Moreover, after the bacilli were taken up by the leucocytes, it was observed that the former degenerated and died. These experiments were repeated and supplemented by Hess,[16] who was able to substantiate Metschnikoff's observations. Besides inoculations in the usual way, Hess made use of a Ziegler cell. This cell consists of a cover-glass cemented to a slide of equal size, so that there remains a capillary space between, open upon one side. Hess inoculated cells of this sort with anthrax bacilli, and inserted them under the skin of various animals. He noticed, in the case of immune animals, that the redness and œdema at the point of insertion were much more marked than in the case of susceptible animals. After allowing the cells to remain various lengths of time, Hess removed them, and examined them immediately with the microscope. He then allowed them to dry, and stained them without first passing them through the flame. He found that in immune animals most of the bacilli had been taken up by the white blood-corpuscles, and were more or less broken up; the relatively few bacilli which had not been taken up by the leucocytes were unchanged. The bacilli contained in leucocytes were never found in chains, they were always separate bacilli. This, in brief, is the *phagocytosis* hypothesis, and it seems very plausible; for it is well known that the leucocytes take up pigment granules, etc. But some observers (Wyssokowitsch, Flügge, Hanau, Klebs) have come to quite different conclusions. They have not been able to find the leucocytes loaded with bacteria in such relatively large numbers as have Metschnikoff and Hess, and where they have found them they contend that the bacteria have attacked the leucocytes, and not the reverse.

LITERATURE.

The following works may be cited as serviceable for those who wish to acquaint themselves with the results and methods of modern bacteriological work:

Koch: Zur Untersuchung von Pathogenen Organismen. Mittheilungen aus dem kaiserlichen Gesundheitsamte, Bd. I. Berlin, 1881.
Flügge: Die Mikro-organismen, 2te Auflage. Leipzig, 1886. (The most complete work on the subject.)
Fränkel: Grundriss der Bacterienkunde. Berlin, 1887.
Hueppe: Die Methoden der Bacterienforschung. Wiesbaden, 1886. (This work has been translated into English by Dr. Herman Biggs.)
Löffler: Vorlesungen über die geschichtliche Entwickelung der Lehre von den Bacterien, Erster Theil. Leipzig, 1887.
Cornil et Babes: Les Bactéries, 2me édition. Paris, 1886.
Duclaux: Chimie Biologique. Paris, 1883. (Contains the methods and results of Pasteur's work.)
Crookshank: Manual of Bacteriology, 2d edition. New York, 1887.
Baumgarten: Jahresbericht über die Forschritte in der Lehre von den Pathogenen Micro-organismen. Braunschweig. (This report is published annually, beginning with the year 1885.)
Koch-Flügge: Zeitschrift für Hygiene. Leipzig. (This journal was founded in 1886, and is devoted mainly to bacteriology. It is published at irregular intervals, about three or four numbers a year.)
The Centralblatt für Bacteriologie und Parasitenkunde, published in Jena, and the Annales de l'Institut Pasteur, published in Paris, are journals devoted to the consideration of bacteriology and of parasitic diseases.

SCHLANGENBAD is a thermal spa in Hesse-Nassau, Prussia. It lies in a picturesque valley at an elevation of about 1,000 feet above the sea. The water contains a very small proportion of mineral constituents, chiefly sodium chloride and sodium carbonate. The temperature of the different springs varies between 83.5° and 92° F. The water is used chiefly for baths, though it is also employed occasionally for drinking. Employment is also made of goats' milk, whey, and herb juices. Schlangenbad is visited chiefly by women suffering from uterine troubles, and from excessive nervous irritability. The season extends from the middle of May to the first of October. *T. L. S.*

SCHOOLEY'S MOUNTAIN SPRINGS. *Location and Post-office*, Schooley's Mountain, Morris County, N. J.

ACCESS.—By the Delaware, Lackawanna & Western Railroad to Hackettstown, thence by stage two and one-half miles to the springs.

ANALYSIS (C. McIntire, Jr.).—One pint contains:

	Grains.
Carbonate of soda	0.072
Carbonate of magnesia	0.200
Carbonate of iron	0.072
Carbonate of manganese	trace
Carbonate of lime	0.178
Chloride of sodium	0.054
Sulphate of lime	0.210
Alumina	0.018
Ammonia	trace
Silicic acid	0.092
Total	0.896
Carbonic acid gas	not determined.

THERAPEUTIC PROPERTIES.—This is a very mild alkaline-chalybeate-carbonated water. The small proportion of salts which it contains, together with the carbonic acid gas, renders it a very pleasant and efficient tonic. The discharge is small, about thirty gallons per hour. The temperature is 50° F.

These springs are situated among the mountains of Northern New Jersey. They have long been a popular summer resort, on account of the beauty and healthfulness of their surroundings and their accessibility. There are several well-appointed hotels.

George B. Fowler.

SCHWALBACH is a spa situated in the province of Hesse-Nassau, Prussia. It lies in the valley of the Münzenbach, about twelve miles from Wiesbaden, and five miles from the health-resort Schlangenbad. Its elevation is 972 feet above sea-level, and as it is well protected against all but the southerly winds, its climate is mild and well suited for invalids. There are eight mineral springs at Schwalbach, known as the Wein-, Stahl-, Rosen-, Paulinen-, Ehe-, Neu-, Linden-, and Adelhaid-Brunnen. There is but little difference in the composition of the waters of these springs. The following is the

analysis of two of the springs, as made by Fresenius. In 1,000 parts there are, of

	Wein-Brunnen.	Linden-Brunnen.
Ferrous bicarbonate	0.057801	0.009902
Manganous bicarbonate	0.009085	0.004680
Sodium bicarbonate	0.245345	0.042317
Calcium bicarbonate	0.572129	0.429277
Magnesium bicarbonate	0.605120	0.395267
Ammonium bicarbonate	......	0.002205
Lithium bicarbonate	......	0.002033
Strontium bicarbonate	......	0.001048
Sodium chloride	0.008630	0.017622
Sodium sulphate	0.006193	0.016156
Potassium sulphate	0.007469	0.006414
Sodium nitrate	......	0.005541
Sodium phosphate	trace	0.000438
Aluminium phosphate	......	0.000197
Silicic acid	0.046500	0.032821
Organic matter, etc	0.000046	0.000003
Total solids	1.558318	0.965921

The gases are carbonic acid and a very small proportion of sulphuretted hydrogen.

Schwalbach is a favorite health-resort, and is visited by several thousand guests every year. The diseases for the relief of which a course of treatment at this spa is recommended are anæmia and chlorosis, epilepsy, chorea, progressive muscular atrophy, neuralgia, neurasthenia, hysteria, and other functional and organic nervous disorders, Bright's disease, diabetes mellitus, chronic vesical catarrh, and various affections of the female sexual organs.

The waters are employed externally and internally, according to the individual indications, and facilities are afforded for pine-needle, mud, vapor, and other baths. The season lasts from May to October. There are excellent accommodations for visitors. *T. L. S.*

SCIATICA. Etiology.—Sciatica differs from the large majority of neuralgias in the fact that it comparatively seldom results from constitutional conditions.

According to most writers, it is much more frequent in men than in women. Among 53 of my own cases, 39 occurred in males, 14 in females. Erb reports 40 males, 10 females; Eulenburg, 54 males, 17 females. Arnoldi is the only one of large experience who arrives at other results. Among 338 cases he found 172 males and 166 females. This experience is entirely exceptional, and undoubtedly does not hold good for the general run of cases.

Sciatica is a disease of middle and advanced life. Among my 53 dispensary cases 1 was twelve years of age; 7 were between twenty and thirty years of age; 10 between thirty and forty years; 18 between forty and fifty years; 7 between fifty and sixty years; 7 between sixty and seventy years; and 3 between seventy and seventy-five years of age. If we take into consideration the rapidly diminishing number of people after the age of fifty years, it is evident that the disease grows relatively more frequent beyond this period of life. Prior to the age of early manhood, sciatica is one of the most infrequent of all forms of neuralgia, and it began at this time in only one of my cases. Caussays reports two cases at the ages of seven and eight years, respectively.

The ordinary predisposing causes of neuralgia have comparatively little influence on the development of sciatica. This is particularly true of heredity, usually so potent in the etiology of neuroses. Very many writers ascribe no influence whatever to this cause, and Anstie appears to be almost the only writer who attaches any importance to it. In my own experience, a few cases have occurred in which the disease appeared to alternate with other forms of neuralgia, or in which the patients had suffered, at some previous time, from other neuroses; but, on the whole, the neuropathic influence appears to have had very little to do with the etiology of the affection.

Anæmia and other conditions of exhaustion likewise have less effect in the production of sciatica than in that of other neuralgias. The patients are often in perfect health at the onset of the attack, but the latter often has a depressing effect on the general condition if the pain continues severe for a long time. In a considerable number of cases, however, the sciatica begins at an advanced age, when the tissues of the body have begun to undergo senile involution. Anstie lays stress upon the fact that the disease is frequent in those who break down at an early period in life, although they may present the outward appearances of excellent health.

The disease has long been supposed to be intimately related to rheumatism—in the narrow as well as in the more vague and wider sense—but the fact of such connection is by no means well established. It is true that many of the patients suffer at times from muscular rheumatism, that sciatica begins not infrequently with an attack of lumbago, and that the supposed causes of "rheumatism" act unfavorably in sciatica; but further than this nothing can be said of the connection between the two diseases.

The term "gouty sciatica" is sometimes applied to the disease when it occurs in gouty subjects, and it is said, at times, to take the place of the ordinary gouty paroxysm. It is doubtful, however, whether sciatica, when it occurs under such circumstances, should not be attributed to the portal congestion, constipation, and hæmorrhoids which are so common in gout.

Infectious diseases are an infrequent cause of sciatica. Syphilis is probably the most important factor in this category, but it is likewise a rare cause. Sciatica may develop during the early or later stages of constitutional syphilis, and may or may not be associated with the formation of gummata along the course of the nerve, or in the surrounding tissues. This form is characterized by the tendency to nocturnal exacerbations, and by its ready amenability to antisyphilitic treatment. We must exercise caution here, however, inasmuch as non-specific sciatica occasionally acts in the same way, and the suspicion of the specific origin of the disease cannot be made a certainty unless other evidences of syphilis are present. R. W. Taylor, who has gone exhaustively into the literature of syphilitic sciatica, has been able to find very few authentic cases. He reports four personal cases, in one of which sciatica developed during the first year after inoculation; in the second it was associated with gonorrhœal rheumatism and epididymitis, and was only complicated with syphilis at a subsequent period; in the third it followed extensive gummata and hemiplegia; in the fourth there was gummous infiltration in the gluteal region, probably producing compression of the nerve. It is not certain, from the history of the latter case, that the pain was really neuralgic.

Malaria is also an infrequent cause of sciatica. Cases have been published in which the neuralgic attack replaced the malarial paroxysm. In these cases the pain is sometimes confined to a small branch of the nerve.

A number of cases have been reported after typhoid fever, especially during the period of convalescence. In one of my patients the neuralgia began during convalescence from diphtheria, and proved unusually intractable to treatment.

In rare cases sciatica is one of the symptoms of lead or mercurial poisoning. Although I have seen pains in the lower limbs develop under such circumstances, no case of genuine sciatica due to this cause has come under my observation. I have seen violent sciatica so often in cases of acute alcoholism that the question has arisen whether there is not some causal relation between the two conditions. But alcoholism may be attended with so many unknown factors which might give rise to sciatica (exposure, compression of the nerve, injury, etc.) that I have not been able to arrive at a positive conclusion.

External agencies, such as muscular effort, traumatism, and exposure, possess an unusual degree of influence in the development of sciatica as compared with other neuralgias. The disease is much more frequent in New York City during the damp, wet months, and a relapse is also much more apt to occur at such times. For this reason it is not uncommon among laborers who work in ditches, cab-drivers, and others whose occupation necessitates constant exposure in all weathers.

Muscular effort is sometimes the only ascertainable cause of the disease. In some instances it follows the muscular strain at once, and may begin with its full severity. An instance of this kind has come under my observation.

Injuries, in the shape of blows, falls, gunshot wounds, etc., may give rise to sciatica, as well as to other forms of neuralgia. We may also include under this heading all cases in which the disease results from pressure due to local processes in any part of the course of the nerve, from its spinal origin to its terminal branches. Among these may be mentioned the following: Spondylitis deformans, cancer of the vertebræ, gummata of the dura mater, neuromata within the spinal canal, intrapelvic tumors, the use of forceps during delivery, exudations into the broad ligaments, accumulation of hardened fæces in the rectum, pressure upon the nerve by a popliteal aneurism, neuromata, syphilitic and other tumors of the nerve or adjacent parts, etc.

In very many cases sciatica is associated with chronic constipation and hæmorrhoids. In such cases it is probable that the dilatation of the hæmorrhoidal veins is a potent etiological factor. In a patient under my observation at the present time, the disease developed under these circumstances, the venous congestion being still further increased by dilatation of the heart.

Sciatica is sometimes seen during the course of diabetes, and is then bilateral. Some authors have also noticed that temporary glycosuria may develop during an attack of sciatica.

In rare cases sciatica is the result of reflex irritation. It may accompany various affections of the bladder and uterus, orchitis and epididymitis, stricture of the urethra, or worms in the intestines. Gonorrhœa plays the most important part among this class. It is often complicated with gonorrhœal rheumatism, but sometimes alternates with the latter affection.

But when all is said, we meet with not a few cases in which the most patient examination fails to reveal the cause of the malady.

Clinical History.—Sciatica is usually preceded by prodromal manifestations, though it sometimes begins suddenly with full severity. Thus, an individual bending over to lift a heavy weight may be seized with the pain along the course of the nerve before he has time to straighten up. In the large majority of cases, however, acute pain does not begin at once. The disease is often preceded—sometimes for quite a long time—by an attack of ordinary lumbago. Gradually the pain spreads to the upper and back part of the thigh, at the same time losing its myalgic character and becoming sharp and paroxysmal. The limb often feels weak before the pain has attained any notable intensity. Perhaps there is slight numbness, or a feeling of coldness or weight in the limb. After a variable length of time the severity of the pain increases, and finally the paroxysms may become intolerable in their intensity. When this stage is reached the limb is usually held in a characteristic position. The thigh is somewhat flexed on the abdomen, and the leg on the thigh; the heel is raised from the floor. A corresponding position is assumed in bed, the limb being usually supported upon the opposite one. In walking, the limb is moved stiffly and gingerly, the weight being borne as much as possible on the opposite limb.

The duration of the disease may vary from a few days (rarely less than a week or two) to twenty or thirty years.

We will now enter upon a more detailed consideration of the symptoms.

Sciatica not only occupies a somewhat isolated position among neuralgias as regards etiology, but the pain also differs in certain respects from that of other neuralgias. The severity of the pain is generally moderate, though in some cases it is unendurable, so that the patient writhes upon the bed and screams out in agony. As a general thing, however, the sufferer keeps as quiet as possible, with the thigh flexed on the abdomen and the leg on the thigh. But he is often unable to maintain one position for any great length of time, on account of an intolerable restlessness in the limb. The pain is generally most severe in the back of the thigh and the region of the hip. At the height of the paroxysm it is apt to radiate into the area of distribution of the crural nerve, more rarely into that of the lumbo-abdominal nerve. The crural pain is sometimes hardly exceeded in violence by the sciatic pain itself. The distribution of the nerve to the leg and foot may alone be affected in some cases, and among others of the kind which have been reported we have also seen a case in which the pain was confined to the sole of the foot (plantar neuralgia).

The pain is of a shooting character, apparently from above downward in the majority of cases, though it is difficult for the patient to determine its direction. But the disease differs markedly from other neuralgias in the fact that there are usually pronounced and constant pain and tenderness along the course of the nerve. This steady pain is sometimes extremely annoying. The tenderness is not confined to the painful points (puncta dolorosa), but seems to be located along the entire course of the nerve. The following are the locations of the painful points: 1, A gluteal point, beneath the gluteal fold, midway between the trochanter major and tuber ischii; 2, a point at the emergence of the nerve from the sciatic foramen; 3, a point at the posterior superior spinous process of the ilium; 4, one or two popliteal points at either side of the popliteal space; 5, a fibular point behind the head of the fibula; 6, two malleolar points, one at the posterior part of each malleolus.

The motor symptoms consist of paresis and spasms of the limbs. After severe sciatica has lasted for some time, the muscles of the entire limb undergo a certain degree of atrophy, and in a couple of months the circumference of the thigh and calf may be nearly an inch less than that of the corresponding parts of the other limb. This appears to be the result of the relative disuse of the limb, as is shown by the fact that the muscles supplied by the anterior crural nerve are also wasted. In rarer cases the limb undergoes a certain degree of rapid atrophy which is not explicable in this manner, and is usually attributed to an implication of the trophic fibres of the nerve in the neuralgic process, or to a reflection of the irritation to the large ganglion-cells in the anterior horns of the spinal cord, from which the nerve takes its origin.

In walking, the patient favors the affected limb as much as possible, and holds it quite stiffly on account of a slight degree of contracture of the muscles. It has seemed to me that the limb, as a general thing, is really weaker than its fellow, and that there is not merely apparent weakness due solely to the severity of the pain excited by movement.

Motor spasms do not play a very prominent part in the history of the disease. Patients sometimes tell us that they suffer, especially at night, from cramps in the calf of the leg, and in rarer cases from twitchings of the entire limb.

C. Handfield Jones has reported a peculiar case of left sciatica of ten years' standing. At first the knee-jerk was absent in both legs. After a time it appeared in the right leg, and later, after improvement in the pain had set in, it reappeared in the left leg. The patient had become an opium-eater. So far as I know, this instance of the disappearance of the knee-jerk in sciatica is unique, and it is impossible to determine whether it stands in any causal relation to the neuralgia.

It has been stated by Eulenburg that the faradic irritability of the nerve is often diminished, and that the galvanic irritability also undergoes changes which may even amount to a reversal of the normal formula of contraction. Legros and Onimus state that they have observed increased faradic contractility in recent sciatica, and diminished contractility in old sciatica. Changes of such a character do not seem to have been seen by other writers, and it is very questionable whether they occur in true sciatica.

Various disturbances of cutaneous sensibility are often noticed. In the majority of severe cases tactile sensibility is blunted to a slight extent, but marked anæsthesia is rare. Hyperæsthesia is still rarer, and is usually con-

fined to circumscribed portions of the skin. Both forms of disturbed sensibility may be present at the same time.

The patients often complain of abnormal sensations in the skin, such as a feeling of cold, more rarely of heat, formication, tingling, etc. These sensations are often present, although tactile sensation is not affected.

The appearance of the integument is often changed. The skin may be pale and anæmic; it is frequently colder to the touch than the opposite limb; perspiration is usually diminished, though it is sometimes increased. These disturbances are probably the result of vaso-motor changes in the affected limb.

Trophic changes are rare. Apart from the muscular atrophy, to which reference has already been made, they include increased growth of hair in the area of distribution of the affected nerve, and rarely certain cutaneous eruptions, such as herpes, erythema, and furuncles. In very exceptional instances hypertrophy of the muscles of the thigh and calf has been observed. These trophic changes play a much less important part in the history of sciatica than they do in that of other neuralgias.

The paroxysms of pain come on at irregular intervals, and rarely present the periodicity which is so often a striking feature of other neuralgias, even when they are non-malarial in origin. They may be brought about by numerous exciting causes, such as the movements of coughing, straining at stool, turning in bed, etc. If the disease lasts for any length of time, the paroxysms are apt to occur with greater frequency but less severity, until finally the patient suffers constantly from pain and the disease enters the chronic stage.

Diagnosis.—The diagnosis in typical cases is usually very easy. The situation and character of the pain, its occurrence in paroxysms, the presence of painful points, the slight disturbance, as a rule, of motion and sensation —all show clearly the nature of the disease. Lazarevic mentions as a pathognomonic sign that there is increased pain and tenderness on extending the knee and ankle and flexing the thigh on the abdomen. He believes that this is owing to the elongation of the nerve produced by this manipulation.

We should not remain satisfied with the mere diagnosis of sciatica, but should at the same time endeavor to discover the cause of the attack. In order to do this we must go into the previous history of the patient and the mode of development of the neuralgia, and, if this is unsuccessful, should carefully examine the adjacent organs along the course of the nerve, bearing in mind the various processes, mentioned in the section on etiology, which may give rise to the disease. As in all other forms of neuralgia, however, we shall meet with not a few cases in which it is impossible to ascertain the cause.

Easy as the diagnosis is in many cases, in others it is extremely difficult. Perhaps no condition offers greater difficulties in this respect than rheumatoid arthritis of the hip-joint. Jonathan Hutchinson even goes so far as to claim that nine-tenths of the so-called chronic cases of sciatica are really cases of rheumatoid arthritis. Although I admit that the differential diagnosis may be very difficult, and a number of cases of errors in diagnosis have come under my own observation, I am convinced that Hutchinson's statement is greatly exaggerated. In rheumatoid arthritis the pain is usually by no means so severe as in sciatica, and it is not confined so exclusively to the distribution of the sciatic nerve. Equally severe pain is felt along the crural, and especially the genito-crural, nerve. On making passive motion at the hip-joint, it will be found that flexion is limited in amount, and, after the limb is bent on the abdomen to a certain extent, further flexion is impossible without tilting the pelvis. Rotation at the hip-joint is also interfered with. In some cases rough creaking can be felt in the joint. The ankylosis in these cases may be either true or false.

In rare cases sciatica may be mistaken for hysterical hip-disease (Brodie's joint). In the latter disease there is remarkable tenderness on the slightest pressure of all the parts surrounding the joint, but uniform, strong compression often feels grateful to the patient. The pain is more diffuse than in sciatica, and the patient is generally a young woman who presents other manifest evidences of hysteria. Brodie's joint is, moreover, much more apt to be mistaken for true morbus coxæ than for sciatica.

When the sciatica is bilateral, it must be differentiated from locomotor ataxia. The very fact that the disease is bilateral should arouse our suspicions. But the pains of ataxia possess more of a fulgurating character than those of sciatica, are more irregular in their distribution and mode of onset, and are generally accompanied by more marked sensory disturbances. With very rare exceptions, the patellar tendon reflex is absent in ataxia, but too much reliance should not be placed on this sign, inasmuch as there are not a few healthy individuals in whom this reflex is absent. In addition, the pains of ataxia are usually accompanied by some of the other symptoms of ataxia (the characteristic gait, bladder disturbances, cincture feeling, Argyll-Robertson pupil, etc.).

Myalgia, or "rheumatism" of the muscles of the buttock and thigh, must also be excluded. The pain is sometimes of a darting character, but does not shoot along any particular nerve. The characteristic puncta dolorosa of sciatica are not present. The patient has, perhaps, often suffered from myalgia in other parts of the body. The pain is absent when the patient lies down and keeps the parts perfectly quiet. Moreover, this condition usually is much more amenable to treatment than sciatica.

Prognosis.—Recovery from sciatica sometimes takes place in a few days, but, as a rule, several weeks at least elapse before the pain disappears completely. The disease also exhibits a very decided tendency to relapse. For months, and sometimes even for years, after an attack of ordinary severity, the patient is liable to have an occasional twinge of pain in the limb after any unusual exertion, exposure, or slight injury. In not a few cases the relapses occur at gradually shorter intervals of time, and the disease finally becomes chronic. In rarer cases the first attack continues for an indefinite period. This is particularly true of those cases in which the disease begins at an advanced period of life, or in which the patients exhibit the signs of early senility. But the obstinacy of the affection does not always appear to depend upon impairment of the general condition. It is often extremely severe and intractable to treatment in robust individuals, who are otherwise apparently in perfect health.

Treatment.—As in all other diseases which exhibit a tendency to run an obstinate or even chronic course, the number of remedies employed in sciatica is legion.

Our first object should be to ascertain the cause of the attack and to combat the primary disease by appropriate measures (antisyphilitic, antirheumatic, antimalarial remedies, etc.). But in the majority of cases we must adopt a purely empirical treatment. It is well to begin by administering a cathartic and by securing sufficient daily evacuations from the bowels.

In my experience electricity, strychnine, and baths have been the most effective curative agents.

Of the various kinds of electricity I now employ only galvanism. It is usually applied as the stabile descending current, or by the polar method. In the former method the anode is placed upon the sacrum or lower lumbar vertebræ, the cathode to the puncta dolorosa; or if none is present, to the most accessible portions of the nerve (sciatic foramen, between the trochanter and ischium, along the thigh, or in the popliteal space). Or the anode, instead of being kept on the sacrum throughout the entire sitting, is shifted to the part first occupied by the cathode at the end of three or four minutes, the cathode being moved to the next lower point, and the whole length of the nerve is then traversed in this way. I have not noticed any difference in the results, however, whether the cathode was applied above or below. In the polar method the cathode is applied to the middle of the back or front of either thigh, the anode successively to the parts mentioned above. The sponges should not be too large, and the current must be of sufficient strength to cause severe pain. In fact I have found, as a rule,

that the stronger the current is, the more marked and lasting is the effect. At the end of the sitting the current may be interrupted a few times in order to produce muscular contractions. This is often very effective in diminishing the stiffness of the limb. The sittings should last about ten minutes, and be held daily, or every other day.

The faradic current has also been used, either with the wire brush applied to the painful points, or as a strong current through the entire course of the nerve. In several cases, however, we have seen the pain aggravated by this current, and have now abandoned its use.

Electrical applications often produce prompt and marked relief. The pains subside very rapidly, the freedom of motion is very much increased, and in favorable cases a permanent cure is effected after a few sittings. In very few cases have I failed to obtain at least some temporary improvement.

Strychnine should be given in initial doses of $\frac{1}{48}$ grain three times a day, the dose being increased rapidly to the point of tolerance by the patient. This drug often produces gratifying results if given in sufficiently large amounts, but it is by no means as efficacious as galvanism. It may, or may not, be combined with the use of electricity.

I have always employed baths in the form of hot sitz-baths, and always as an adjuvant to other methods of treatment. The water should be as hot as the patient can bear, and the baths should last for five or six minutes. They may be repeated once or even twice a day, and are often followed by a certain amount of relief. If taken at bedtime they may enable the patient to obtain refreshing sleep.

Local irritation is also a valuable adjuvant in some cases. It may be produced by blisters, or by the actual cautery. Some writers even recommend the production of a blister by the application of a sufficiently strong current of galvanism, but this causes an unnecessary amount of pain. It is sometimes advisable to apply the blisters in successively lower positions, until the entire upper part of the nerve has been treated in this way. The actual cautery is to be applied lightly over the course of the nerve, since the production of an eschar is not necessary to the relief of the pain.

Among other non-medicinal agents massage has also been employed. Schneller has recently reported fifteen cases treated in this way with successful results. The average period required to effect a cure was two and a half weeks. Huenfault reports the cure in two weeks, by massage, of a case which had resisted all other methods of treatment.

Favorable results have also been reported from congelation of the entire limb by means of chloride of methyl.

Hypodermic injections of various substances, such as cold water, ether, nitrate of silver, cocaine, osmic acid (ʒ ss.–j. of a one per cent. solution) into the nerve have also been used, but the results are not very gratifying. It should be remembered that abscesses occur not infrequently from this method of treatment.

Numerous drugs are employed occasionally in obstinate cases, viz., morphine, arsenic, quinine, iodide of potassium, aconitine, atropine, gelsemium, and turpentine.

When the pain is intolerable we are often compelled to give a hypodermic injection of morphine in order to secure temporary relief. In rare cases a single injection is followed by marked permanent benefit. But this remedy should be used as sparingly as possible, inasmuch as we are unable to determine in advance the duration of the disease, and the patient may fall into the opium habit in consequence of its protracted administration. A case of this kind is now under my observation.

Aconitine sometimes produces excellent results, but its effects are far inferior in sciatica to the brilliant results so often obtained in trigeminal neuralgia. Arsenic will often be found a useful remedy in this disease, especially in the chronic cases occurring in old people. The same remark may also be made of iodide of potassium. I have seen very little benefit from the other remedies mentioned above.

Finally, surgical interference may be resorted to. Fayrer reports a case of aggravated sciatica of long standing, in which there were fulness and tenderness in the course of the nerve near its origin, in the upper part of the limb, together with a sense of fluctuation. A long, narrow knife was introduced into the swelling, until it entered the sheath of the nerve. This gave exit to a couple of drachms of clear serous fluid, and was followed by immediate relief. Fayrer states that he has seen other cases of a similar, but not so well-marked, character.

Nerve-stretching has also been employed in a large number of cases, but the results have not been as good as the first reports led us to expect. The stretching may be performed subcutaneously, by flexing the thigh forcibly on the trunk, while the knee is kept fully extended. Woelfler reports one brilliant result from this plan, but in thirteen other cases it proved an entire failure.

Stretching of the nerve after its exposure by incision has also been successful in a number of obstinate cases, and as the operation is unattended with danger it is always worthy of trial in desperate cases.

Leopold Putzel.

SCLERA, CORNEA, CRYSTALLINE LENS, VITREOUS BODY, ZONULE OF ZINN, AQUEOUS HUMOR. The sclera (sclerotic) and cornea form the outer, so-called hard, membranes of the eyeball which determine its shape. While the former is translucent only, the latter is transparent, with a refracting index which is almost equal to that of water.

Both the *sclera* and the cornea in the ideal eyeball form portions of a sphere. Generally, however, their curvature is only approximately spherical. Five-sixths of the globe are formed by the sclera, the anterior sixth by the cornea, which is inserted like a watch-glass upon the sclera, and has a smaller radius of curvature (see Fig. 3397). The depression which is formed in the sphere by this mode of insertion of the cornea upon the sclera is called the *sulcus scleræ*. The diameters of the eyeball are not equal in all directions. The antero-posterior diameter, the longest, averages 24 mm., while the vertical one is only about 23 mm., the horizontal diameter being between these two, or about 23.5 mm. The posterior portion of the sclera around the optic-nerve entrance is about 1 mm. thick; from this point it gradually tapers off toward the insertion of the cornea, near which its thickness is reduced to 0.5 or 0.4 mm.

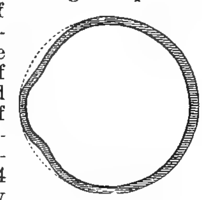

FIG. 3397.—Outline of the Sclera and Cornea.

The increased thickness in the posterior portion is mainly due to the fact that the sheaths of the optic nerve here enter the tissue of the sclera and coalesce with it. Close behind the insertion of the cornea the sclerotic tissue is also increased in quantity by the insertions of the tendons of the external ocular muscles.

At the sulcus scleræ the translucent tissue of the sclera passes over into the transparent tissue of the *cornea*. This is done in such a manner that the inner layers become sooner transparent than the outer ones. This part is called the *limbus corneæ* (sclero-corneal junction). The translucent tissue reaches farther over the transparent tissue at the upper and lower margins of the cornea than at the inner and outer ones, and thus the outline of the anterior corneal surface is that of an ellipse, while that of the posterior surface is circular. The diameters of the anterior corneal outline are 11.6 and 11.0 mm., respectively. The curvature of the cornea has also been said to be elliptical, causing, so to speak, a normal astigmatism (Donders, Knapp, and others). However, more recently, Aubert has come to somewhat different conclusions with regard to the curvature of the cornea, which he expresses in the following words: "We can distinguish between two zones in the cornea, of which one, the marginal zone, remains curved in accordance with the anatomical shape of the eyeball, while the other, the polar zone, serves the optical requirements. The shape of the

eyeball is such that the part defined by the sclerotic is almost spherical, with a radius of from 11 to 12 mm. The margin of the cornea has almost the same curvature as the sclerotic, of which it is a direct continuation. This portion then passes gradually over into a part of the cornea of a stronger curvature—a zone of the cornea which is immaterial for optical purposes, since the rays which fall upon it are kept from entering the interior of the eyeball by the iris. It is only where this sclerotic curvature of the eyeball is totally changed that the part of the cornea begins which is material for vision, and which forms an area of from twelve to sixteen degrees around the optical axis. The curvature of this part is such as to refract the rays of light falling upon it in a manner to unite them upon the retina. We may, therefore, speak of two zones (of curvature) in the cornea, of which the one, the polar, is the *optical zone*, while the other, the marginal, may be called its *scleral zone*. Their limits are given by the iris and pupil."

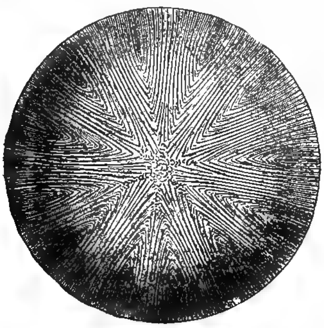

Fig. 3398.—Adult Lens, Anterior Surface. (Arnold.)

The cornea is thicker at its periphery than in its central portion, the thicknesses being 1.1 mm. and 0.9 mm., respectively.

Close to the inner surface of the sclerotic (*cf.* art. Iris) lies the uveal tract, and upon this (*cf.* art. Optic Nerve and Retina) is the expansion of the optic nerve, the retina. The fibres of the optic nerve enter the posterior pole of the sclerotic, somewhat to the nasal side, by numerous openings, which give this portion of the sclerotic the appearance of a sieve. From this it has been called the *lamina cribrosa* of the sclera. On its outer surface the sclera is surrounded by *Tenon's capsule*, from which it is separated by *Tenon's space*, a lymph-space.

The large cavity surrounded by the sclera (and choroid and retina) is filled with the *vitreous body*, a transparent, gelatinous substance. The general shape of the vitreous body is spherical. Its anterior surface, however, which lies at the level of the ciliary processes, has a central depression (*fossa patellaris*) in which lies the crystalline lens. Its posterior surface is also slightly changed from the spherical, by reason of its filling the physiological excavation of the optic papilla.

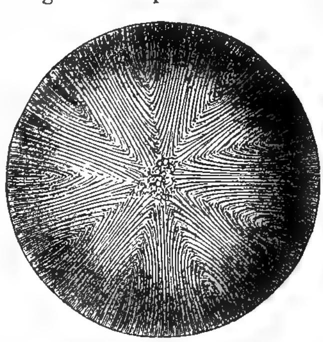

Fig. 3399.—Adult Lens, Posterior Surface. (Arnold.)

In front of the vitreous body lies the *crystalline lens*, with its suspensory ligament (*zonule of Zinn*). The crystalline lens is a perfectly transparent, lens-shaped body. It lies posteriorly in the fossa patellaris of the vitreous body; anteriorly it touches the pupillary edge of the iris. It is biconvex, and its equator lies at the level of the highest prominence of the ciliary processes. The curvature of its surfaces is unequal, the posterior surface having a stronger curvature than the anterior one. The equatorial diameter of the lens is from 9 to 10 mm., while the antero-posterior diameter is on an average 3.7 mm. It consists of a transparent capsule and the lens-substance proper. On both surfaces of the lens star-like figures may be seen, as are represented in Figs. 3398, 3399, and 3400. In the new-born we find three radii which, starting from the *anterior* and *posterior* poles, form angles of about 120°. While, on the anterior surface, one of these radii goes upward, and the remaining two downward and to the sides, these directions are reversed on the posterior surface. These radii never seem to reach the equator. In the adult the radii branch off, and their number is considerably increased. These radii have been called the sutures of the lens. (See Figs. 3398, 3399, and 3400.)

Fig. 3400.—Lens of the Newly-born, seen from the Side. (Arnold.)

The curvature changes with age, the lens being more convex in childhood and becoming gradually flatter. Its colorless structure also gradually takes on a yellowish amber tint with age. Its consistency is much firmer than that of the vitreous body.

The lens is held in its position by fibres which come from the ciliary processes, and attach themselves on the anterior and posterior surfaces of the capsule of the lens, close to its equator. These fibres together form the *suspensory ligament* (*zonule of Zinn, zonula ciliaris*). They come from the vitreous body (Arnold), and after having closely followed all the windings of the inner surface of the ciliary processes, they are bent almost at right angles toward the axis of the eyeball, and then attach themselves to the capsule of the crystalline lens. It was formerly thought that a triangular space could be demonstrated between those fibres that go to the posterior, and those that go to the anterior, lens-capsule, and this was given the name of *canal of Petit*.

The anterior chamber (the space which is bounded by the cornea, anterior surface of the iris, and as much of the anterior surface of the lens as lies in the pupillary space), and also the posterior chamber (the prismatic space bounded by the posterior surface of the iris, the zonule of Zinn, and the remaining portion of the anterior surface of the lens), are filled with a fluid called the *aqueous humor*. This water-like fluid closely resembles serum, but contains but little albumen.

Microscopical Anatomy.—*Cornea.*—The cornea consists of the anterior epithelium, *Bowman's membrane* (*Reichert's membrane, membrana elastica anterior*), the parenchyma or the corneal tissue proper, *Descemet's membrane* (*membrana Duddeliana, Demoursii, humoris aquei, lamina elastica posterior*), and the endothelium (*posterior epithelial layer*). (See Fig. 3401.)

The epithelium of the cornea is made up of a large number of layers like that of the skin, with the difference, however, that the cells of even the most superficial layer are never changed into horny scales, but have a nucleus like the cells of mucous membranes. (See Fig. 3401.) The innermost layer of the epithelium is, as a rule, a single layer, and consists of long cylindrical or club-shaped cells with an oval nucleus. Although these are in a general way the types of shape of these cells, they show all sorts of varieties in shape, into which they mould each other during their growth. It is not rare to find cells of two nuclei among them, which fact has led Waldeyer to the opinion that from this basal layer all other layers are derived.

Outward from the basal layer are several layers of cells which are more broad than they are high, and are polymorphous. These are characterized by two or more offsets, by which they are inserted in the interstices between the cells of the underlying layer. Their nucleus is rather spherical, and their shape depends on the pressure they exert on each other. Outward from these layers there follow two or three layers of serrated cells, that is, cells which have in all directions minute prick-like offsets by which they anastomose with each other. The most superficial portion of the epithelium consists of a number of layers of cells, becoming gradually more and more flattened, and having a flat nucleus, around which

the cells are slightly thickened. (See Fig. 3403.) Viewed from the surface these cells constitute a delicate mosaic.

All of these cells and layers are firmly bound together by a small amount of cementing substance.

The parenchyma of the cornea, that is, the corneal tissue proper (substantia propria), consists of the stroma, in which are embedded a system of canals (*corneal canals*) with cellular elements, a large number of nerves, and at its periphery a wreath of blood-vessels.

The stroma consists of very fine connective-tissue fibrillæ, which are somewhat wavy and intersect each other at varying angles. A cementing substance unites them with each other, and into fasciculi. Several fasciculi together are by the same cementing substance united into lamellæ, which, in turn, are bound together more or less parallel to the surfaces of the cornea. These lamellæ are thinner and more closely packed in the anterior portions of the cornea than they are near its posterior surface.

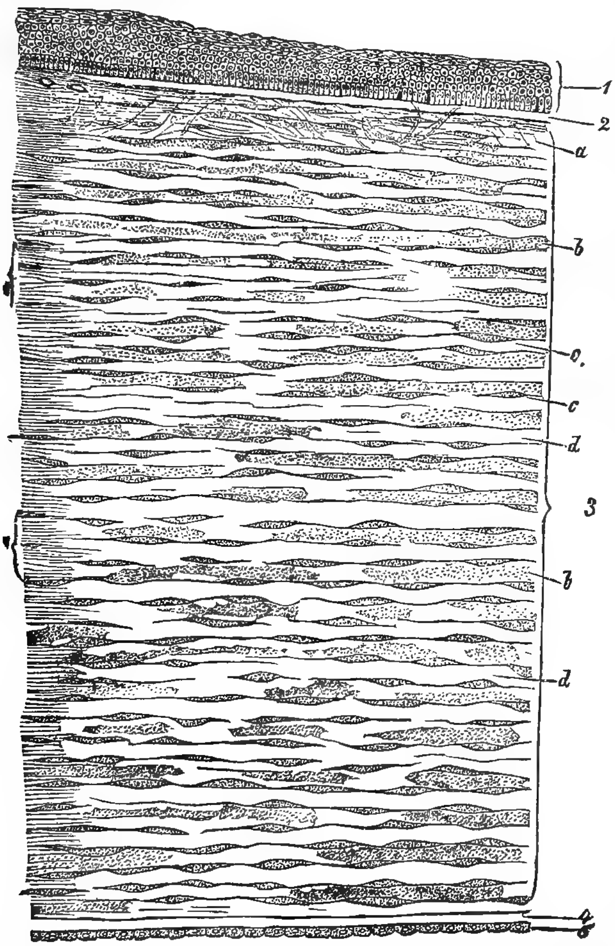

FIG. 3401.—Section through Human Cornea. (Waldeyer.) 1, Epithelium; 2, Reichert's or Bowman's membrane; 3, parenchyma of the cornea; 4, Descemet's membrane; 5, endothelial layer. *a*, Anterior layers of the substance proper of the cornea, fibres going to Bowman's layer. The canals are closer to each other. *b*, Points which represent transversely cut fibres and fasciculi; *c*, corneal corpuscles, appearing fusiform in section; *d*, fasciculi cut lengthwise, and therefore appearing homogeneous; *e*, *e*, sclero-corneal junction.

Between these fibrillæ, fasciculi, and lamellæ of the stroma of the cornea, and within the substance which cements them together as a whole, we find a system of canals which have received the name of *Von Recklinghausen's corneal canals*. (See Fig. 3404.) These canals, differing in width, intersect and communicate with each other at different angles. Here and there they have an enlargement which is called a lacuna. These lacunæ are especially found in the interlamellar canals, where they are seen to lie in rows parallel with the lamellæ. They are flattened in an antero-posterior direction, and therefore, in sections, they appear spindle-shaped. In a plane view they vary extremely in shape, according to the number of canals which are connected with each of them. As the lamellæ of the corneal stroma differ in thickness, so the canals and lacunæ differ in calibre in such a way that the canals and lacunæ are smaller and narrower in the anterior portions of the cornea than in the posterior ones. These canals and lacunæ are easily demonstrated by staining the corneal stroma by means of nitrate of silver or chloride of gold, or by injecting some colored fluid into them. (See Fig. 3404.)

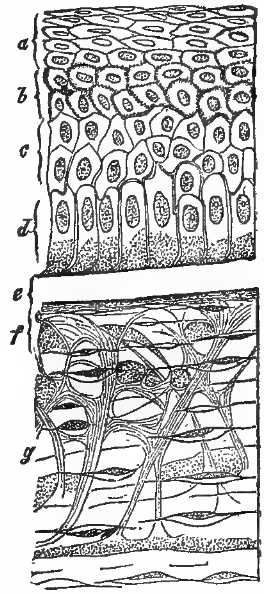

FIG. 3402. — Meridional Section through the Cornea of the Calf, (Waldeyer.) *a*, Flattened epithelial cells; *b*, prickle cells; *c*, polymorphous cells; *d*, basal layer of club-shaped cells; *e*, Bowman's layer; *f* and *g*, substantia propria of the cornea.

Within the lacunæ (see Fig. 3405) lie the so-called fixed corneal cells (*corneal corpuscles*). When isolated they are found to be flat protoplasmic bodies, with a round or oval nucleus and several offsets. These cells never wholly fill the lacuna in which they lie. Usually they are seen to adhere to one wall of it, and to fill about two-thirds of its cavity. Their offsets can generally be traced for a short distance within the canals which communicate with their lacunæ. Although called fixed cells, they are not so in the full sense of the word, and they have been observed to change their position within the lacuna. Near the sclero-corneal juncture, and especially in the eye of the negro, these cells contain sometimes a granular brown pigment which is enclosed within their protoplasm, leaving the nucleus free.

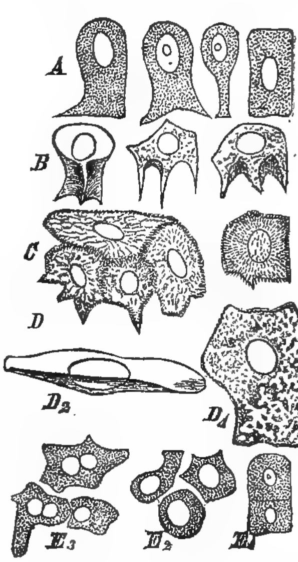

FIG. 3403.—Isolated Cells of the Corneal Epithelium. (Waldeyer.) *A*, from the basal layer; *B*, polymorphous cells; *C*, prickle-cells; *D*, flattened cells; D_1, plane view; D_2, side view; E_1, E_2, E_3, young cells from the middle layers; E_1, cell undergoing division; E_2, cells with one nucleus; E_3, cells with several nuclei.

While some authors (Kuehne and others) hold the opinion that the corneal canals and lacunæ are filled with protoplasm, thus forming a solid network within the connective tissue of the cornea, the large majority of authors consider them to be lymphatic canals.

In these canals we find, further, a limited number of

lymph-cells (wandering cells), which differ, of course, in nothing from the lymph-cells found in other tissues.

Another system of canals which is in communication with the lymph-canal system, but which lies almost at right angles to the latter, consists of the canals in which the nerves of the cornea are situated.

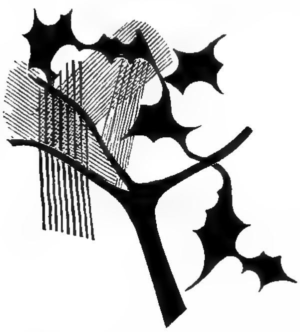

FIG. 3404.—Interfibrillar and Interlamellar Canals, and one Nerve-canal Injected. They all communicate with each other. The lines of the interfibrillar canals are wrongly drawn as straight lines in the cut. They are in reality wavy.

The anterior surface of the parenchyma of the cornea is formed by a layer which, varying in thickness in different eyes, with a moderate magnifying power appears structureless, and very much resembles a vitreous membrane. This is called *Bowman's*, or *Reichert's, layer*. (See Fig. 3398.) With a higher magnifying power this membrane is seen to be striated, and therefore to consist also of different layers, and to be, in fact, only condensed corneal tissue. Fibres are seen to go to it from the adjacent layers of the corneal parenchyma, and to join it at varying angles. With the proper agents it can be split into layers, and even fibrillæ. Close upon its outer surface lies the corneal epithelium, and some authors have described ridges on it into which the epithelial cells are said to fit.

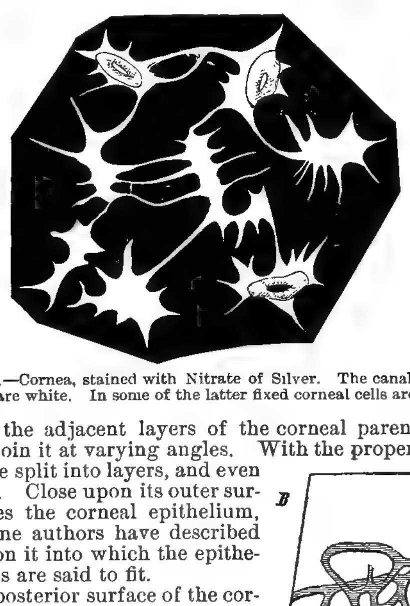

FIG. 3405.—Cornea, stained with Nitrate of Silver. The canals and lacunæ are white. In some of the latter fixed corneal cells are seen.

The posterior surface of the corneal parenchyma is bound by a thinner, double-contoured, elastic vitreous membrane, which seems to have more claims to be regarded as an independent membrane. This is commonly called *Descemet's membrane*. (See Fig. 3398.) Some authors consider this membrane also to be only a condensation of the corneal tissue. It can, however—and this often happens in pathological conditions—be perfectly detached from the parenchyma. This is not the case with Bowman's layer. The fact that it is an elastic membrane, and rolls itself up when freed from its adhesion to the corneal parenchyma, seems no longer to be doubted.

On its inner surface Descemet's membrane carries one layer of epithelial (endothelial) cells. (See Fig. 3406.) These cells vary considerably in height in different eyes, and in shape in one and the same eye. In sections they appear cuboid, in surface views they are hexagonal, rhomboid, or square, or, in general, have a shape which is dependent on the pressure which the different cells exert upon each other during their growth. They have generally a round nucleus, and are held together by a small amount of cementing substance.

Between these endothelial cells we find very frequently, perhaps oftener in old eyes than in young ones, a varying number of roundish transparent bodies which sometimes coalesce with each other. (See Fig. 3409.) They are usually situated near the periphery of Descemet's membrane, very much resemble the colloid excrescences on the lamina vitrea of the choroid, and crowd the surrounding endothelial cells aside. They are usually called *vitreous warts* of Descemet's membrane (Hassal).

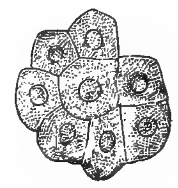

FIG. 3406.—Endothelial Cells of Descemet's Membrane. (Waldeyer.)

The corneal parenchyma does not contain any blood-vessels, except in a portion of from one to three mm. in width at the corneo-scleral junction. The arteries going to this wreath of blood-vessels come from the anterior ciliary arteries, either directly, or indirectly by way of the conjunctival arteries. They are found in loops, which unite to form a narrow network of capillaries. The veins are of a rather large calibre. (See Fig. 3407.) Several authors have described two separate wreaths of blood-vessels, one of which is said to lie closer to the anterior, the other closer to the posterior, surface of the cornea. The loops formed by the capillaries often show a number of teat-like projections toward the centre of the cornea.

At its periphery the cornea is entered by from forty to forty-eight larger nerve branches which come from the anterior ciliary nerves of the sclerotic and conjunctiva. After having entered the cornea these nerves very soon lose their double contour, branch off dichotomously, and thus form a network within the stroma of the cornea. (See Fig. 3408.) From this network branches go forward at different angles toward Bowman's layer, and near it form another network. At this part the axes-fibrillæ and axes-cylinders pierce Bowman's layer almost at right angles, form one network around the basal cells, and another between the more superficial layers, from which fine branches can be traced into the most superficial layer. Whether they end in these cells or protrude on the surface and form special nervous corpuscles there (Cohnheim), is, as yet, an unsettled question.

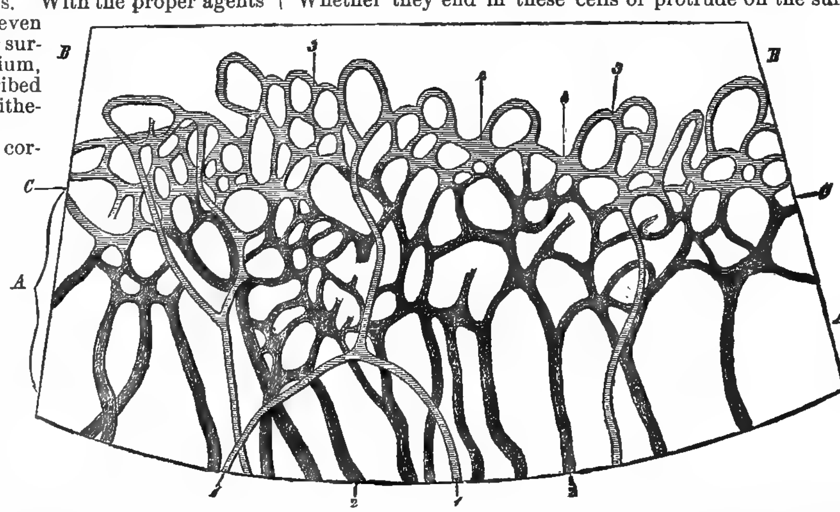

FIG. 3407.—The Loops of Blood-vessels found in the Periphery of the Cornea. *A*, Region of the bulbar conjunctiva; *B*, region of the cornea; *C*, line of junction between cornea and sclera. 1, Arteries; 2, veins; 3, marginal loops; 4, lacuna-like enlargements where several loops join each other and the veins. (Waldeyer.)

As has been already stated, the nerves lie in canals, which communicate with the lymphatic canals of von Recklinghausen and can be injected. These nerve-canals seem to have a layer of endothelial cells.

At the *corneo-scleral junction* the corneal epithelium goes directly over into the conjunctival epithelium.

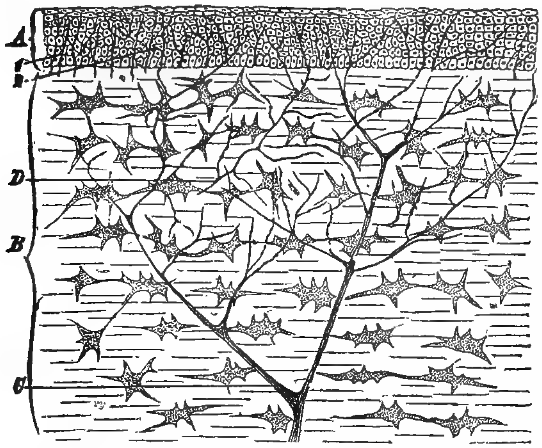

FIG. 3408.—Oblique Section through Human Cornea stained with Chloride of Gold. (Waldeyer.) *A*, epithelium with intra-epithelial nerve-plexus; *B*, substantia propria of the cornea; *C*, nerve branching off dichotomously; *D*, axes-cylinders; 1 and 2, anastomosing axes-fibrillæ.

Bowman's layer and the anterior layers of the corneal parenchyma pass over into the conjunctival tissue, and the bulk of the parenchyma of the cornea becomes scleral tissue. The membrane of Descemet and the adjacent layers form a network of fibres which lies on the inner surface of the tendon of the ciliary muscle, and is called *ligamentum pectinatum* (*pectineum*). (See Fig. 3409.) In accordance with this arrangement, the anterior portion of the cornea has been called the conjunctival, the middle the scleral, and the posterior the choroidal, portion of the cornea.

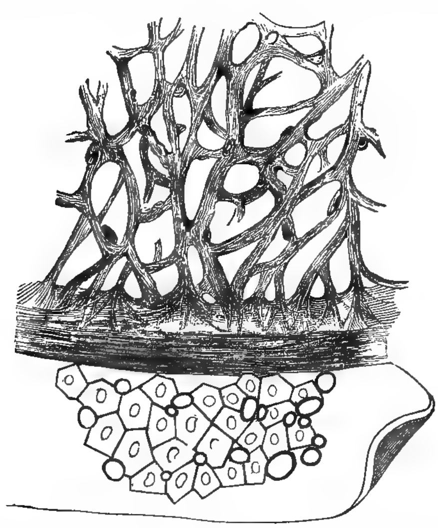

FIG. 3409.—A Portion of Descemet's Membrane and the Ligamentum Pectinatum. On Descemet's membrane may be seen some endothelial cells, and between them a number of glassy warts.

The fibres of the ligamentum pectinatum, when detached, appear as tough vitreous fibres to which a number of endothelial cells adhere. These fibres form a network, the meshes of which (*Fontana's spaces*) are in communication with a system of lymphatic spaces which lie between the inner fibres of the corneo-scleral junction and go to Schlemm's canal.

The fibres of the ligamentum pectinatum are lost in the tissue of the ciliary body and iris.

The tissue of the *sclera*, like that of the cornea, consists of very fine connective-tissue fibrillæ, which are, however, not quite so transparent, and differ from the corneal fibrillæ in their chemical character. It contains, moreover, some elastic fibres. The scleral fibrillæ, like those of the cornea, are bound together by a cementing substance, and thus form fasciculi. The scleral fasciculi are not arranged in more or less parallel lamellæ, but are interwoven at different angles. In a general way, the fasciculi in the sclera run in a meridional (longitudinal) direction. An equatorial (circular) arrangement of the fasciculi, however, is found constantly around the optic-nerve entrance and near the corneo-scleral junction, behind the ligamentum pectinatum.

Between the fasciculi of the sclera, and within the cementing substance, we find a network of lymphatic canals similar to those of the cornea. Their arrangement is, however, very irregular, and resembles more the arrangement found, for instance, in the tissue of larger tendons. This system of lymphatic canals is readily demonstrated by staining with nitrate of silver or chloride of gold, or by injection. We find then that the scleral system of canals has also lacunæ, like the corneal ones, and embedded in these lacunæ are stellated cells, the analogue of the fixed corneal cells. They resemble the latter in shape, are protoplasmic bodies with a number of offsets and a round or oval nucleus. Near the corneo-scleral junction, and around the optic-nerve entrance, these cells are often found to contain a granular brownish pigment. This is especially the case in negroes' eyes. A small number of lymphatic (wandering) cells are also found in the canals of the sclerotic.

At the optic-nerve entrance (see article Optic Nerve and Retina) the sheaths of the optic nerve merge into the tissue of the sclerotic, the dura-mater sheath joining the outer layers, the pia mater mingling with the inner layers of this membrane. The intervaginal space reaches into the sclera to a varying depth, sometimes splitting this membrane for a short distance into two portions. The fibres of the sheaths of the optic nerve make a part of the equatorial (circular) fibres of the sclera found around the optic-nerve entrance.

The tendons of the six extra-ocular muscles are inserted upon the sclera at very acute angles. Their fibres are seen to enter the scleral tissue, and may be traced for some distance, when they are gradually lost. According to Loewig, the fibres of the tendons of the recti muscles form longitudinal (meridional) fibres in the sclera, while the fibres of the oblique muscles form circular (equatorial) fibres.

As we stated above, the optic nerve is not admitted into the eyeball by one large round opening in the sclera, but in such a manner that its bundles enter the eyeball separated from each other by a sieve-like network of fasciculi of the sclera (*lamina cribrosa*).

The outer and inner surfaces of the sclera are covered with a layer of flat endothelial cells, of a more or less rhomboid shape. These cells can be easily demonstrated by staining with nitrate of silver. On the inner surface of the sclera the endothelial lining is pierced by numerous fibres, which unite the choroid with the sclera and form the *lamina fusca*.

This name has been given to the network of fibres, intermingled with pigmented stellate cells, which remain adherent to the sclera when the choroid is torn from it. On the outer surface of the sclera a similar condition obtains, the endothelial layer being pierced by many fibres, which form the loose episcleral tissue, and join the conjunctiva anteriorly and posteriorly to Tenon's capsule. Endothelial cells are also found adhering to these fibres.

The whole thickness of the sclera is pierced in a number of places by blood-vessels and nerves, which in this manner enter the eyeball and go to the uveal tract or come from it. These are the ciliary arteries and nerves,

and the venæ vorticosæ. Blood-vessels and nerves are surrounded by a lymphatic space with an endothelial membrane. The posterior ciliary arteries and nerves frequently lie together in one such sheath. By these sheaths the suprachoroidal lymph-space directly communicates with Tenon's space.

During their passage through the sclera both the anterior and posterior ciliary arteries give off branches for this membrane. The same is done by the nerves.

The anterior ciliary arteries enter the sclerotic with the tendons of the recti muscles.

At the corneo-scleral junction we find always a larger number of blood-vessels of an arterial character. Aside from these there is a venous plexus (Leber) which surrounds the periphery of the cornea, lying near the inner surface of the corneo-scleral junction. There is, furthermore, always a large canal to be found in this tissue just to the outer side of the insertion of the tendon of the ciliary muscle and the ligamentum pectinatum, which seems to be a lymphatic canal, and goes by the name of *Schlemm's canal*. In longitudinal sections it appears as an elongated opening with an endothelial lining. Its inner wall is perforated, and by means of Fontana's spaces and the lymph-fissures in the tendon of the ciliary muscle, Schlemm's canal seems to communicate with the anterior chamber. Leber contends that what by others is maintained to be a lymphatic canal, is the very venous plexus so well described by him. I am of the opinion that there is a venous plexus, and, aside from it, also a lymphatic canal, which latter corresponds to what has been called Schlemm's canal.

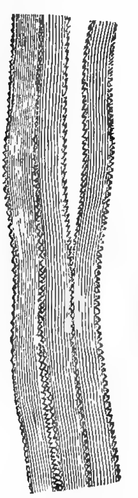

FIG. 3410.—Isolated Lens-fibres stained with Nitrate of Silver. (Arnold.)

The *crystalline lens* consists of the lens-capsule (anterior and posterior), the intra-capsular epithelium, and the lens-substance (lens-fibres, lens-bands).

The lens-capsule forms a hyaline sac, so to speak, in which the remainder of the constituents of the lens are inclosed. It is one continuous membrane. From the clinical distinction between an anterior and a posterior capsule, it might seem to follow that we have to deal with two different membranes, but this is not the case. There is, however, a distinct difference between that part of the capsule which covers the anterior surface of the lens and the portion which covers the posterior surface, in so far as the former is considerably thicker than the latter. The reduction in thickness takes place near the equator of the lens. This difference in thickness seems to be mainly due to the fact that a much larger number of the fibres of the zonule of Zinn (suspensory ligament) merge into the capsule in front of the equator of the lens than behind it.

The lens-capsule is an elastic hyaline membrane. In a plane view it appears homogeneous. Its transverse section, with a very high magnifying power and after the use of certain reagents, shows a fine striation. Its elastic nature is proven by the fact that it rolls up when severed from the lens-substance.

The inner surface of the anterior lens-capsule is lined by a single layer of epithelial cells. In a plane view they appear more or less hexagonal. In transverse sections their height is about that of the thickness of the lens-capsule; yet their size and shape vary in different eyes. They are held together by a small quantity of cement-substance. Their nucleus is round or oval. This epithelial layer does not reach beyond the equator of the lens, and near it we find that the cells become elongated, cylindrical, and gradually assume the form of lens-fibres. The view which is maintained by almost all investigators on this subject, that the continued formation of new lens-fibres takes place at the equator, has of late been declared absolutely incorrect by Robinski. The opinion advanced by him is that new cells are formed all over in the epithelial layer by karyokinesis, and that the process is therefore not confined to the equator.

The posterior capsule has no epithelial lining.

The lens-substance consists of the so-called lens-fibres (lens-bands, lens-tubes). Isolated lens-fibres appear as flat bodies with a very fine longitudinal striation (see Fig. 3410), and in rare cases also a transverse one. When they happen to lie on edge they appear much thinner. In transverse sections they are seen to be in reality hexagonal prisms (see Fig. 3411), which are smaller and thinner when taken from the nucleus of the lens than when taken from its periphery. While the younger and peripheral lens-fibres have an oval nucleus somewhere in their protoplasmatic body, the older and central lens-fibres have none for the most part.

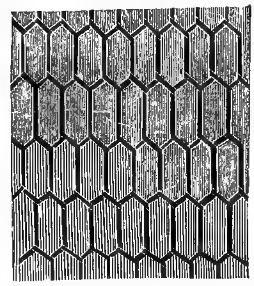

FIG. 3411.—Section through a Frozen Lens stained with Nitrate of Silver, showing Hexagonal Shape of Lens-fibres. (Arnold.)

The lens-fibres have also been called lens-tubes, since they evidently consist of a tough peripheral substance and a more fluid one within this. The latter is called *liquor Morgagni*. This fact is especially evident in the young lens-fibres near the periphery. As we come nearer to the centre of the lens, the Morgagnian fluid disappears gradually, and the fibres grow flatter and harder. The outlines of the fibres in the nucleus of the lens are rough and indented, and their lines of union with each other resemble bone-sutures. All the fibres are held together by a small quantity of cementing substance.

From the foregoing it will be seen that in the lens-substance we find layer upon layer of lens-fibres arranged in a more or less concentric manner. The peripheral fibres are the youngest ones, the central fibres are the oldest ones. The latter form the nucleus of the lens. The whole of the lens-tissue is epithelial in nature, and the old nuclear lens-fibres correspond to the oldest epidermic cells which have undergone a horny metamorphosis. In a meridional section through the poles of the lens, the nuclei of the lens-fibres are seen to be arranged in a convex line, with the convexity toward the capsular epithelium and near it. (See Fig. 3412.)

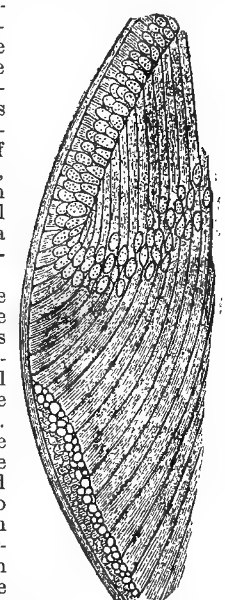

FIG. 3412.—Meridional Section through Lens of the Embryo of the Calf. (Arnold.) Shows the arrangement of the nuclei of the lens-fibres.

According to J. Arnold, the peripheral lens-fibres are from 0.010 to 0.012 mm. in breadth, and from 0.0045 to 0.0055 mm. in thickness; while the central ones are but 0.007 to 0.008 mm. in breadth, and from 0.0022 to 0.0021 mm. in thickness. Their length, according to Robinski, averages in the eye of the newly-born 5.5 mm., while in the eye of the adult it varies from 7.18 to 10.64 mm.

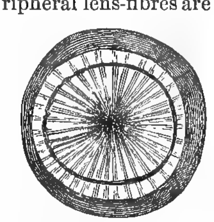

FIG. 3413.—Equatorial Section of the Human Vitreous Body, hardened in Mueller's Fluid. (Schwalbe.)

The *vitreous body*, which fills about the posterior two-thirds of the eyeball, consists of a more solid mucoid part and a thin fluid one, which runs off when the vitreous body is taken from the eyeball. The firmer portion amounts to 0.021 to 0.07

parts in 100 parts of vitreous body, according to Lohmeyer. This substance seems to form a number of very thin meridional and equatorial septa in which the fluid portion of the vitreous body (*vitrina ocularis*) is held confined. (See Fig. 3413.) It is very difficult to demonstrate these septa, yet their existence seems to be generally admitted. Concentric (equatorial) septa seem to be wanting in the more homogeneous central portion of the vitreous body, while they appear to be very numerous in its periphery. Probably for this reason the peripheral portion of the vitreous body is denser and firmer than are its central portions. From the lymphatic canals of the optic nerve a central canal in the vitreous body may be injected, which reaches from the optic papilla to the fossa patellaris. In this canal (*canalis hyaloideus*) during fœtal life the hyaloid blood-vessels go to the crystalline lens. After birth these blood-vessels

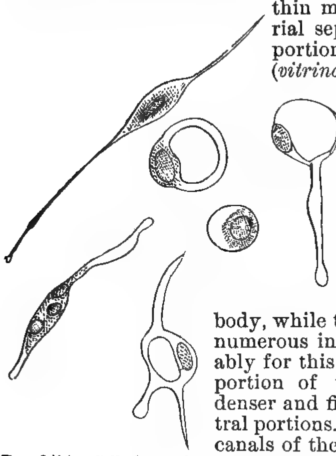

FIG. 3414.—Cells from the Vitreous Body.

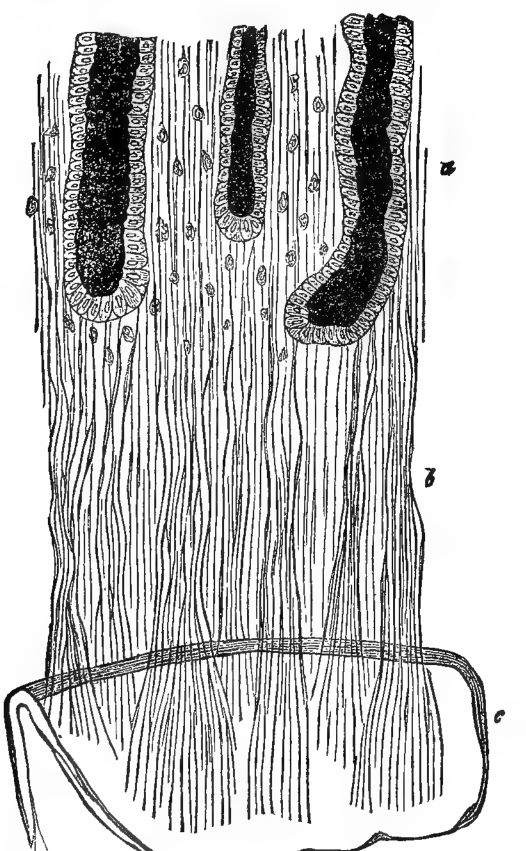

FIG. 3415.—Zonula Ciliaris (Suspensory Ligament of the Crystalline Lens). Plane View. The pigment of the ciliary processes remains lying on the pars non-plicata (*a*) of the zonule; the fibres of the pars plicata (*b*) go to the lens-capsule (*c*) and merge into it. (Arnold.)

no longer exist, excepting in a few cases in which persistent hyaloid blood-vessels may be found as an anomaly.

A number of authors have described a separate membrane, as *membrana hyaloidea*, which was said to cover the whole of the vitreous body, and thus to lie between it and the inner surface of the retina. Others contend that no such separate hyaloid membrane exists. The latter seems to be the correct opinion.

The vitreous body always contains a number of cellular elements, but their mass in the normal condition is but small in comparison to the bulk of the vitreous body. There are usually more cells to be found in its peripheral parts than in the central ones. The nature of all of these cells is that of lymph (wandering) cells, which enter the vitreous body from the surrounding membranes. (See Fig. 3414.)

With regard to their shape these cells (like all wandering cells) differ very greatly. There are simple round cells with one or more nuclei; there are round cells containing one or more vacuolæ, which sometimes crowd the nucleus aside so as to give the cell the appearance of a seal ring; there are, furthermore, cells with one or more offsets, some of which are very long.

Fibres, which by some investigators have been found in the vitreous body, seem to be pathological in nature.

The *suspensory ligament* of the crystalline lens (zonule of Zinn) springs from the vitreous body near the ora serrata of the retina. (See article Optic Nerve and Retina.) It lies at first close to the retinal (inmost) portion of the ciliary body, and has, therefore, here a pars non-plicata and a pars plicata just like the ciliary body. At the level of the ciliary processes the suspensory ligament is bent toward the axis of the eyeball, and is inserted into the lens close to its equator. This ligament consists of tough glassy fibres which sometimes show a fine transverse striation. They are held together in the manner of a membrane by a very small amount of a homogeneous cement-substance. From the ciliary processes these fibres are seen to go in the main to the anterior capsule of the lens, while a few go to the posterior capsule, and some return to the vitreous body. It was formerly thought that there was a triangular space bounded by the two portions of the suspensory ligament and the equator of the lens (canalis Petiti). Such a single large space does not actually exist, but the fibres crossing each other on their way in different directions leave a multitude of small spaces between them. At their point of insertion upon the lens-capsule the fibres of the suspensory ligament are lost in the tissue of the capsule. The cells which are sometimes found lying upon and between the fibres are lymph-cells.

Adolf Alt.

SCLERA, DISEASES OF THE. Although the sclera becomes secondarily involved in various morbid processes originating in other parts of the eyeball, primary disease of this structure is comparatively rare. Scleritis, or inflammation of the sclerotic, as a primary affection, is recognized only as originating in a narrow zone of the sclera, bounded in front by the cornea and behind by the insertion of the recti muscles. In this situation we meet with two varieties of scleritis—simple and complicated.

SIMPLE SCLERITIS (episcleritis) commences as a localized subconjunctival hyperæmia at a short distance from the corneal margin. As the episcleral tissue becomes infiltrated, a smooth swelling appears, which is but slightly elevated above the surrounding surface, and is usually of a dingy yellowish-red color, sometimes resembling a pustular formation, though ulceration or loss of substance never occurs. The conjunctival vessels over and around the swollen part are more or less engorged, but the conjunctiva in general remains normal. After a few days or weeks the nodule assumes a dull violet hue and becomes flatter, in which form it may remain stationary for a long time, or may gradually disappear, leaving a more or less permanent dull gray or ash-colored spot. Occasionally two or more such nodules are present at the same time, or as one disappears others may develop. The slow progress and tendency to recurrence of these nodules frequently render the disease tedious and protracted. One or both eyes may be affected, or as one recovers the other may undergo the same process.

The subjective symptoms are seldom severe; they con-

sist in an unpleasant sensation of weight or pressure in the eye, undue sensitiveness to light or cold, and perhaps slight headache; rarely there may be considerable photophobia and sharp pain. This disease belongs almost exclusively to adult life, and is most common in elderly people. The gouty, the rheumatic, and the scrofulous diatheses are all credited with lending a predisposition to this form of scleritis.

Treatment.—Any special dyscrasia on the part of the patient must be taken into account and suitably dealt with; and while exercise in the open air is to be enjoined, the eye must be protected from strong light and from sudden changes of temperature. The local use of sulphate of atropine is allowable in the early stages, especially if there be marked symptoms of irritation. In the absence of these, instillations of solution of eserine—gr. ij. ad ℥ j. (eserine, 0.10; water, 25.00)—twice daily, are often very efficacious. Massage, with the employment of oxide of mercury ointment (amorphous yellow oxide of mercury, 1 part, and fat or vaseline, 25–50 parts), has been highly recommended. Dry or moist heat, applied to the eye in the usual way, several times daily, may be beneficial.

In regard to internal medication the choice of remedies will depend on various circumstances. Mineral waters, iodide of potassium, salicylate of soda, proto-iodide of mercury, hypodermic injections of pilocarpine, and many other remedies have been used with more or less success, according to the special indications present in the individual case.

COMPLICATED SCLERITIS (sclero-keratitis, scrofulous scleratitis).—This is a much more serious affection, owing to the involvement of the cornea, iris, and ciliary region in the inflammatory process, and also to the tendency which exists to disastrous changes in any or all of these parts. Sclero-keratitis, commencing on the sclerotic, begins with one or more dusky infiltrations of the sclerotic, as in simple scleritis, but close to the corneal margin, the cornea being involved from the first, or after the scleral affection has existed only a short time; the pericorneal tissues are more deeply and more generally involved than in simple scleritis, and in some cases the cornea becomes extensively opaque; sooner or later the iris may participate in the inflammation, as is shown by visible changes in its appearance and by the presence of posterior synechia, or the entire ciliary region may become intensely congested and sensitive (irido-cyclitis). The special dangers to which the eye is subjected in any given case may be approximately estimated by the severity of the disease in the several parts affected—extensive changes in the cornea threatening permanent opacity of this structure; in the iris, more or less complete posterior synechia, and in the ciliary region, ciliary staphyloma. There may be one or more foci of inflammation; when there are several of these, the entire pericorneal zone may be involved, or the same thing may happen more slowly through repeated relapses, each time a different area of this zone being attacked. The low dusky swelling of the sclerotic, continuous with a patchy opacity of the adjacent cornea, is the characteristic objective sign of this disease, which, as a rule, is subacute in all its manifestations. Occasionally, however, the inflammatory process is more active, and there are intense photophobia, considerable lachrymation, and severe pain. The disease may at any time subside, leaving a dull grayish, thickened appearance of the sclerotic, and a corresponding irregular marginal opacity of the cornea. If several foci have been present, the cornea will have the appearance of being irregularly encroached upon by the sclerotic. With the subsidence of the inflammatory process the dull slaty-gray sclerotic may present a zone of thickened tissue around the cornea, which sometimes looks as if it were pushed forward, giving the anterior part of the eyeball an elongated appearance; or, more frequently, the sclerotic immediately around the cornea yields in certain places, and an irregular, nodular-looking projection is formed behind the cornea. This nodule is sharply defined anteriorly, but becomes gradually flattened toward the level of the normal sclerotic posteriorly. After repeated attacks of inflammation the staphylomatous bulging may involve the entire circumcorneal zone of the sclerotic, giving rise to great enlargement and distortion of the anterior part of the eyeball (Fig. 3416); at the same time the iris may become expanded from the periphery, and the anterior chamber is often considerably enlarged. The development of staphyloma from this cause does not often depend on increased intraocular tension, but on a gradual expansion of the softened sclerotic, and the most extensive changes in the form and appearance of the eyeball are not inconsistent with fairly good vision.

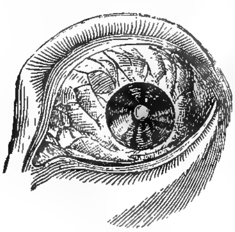

FIG. 3416.

The subjects of this disease are usually young adults, and it affects women far more frequently than men. "It is not known to be associated with any special dyscrasia, but it generally goes along with a feeble circulation and a liability to 'catch cold;' in some cases there is a definite family history of scrofula or phthisis" (Nettleship).

Treatment.—During the irritative stages soothing remedies are indicated. Protection from cold air and strong light is always advisable, warm fomentations are generally beneficial, and instillations of atropine are useful if there is much irritation, especially if the iris is at all involved.

In the more acute forms of this disease the writer has seen great improvement follow the use of antipyrine in doses of fifteen grains several times daily. Mercury may be used in moderation if the patient is not too anæmic. Iridectomy may be performed if there are extensive adhesions of the iris and a tendency to the development of staphyloma. If vision is destroyed and the eyeball is greatly enlarged, an operation for the removal of the staphyloma may be indicated.

Staphyloma of the sclera (ectasia) occurs under the most varied conditions, but usually as the result of prolonged increase of intraocular tension.

As a *congenital* anomaly of rare occurrence there is sometimes a partial bulging of the sclerotic, associated with congenital coloboma of the choroid (scleral protuberance of Von Ammon). There may also be a general uniform bulging of the sclerotic, associated with enlargement of the cornea, existing from the earliest infancy, and known as congenital "buphthalmus;" it commonly affects both eyes. Nothing is known of the etiology of this rare affection.

Extensive destruction of the cornea from suppurative keratitis is commonly followed by more or less complete corneal staphyloma, and this may extend to the sclera, giving rise to more or less general enlargement of the eyeball. Irido-cyclitis and irido-choroiditis, followed by occlusion of the pupil, give rise to increased tension of the eyeball, which, in the course of time, if not relieved, causes scleral staphyloma, usually in the ciliary region. Protracted increased tension from neglected glaucoma (glaucoma consummatum), or from dislocation of the lens, is a common cause of scleral staphyloma. Under these circumstances the bulging is usually far back, behind or between the insertion of the recti muscles.

In an ectasia following inflammatory or glaucomatous processes the protruding part is lined by a corresponding portion of the stretched and attenuated uveal tract. Bulging of the sclerotic may occur at any part, during the course of suppurative panophthalmitis, prior to rupture of this tunic and the escape of the contained pus.

Intraocular growths likewise cause bulging of the sclerotic, either by softening of the tunic in the vicinity of an intraocular growth, by the increased tension which such growths induce, or by simple expansion from excessive development of the growth. For the diagnosis of these conditions, see article Eye, Tumors of the.

Ectasia of the sclerotic at the posterior pole (sclero-ectasia posterior), as met with in axial myopia, is a condition of frequent occurrence. (See Myopia.) Its presence is easily determined, by means of the ophthalmoscope, by

the existence of a crescent or irregular circle of choroidal atrophy, which nearly always commences at the temporal side of the optic papilla. *F. Buller.*

SCLEREMA NEONATORUM. This rare affection is in no way connected with scleroderma, although the latter was at one time called sclerema of adults. It usually shows itself in the first days of extra-uterine life, having in all probability begun in fœtal life.

The first marked symptoms are commonly observed from the third to the sixth day after birth, when the lower extremities are seen to show considerable areas of shining, tense, white skin, sometimes tinged with red, or of a dirty-brown or yellowish color. The tissues are œdematous, pitting on pressure with the finger, while the skin is so much thickened that it cannot be pinched into folds between the thumb and fingers. Beginning in the calf, the disease soon extends to the thigh, spreads over the abdomen, up the trunk, involves the head and upper extremities, and, in fine, after a brief period (three hours to three days) invades the entire body. Of course we can know nothing of the subjective symptoms, but the rapid fall in body-temperature, the frigidity of the affected parts, and the general depression of functional activity point to a serious general condition.

The infant's bodily movements are imperfect and restrained; it lies numb and stiff, usually with closed eyes and wrapped in lethargic slumber; it declines food, partly on account of mental hebetude and partly because of the difficulty of making the movements of the mouth necessary to nursing. The heart is weak, and the pulse is rapid and sometimes almost imperceptible. The respirations are irregular and shallow, with occasional râles. The patient occasionally utters a complaining whine. The urine and stools are diminished in quantity.

The symptoms mentioned usually increase in severity with continually falling bodily temperature and increasing weakness, until death ends the scene at the end of from four to ten days.

Sclerema neonatorum is almost invariably fatal, though recovery has been noted in a few cases where the disease was not extensive. The cause of the disease seems to lie in an extensive implication of the blood-vessels. Atelectasis of the lungs, congenital disease of the heart, or other constitutional anomalies have been brought forward as explanatory of the origin of the disease. Surrounding and pre-natal conditions of an unfavorable hygienic character—want, privation, etc.—appear to have some influence in the causation of the disease.

Anatomical examination shows deep involvement of all strata of the cutaneous envelope. The widespread infiltration of the subcutaneous tissues allows the easy separation of these layers from the deeper layers of muscles and the fasciæ. On section a yellowish-white serous fluid, mostly composed of oil-globules, exudes. Of the internal organs, the lungs and kidneys are usually hyperæmic, while the brain and the serous membranes are usually œdematous. The brief duration of the affection, however, usually allows only the earlier stages of these changes to be observed.

The treatment of sclerema neonatorum is of a roborant and restorative nature, and should be undertaken at the earliest possible moment. Rubbing with hot blankets, etc., and the internal administration of restoratives may relieve the patient, and, if begun in time, may work a cure.

(The above article is based upon that of Schwimmer, "Ziemssen's Handbuch," Vierzehnter Bd., Erste Hälfte, S. 451.) *Arthur Van Harlingen.*

SCLERODERMA. An affection of the skin chiefly characterized by changes in the color and density of the integument, and in some cases accompanied by marked deformity.

Two varieties are usually described, *Scleroderma diffusa* and *Scleroderma localis.*

Scleroderma Diffusa.—This is the affection described first, under the name of *sclérémie des adultes*, by Alibert, in 1817. The affection occurs most commonly in women and in adult life. No previous ailment seems to exercise a predisposing influence, unless it be rheumatism. The immediate cause in many cases has been exposure to dampness and cold.

The induration, which is so marked a symptom of the affection under consideration, is variously described in different cases, and writers seem to vie with one another in their attempts to express vividly the peculiar sensations offered to the sight and touch.

In some cases the skin is described as being of stony or board-like hardness, or feeling like that of a frozen corpse, without the sensation of cold. In other cases it is compared to brawn or leather. Adherence of the skin to subjacent tissues is not uncommon—"hide bound," or "perfectly immovable," are the expressions used. In a case coming under the writer's personal observation, the skin over the forearms was so bound down that the limbs seemed as if carved out of wood. The underlying muscles, particularly those of the limbs, are generally more or less wasted.

One of the most distinctive characteristics of this variety of scleroderma is symmetry and diffusion as distinguished from localization. Commencing, as in most of the cases reported, on the back of the neck, the disease spreads equally on either side of the median line; or, when it begins in the limbs, both are usually attacked at once.

The surface covered is almost invariably large; those cases reported in which the disease seems to tend toward localization, are usually to be regarded as, in all probability, belonging to the other variety of the disease.

A marked characteristic of this variety of scleroderma is that no distinct boundary exists to the affected areas; they seem to melt imperceptibly into the surrounding skin.

The color of the affected skin varies much in different cases. In many cases pigmentation exists to various degrees, while in other cases the skin either retains its normal tint, or becomes pale-yellowish or waxy in color. A curious fact is that the pigmentation seems much deeper in the immediate neighborhood of the sebaceous follicles. In a certain number of cases, it is said that spots or patches of pigmentation at various points precede and presage the induration of the skin in these localities. This, however, is more likely to occur in the circumscribed and localized form of scleroderma.

Neither fever nor local inflammatory reaction of any kind ushers in, accompanies, or follows the appearance of the disease in any typical case. Œdema is rarely, if ever, observed in diffuse scleroderma. Occasionally swelling of the hands or feet has been observed as a result of mechanical interference with the circulation.

The rapidity with which the disease attacks and spreads over the skin varies in different cases. In some, large areas of skin become indurated in a very short time; in others, the onset is slow and insidious.

In no case is there any marked elevation of the indurated skin above the level of the surrounding and unaffected parts, though tubercular elevations have occasionally been observed. Where the tightened skin plays over prominent bony parts, as the knuckles, a tendency to ulceration is often observed.

Cutaneous sensibility in most cases remains unaltered. The appendages to the skin, the glands and hair, are rarely affected.

Scleroderma diffusa runs a very chronic course; many cases may be under observation for years with little or no change apparent, and this under the persistent employment of decided and varied treatment. The existence of scleroderma does not necessarily exclude that of other skin diseases; acne, comedo, and eczema have been observed simultaneously, and in the same localities.

Scleroderma diffusa is not in itself a fatal affection. In the few cases in which death has occurred while the patient has been under observation, it has usually occurred from some intercurrent disease, totally unconnected with the scleroderma. It is true that, in one case recorded, death was hastened by the extremely inflexible condition of the facial integument, which interfered

greatly with deglutition, while in some others respiration was much impeded through immobility of the thoracic walls.

The pathological anatomy of scleroderma diffusa is simply that of a hyperplasia of the fibrous element of the papillary layer and corium, with decrease of subcutaneous fat and increase in pigment deposit.

SCLERODERMA LOCALIS.—The symptoms and course of this disease, or form of disease, are very different from those of scleroderma diffusa. The affection is sometimes preceded by nervous symptoms, neuralgic pains, rheumatism, etc. At other times there are no general prodromes. The advent of the local symptoms is usually insidious, so that they are not often observed until the disease has made considerable progress. The most prominent skin symptoms are the appearance of parchment-like patches, with sclerotic striæ. In a typical case described by Bésnier the patches were irregular in shape, usually elongated in the direction of the axis of the body and members, isolated or confluent, sometimes symmetric, sometimes asymmetric. At first sight these patches can be distinguished from the surrounding skin only by their deeper color, their finely striated surface, slightly depressed beneath the level of the surrounding skin, and particularly by a lilac border composed of fine blood-vessels.

To the touch the affected patches seem slightly rough, dry, parchment-like, and superficially indurated, so that the skin can be pinched up only in thick folds. Sensation is in no way altered.

The striated patches are sometimes fine and diffuse, and hard to recognize, at other times they are united, forming large patches of convergent stripes.

The localized patches of scleroderma may be observed in any part of the body, but are more common on the trunk. The cases which have been observed by the writer have presented only the parchment patches (morphœa) with lilac areola, and have been observed about the clavicles and on the face.

In addition to the more characteristic patches above described, keloidal lesions and areas of pigmentation are observed at times. Occasionally also ecchymoses and phlyctenular lesions occur, and hyperæsthetic points, but these are usually evanescent. In some cases deep-seated and superficial neuralgic pains precede and accompany the appearance of the lesions, occurring in attacks often nocturnal. In other cases no such symptoms are present.

Accompanying the skin symptoms, rheumatic pains with articular symptoms, anchyloses, and even osseous degenerations have been reported. The hands and fingers, in particular, are said to be involved. The disease runs a very chronic course, and but few cases have been followed through their entire evolution. It will be seen from the above description that scleroderma, whether of the diffuse or localized form, presents itself in so many varieties as to make it difficult of definition. As to the nature of the localized form, all the evidence points toward a tropho-neurotic origin.

Arthur Van Harlingen.

SCROFULODERMA. There are a number of skin diseases so closely connected with the condition of the system called scrofulous as to be properly designated *scrofulodermata.* Of these, one of the commonest is that which begins in one or more of the superficial lymphatic glands, especially under the jaw, about the neck and clavicular region. The glands become enlarged and the process extends to the skin overlying them, which becomes red and infiltrated. Finally a cold abscess forms, and is discharged through the skin, and an ulcer of slow progress, with undermined violaceous border, results.

Bésnier calls scrofulous nodes, especially when they occur superficially, "scrofulous gummata," on account of their resemblance to syphilitic gummata. The most superficial of these gummata begins as a small infiltration or node in the skin, of a livid red color. Increasing in size, slowly at first, and later more rapidly, it sometimes extends in one or more directions, involving the entire skin, and softening at one or more points to form small ulcers, with burrowing sinuses extending from one to another. The discharge from these ulcers is usually sero-purulent or sanious, and occasionally bloody, and the skin may be undermined by numerous communicating galleries. Occasionally the disease takes on a diffuse, infiltrating form, spreading in an irregular patch over the skin, involving its entire surface, and giving rise to serpiginous shallow ulcers.

The scrofulous ulcer never shows any disposition to heal. It may look as if it were on the very verge of cicatrization, but it does not actually scar over, or, if it does, a week or two later the cicatrix may open in one place while forming in another.

In addition to the localities above mentioned, this form of scrofuloderma may occur over the cap of the shoulder, in the groin, and elsewhere. It is generally accompanied by other signs of the scrofulous condition, by old scars, etc.

This form of scrofuloderma is to be distinguished from lupus vulgaris and from syphilis by the concomitant general symptoms of scrofulosis and by the peculiar features of the lesions, which differ materially from those of lupus and syphilis. The characters of the primary lesions, the form of the ulcers and their course, and the amount of crusting differ materially. Where the diagnosis between scrofuloderma and syphilis is difficult, the history in some cases will aid.

Another and rarer form of scrofuloderma is characterized by the formation of papillary, wart-like, or fungous growths of a pale, bright, dusky, or violaceous red color. The surface of these growths soon ulcerates, with a thin discharge and some crusting. These lesions are apt to occur upon the backs of the hands, and may extend to such depth as to lead to bone-changes. The course of this form of scrofuloderma is exceedingly chronic.

A fourth variety of scrofuloderma may be referred to, which shows itself in the form of small, hard, scattered, flat papules with a raised violaceous areola. The lesions may occur upon any part of the body, but are usually met with upon the forearms, legs, and face. At first they look like the pustular syphiloderm, but crust over after some weeks, leaving a depressed pit-like cavity, of a size to receive the head of a pin, in the lesion. Finally the lesion disappears, leaving a punched-out scar like that of small-pox. This form of scrofuloderma is chronic to an extreme degree. New lesions form while the old ones are cicatrizing; and while the affection does not give rise to any pain or other annoying sensation, it is very rebellious to treatment.

The treatment of scrofuloderma is both general and local. Cod-liver oil, iodine—usually in the form of iodide of potassium, or of Blancard's pills of iodide of iron—and iron alone, are most frequently serviceable. Milton has reported excellent results from the administration of calomel or gray powder, two or three times a week at bedtime for a fortnight, with a saline every morning, so as to produce a daily action of the bowels. Then the mercurial is suspended for from a fortnight to a month, the saline being continued. If the appetite fails, bitters and mineral acids are to be given. Locally a mild zinc ointment is applied. Milton lauds this treatment as curing where all else fails.

Locally the ulcers are to be treated, as a general thing, with stimulating ointments, preferably those containing mercury. Ointments and powders of iodoform are also useful. Tincture of iron and chlorinated soda solution may also be used. Where the disease is extensive, scraping with the curette or sharp spoon, to remove the morbid tissue, as in lupus, is the quickest method.

[TUBERCULOSIS OF THE SKIN.—Our knowledge of tuberculosis of the skin is of recent date, and even now but little is known of this affection on account of its comparative rarity.

Tuberculosis of the skin usually shows itself as a single roundish or oval ulcer, which soon becomes crusted over, giving rise to little pain. On removal of the crust a reddish-yellow granular surface, bleeding easily, is observed. The walls of the ulcer are only slightly infiltrated, soft, not undermined, though sometimes movable

over the subjacent tissues. The edges are not smooth, but irregular and eroded, with occasional pits filled with pus. It is extremely rare to find any miliary tubercles.

The ulcer grows by gradual destruction of the edges in an irregular way, presenting occasionally a serpiginous appearance. The tuberculous ulcer is never large, rarely exceeding the area of ten to twenty square centimetres. It shows no tendency whatever to heal. The seat of the ulcer is almost always about some mucous orifice, as the mouth, anus, or vulva, or on the glans penis. The diagnosis is to be made by exclusion.

The treatment, in addition to that described above under scrofuloderma, consists in scraping and applying pyrogallic acid. The prognosis is usually unfavorable.

Arthur Van Harlingen.

SCULLCAP (*Scutellaria*, U. S. Ph.), *Scutellaria lateriflora* Linn.; order, *Labiatæ*. This genus consists of scentless bitter perennials, destitute of the aromatic properties found in most species of this large order, and further distinguished by a peculiar helmet-like development of the upper sepal, to which it owes its name. Calyx two-lipped, persistent; closed-in fruit until maturity, when it splits and opens widely. Corolla labiate, ascending; stamens four, also ascending, and under the upper lip of the corolla; lower anthers one-celled. Leaves opposite, petiolate; flowers axillary, usually solitary, sometimes in apparent spikes or racemes. There are about ninety species, forming a very distinct and natural genus, distributed over nearly the whole north temperate zone. There are about a dozen in the United States. The above-named species is a branching herb, from one to two feet high, with small flowers arranged in one-sided racemes, whose floral leaves are reduced, excepting those near the base, to small bracts. It has opposite, ovate-oblong or lanceolate, coarsely serrate, pointed leaves about two inches long. Stems squarish.

The commercial Scullcap is the entire herb, or the leaves and branches, dried. It has but little odor, and a bitterish taste. Both this and other species of *Scutellaria* have had from time to time some transient or popular reputation in medicine for the cure of mad-dog bites, chorea, epilepsy, or other nervous diseases; also as tonics, antiperiodics, etc. The present species, *S. lateriflora*, is considerably used by the Eclectic school of practitioners, and in home medication. It is reputed to be antispasmodic, anticonvulsant, etc., and is given for restlessness and wakefulness. Its composition has not been determined, and there is nothing in its obvious action to indicate that it has any particular value. Dose from five to ten grams (ʒ j. ad ʒ iij.).

ALLIED PLANTS, ETC.—See PEPPERMINT. Lycopus resembles it in properties. *W. P. Bolles.*

SCURVY, or SCORBUTUS. Philologically considered, the word "scurvy" appears to be of North country or Scandinavian origin, being derived from the Swedish *skörbjugg*, or the Danish *skojærbug*, signifying soft or relaxed stomach, the relaxation of the abdomen being one of the characters of this malady. The German *scharbock* and English scurvy have the same sense. As the disease, scurvy, prevailed among the ancient Danes, it is probable that they have given us the word, which, together with numerous other technical terms applied to navigation, has left an imprint on our language showing plainly the Viking influence.

Symptomatic definitions of scurvy are almost too well known to require repetition. On running over a number of them, selected at random from standard works, three distinct points are fixed in the mind, namely: 1, Skin and muscle lesions; 2, mouth and gum phenomena; and, 3, physical, physiological, and psychical depression. Besides this, the definitions agree in attributing the alteration of the blood to a defective alimentation. Many writers speak of scurvy as a nosohæmia of the same nature as purpura, from which it differs in greater intensity only. However strange the statement may seem, scurvy should properly be classed with the condition of multiple neuritis known as beriberi. The two diseases do not resemble each other in all essential points, yet we see in beriberi the result of insufficient alimentation brought about by the abuse of a vegetable regimen, and the absence of meat, salt, and fat, and one that is best treated by butter, cocoanut oil, and fat meats; while scurvy, which originates from the abuse of an animal regimen and the absence of fresh vegetable matter, is cured most readily by a diet of fresh succulent vegetables.

Few diseases have been more observed and written about than scurvy, and few have so exercised the sagacity, and sometimes the imagination, of medical writers. The bibliography of the disease is enormous, and, so far from settling mooted points in the pathology of scurvy, it only adds to the confusion.

To write the history of scurvy would almost be to write the history of medicine and to chronicle the sanitary circumstances of most human events, since the disease has occurred from time immemorial both on sea and on land. (See Army Diseases.) To pass in chronological review the various epidemics of scurvy of which a record is preserved would serve no good purpose. The disease was often described, but the first use which we find of the present name was in the sixteenth century, when a learned botanist, Enricus Cordus,[1] says of an antiscorbutic, the *Chelidonium majus*, "Saxones vero Scharbock's-Kraut (eam nominant), quod forte morbo quod illi Scharbock nominant medeatur." From this period clinical pictures of scurvy, more or less exact, occur in various publications up to the time of the appearance of the magnificent works of Lind, of Krebel, and of Mahé. The word "scurvy" is no longer on the "Statistical Reports of the British Navy," and Sir Thomas Brassey says that the disease has been unknown for eighty years in the Royal Navy, or in the better class of merchant ships.[2] With the opening of the Suez Canal, the recent improvements in steam machinery, and better methods of preserving food, it is certainly humiliating to find that scurvy should occur in the merchant marine, as it has occasionally done within the last decade. The English Government has made energetic efforts to diminish and stamp out scurvy from its commercial marine, and these efforts have been nobly upheld by *The Lancet* and the English medical press generally. Yet the high naval authority quoted above informs us that of late scurvy has been by no means rare in the British merchant service. A naval medical officer tells me that he knows of the occurrence of a number of cases of scurvy on board a British man-of-war on the South Pacific station, and that he has seen one case in the United States Navy. Dr. Guillemard reports the death of the boatswain, from scurvy, on board a well-found English yacht cruising in the Malay Archipelago in 1883.[3] Cases of scurvy have also lately come to the notice of the United States Marine Hospital Service. Four cases are reported from the Marine Hospital at San Francisco, in 1880, with one death, and another death from the same cause is reported in 1881. Both cases were complicated with pneumonia. Six cases were received into the Contract Hospital at Astoria, Ore., in 1881, and in 1885 the barkentine William Phillips, from Iloilo, Philippine Islands, arrived at Norfolk, Va., with scurvy on board. During the year ending June 30, 1887, the following cases of scurvy were treated in the United States Marine Hospitals: At Boston, 6; Chicago, 1; Port Townsend, 1; San Francisco, 4; Vineyard Haven, 2; and Wilmington, N. C., 1. Of this number 12 recovered and 3 improved. Only a few years since I had an opportunity to study, in the Baltimore Infirmary, a number of cases from a vessel that had come around Cape Horn. In the spring of the year 1887, in the remote parish of Hornstrandir, Iceland, 62 out of 400 died from typhoid fever. After the fever had worn itself out, Hornstrandir was attacked by scurvy, with several fatal cases.

While the existence of beriberi corresponds more or less to the geography of insufficient alimentation, scurvy may be said to have no distinct geographical limits, since its symptoms are likely to appear on land or at sea, in the tropics or at the poles, under diametrically opposite meteorological states, when the conditions necessary for its development are present. The polar regions have long

been regarded as the principal home of scurvy; but the geographical voyages of Kotzebue through Behring Strait (1815, 1818); that of Sir John Ross to the Arctic, accomplished without the loss of a man; and that of the late circumpolar expeditions, among which scurvy did not appear, are an evidence of what sanitary and preventive measures may do to ward off the effects of extreme polar cold.[4] On the other hand, numerous facts attest the existence of scurvy in such warm places as India, Aden, Hindustan, Brazil, Egypt, Algeria, and Senegal. In the arid plains on the way to California, before the days of the Union Pacific Railway, emigrants were often attacked with scurvy, and entire caravans would perish from this cause. In late years almost the same thing has occurred in Australia. I have also seen it on the Rio Grande River in Texas, among persons whose diet was mainly beef and black coffee. In fact, having to subsist for some time upon the same diet, I had personal experience of the premonitory symptoms. Although we were surrounded by thousands of cattle, milk was not to be had, and we were also wholly deprived of fresh vegetables, on account of the extreme heat and dryness.

The foregoing observations show that this disease is by no means extinct, and that it may again become active whenever the conditions are favorable to its development. Nor is it confined wholly to the higher order of animals. I have seen the experiment of feeding two rabbits, one exclusively on meat, the other on vegetable diet. After a few weeks the animal fed on meat developed symptoms of scurvy, while the other was sleek and fat. Hogs, though growing fat on an exclusive animal regimen, become scorbutic. It has also been observed that monkeys and gorillas on board ship become scorbutic at the same time that the sailors are affected. It would be surprising, then, if the African should escape scurvy, as he was formerly supposed to do, when placed under the same conditions as his white brother. The fact is that the negro victims on board the slavers lived principally on vegetable diet, such as manioc, while the crew lived on salt provisions, and in addition had to contend with the circumstances of a previous voyage. The blacks, when subjected to the same dietetic causes as the whites, contract scurvy with them, as is shown by the history of sieges when both races had to live on the same food. Scurvy, therefore, is impartial in the selection of its victims; nevertheless, it would seem to be a disease of civilization rather than of primitive life, since it appears to spare degraded savages who subsist on roots and grubs, and Eskimos and Kamschatdales, whose diet is highly nitrogeneous.* Properly speaking, scurvy is not a disease of famine. The Terra del Fuegan and the African negro may starve from want of vegetable food, but they do not die from scurvy. On the other hand, according to Parkes, men fed on a uniform diet of fat have gained in weight but have become scorbutic.

Regarding the etiology of scurvy two sets of opinions prevail. The first admits but one cause in the production of the malady, viz., the prolonged deprivation of fresh vegetable food; the second admits a variety of causes—physical, moral, and dietetic—which may produce scurvy when combined, or when one or the other of them is associated with some adjuvant cause of a different nature.

Generally speaking, scurvy is engendered by the persistent and prolonged action of causes susceptible of weakening the metabolism of the general nutrition. And doubtless there are many causes which may contribute to this.

Among physical causes may be enumerated the rotation of the seasons, overcrowding, and excessive fatigue, or its opposite, enforced immobility. Other considerations being equal, humidity of the atmosphere favors the development of scurvy. Numerous reports by different authors show that dampness and atmospheric changes constitute the most invariable elements among the predisposing and exciting causes of scurvy. Epidemics of scurvy have prevailed among soldiers living in cold, damp casemates, though provided with a suitable ration; it has appeared on board ships and in fleets where fresh provisions abounded—for instance, in the squadron of Admiral Martin cruising in the English Channel; and the bad weather experienced in doubling the Cape of Good Hope or Cape Horn has, for a long time, been recognized as one of the causes of scurvy. Of course it would be imprudent to say that cold and damp, overcrowding, or any one of the forementioned causes is an indispensable factor in the outbreak of scurvy. They may have acted like sparks in lighting up the effects of a train of previously existing unhygienic circumstances.

Fatigue is mentioned by most writers as an adjuvant cause. The assertion finds its application in the instances of overworked and underfed prisoners, in the disastrous retreats of armies, during sieges, in shipwrecks and disasters at sea. Among recent examples is the outbreak of scurvy among the enfeebled men of the Spanish squadron returning from the bombardment of Callao.

Immobility or inaction, whether forced or voluntary, takes a part in the genesis of scurvy. It has often been observed in prisons and asylums. The crews of ships doing blockade duty have been attacked with scurvy, which has disappeared as if by magic on making preparation for an engagement or on going into battle. According to Dr. Charles Smart, United States Army, the average annual rate of cases of scurvy reported to the War Office during the eighteen years before the Civil War was 23.3 per thousand of strength, or nearly twice as large as that which prevailed among our white troops during the years of the war.[5]

To these causes may be added those referable to defects in lodging, bedding, clothing, and antecedent physical state. We may mention the filthy bedding in such dark, ill-ventilated places as the forecastle of most merchant ships as perhaps concerned in the causation, and it is well known that the excesses in which men indulge when ashore furnish a strong predisposing cause, so that men leaving port on a long-distance sailing ship, after a debauch, are more likely to acquire a scorbutic taint than those who have kept sober.

Next to the physical are the mental and moral causes. Psychological misery and moral depression in prisoners have long been looked upon as preponderating causes, and in years gone by nostalgia was thought to have caused scurvy on board French ships. A comparatively recent example, in which the alimentary origin cannot be admitted, is the outbreak of scurvy among French prisoners at Ingolstadt (1871), who, according to report, received excellent rations of fresh meat and potatoes. In this instance the malady was thought to be owing to the damp cold of the casemates, to inactivity, and to mental depression. Deported convicts and prisoners on board ships have also suffered from scurvy, though receiving the same ration as the crew. Notable instances of late years are the epidemics of scurvy on board the French transports which conveyed political convicts to Caledonia in 1873. On board the Var and the Orne the food of these unfortunates is said to have been irreproachable as to quantity and quality; they received exactly the same ration as the crew and the free passengers, except that they had only half a ration of wine and no brandy; the drinking water was excellent, and clothing and bedding were sufficient. But chagrin, want of employment, ennui, and painful preoccupation affected the prisoners, and they slept in a vitiated atmosphere that was damp and hot. Recent travellers also speak of the prevalence of scurvy among Siberian prisoners.

Physical and moral causes may together engender scurvy, more particularly after prolonged and uniform usage of salt provisions that have undergone an isomeric modification that causes a loss of their reparative properties. Salt in itself is, however, not a cause of scurvy. The experiment of drinking sea-water for a month has been followed by harmless results, and numerous instances are reported in which the prolonged use of salt provisions has not been followed by scurvy. On the other hand, we have examples of the outbreak of the mal-

* It has been suggested that the marked absence of salt may account for this immunity. Having spent two seasons among the Eskimos of Behring Strait, I have been impressed with the fact of their aversion to all salted articles of food.

ady in cases in which salt food has not been employed. Yet it cannot be denied that the chief cause of scurvy is to be found in the absence or the insufficient quantity of certain materials or principles necessary to good alimentation, and notoriously in the prolonged deprivation of milk, and of fresh vegetable food. Epidemics of scurvy in English and Scotch prisons have often been attributed to the privation, or to the suspension, of the ordinary ration of milk served to the prisoners. The uniformity and monotony of the diet in most merchant ships are not conducive to the preservation of health. Sir Thomas Brassey says the allowance differs little, except in quantity, from the dietary in use during the last century; and this notwithstanding the great improvements in the preservation of meats and vegetables. The abuse of tobacco is also claimed to be a pathogenic factor in scurvy.

For convenience of description the ordinary phenomena of scurvy may be divided into three degrees or periods. The first period, that of evolution, is marked by general adynamia. The physiognomy is expressive; the characteristic pale-yellow tint of the skin being distinct from that of icterus, or of any other cachexia. Extreme lassitude, with an undefinable sensation of malaise in the voluntary muscular system, is accompanied by a sad and downcast air, disturbance of the appetite, dyspnœa, insomnia, hebetude, and other indications of diminished vitality. These are followed usually, though not always, by gingivo-buccal symptoms. At the margin of the gums, and in the intervals of the teeth, appears a change of color and consistency, owing to alteration of the capillaries; the gums become livid, soft, and bleeding; and the breath has a characteristic earthy, fetid odor. Pains occur in different parts of the body, more particularly in the lower limbs, and extravasation of blood in the outer skin and other tissues causes small purpuric spots that often assume a large size and induce a brawny hardness in the cellular tissue of the legs.

In the second period these symptoms are greatly aggravated. The purpuric spots become true ecchymoses, varying in color from yellow-brown to blue-black; the sanguineous infiltration, affecting the muscles of the calf and thigh, causes a characteristic induration; the loosened teeth sometimes fall out; and the alteration may extend to the osseous system, causing detachment of the epiphyses, if the subject is young, and sometimes exostosis and periosteitis. In addition to these, there may be bleeding from the mucous membranes, painful dyspnœa, a relaxed and pendulous condition of the abdomen, and fever.

In the third or last period the aspect of the patient is that of a breathing cadaver. In addition to the fever and other symptoms already described, there follows a general prostration, with septic or putrid hæmorrhages; the legs assume a sphacelated appearance; phlyctænæ are followed by rapidly extending and spontaneous ulcerations of the skin; fractures which have long been united again separate; necrosis of the tibia and bones of the foot occurs, and marasmus supervenes. Death occurs from extensive suppuration, from the intensity of the hectic fever, or by hæmorrhage, visceral lesion, or syncope.

So little is known of the pathological lesions of scurvy that the subject may be dismissed in a few words. Although the disease is dependent upon some chemical alteration in the quality of the blood, it cannot be said that we know positively of any morphological modification of this fluid that is proper to scurvy. The same may be said of the other morbid changes that have been noted. Beyond the sanguineous effusions into the splanchnic cavities; softening, or more often hardening, of the muscles; the occasional cartilaginous detachment of the ribs, and caries of the bones, scurvy has no anatomical characteristics that are not common to many other diseases.

It is rather in the complications of scurvy that the more marked anatomical lesions are to be found. To study even the more immediate of these complications would require systematic examination of most of the organs of the body, since pleurisy, pneumonia, pericarditis, etc., are morbid processes occurring side by side with scurvy under the influence of accessory causes; and many great epidemics of disease, especially in armies, have been preceded, accompanied, or followed by scurvy. In fact, scurvy may color or modify many diseases or accidents, prolong convalescence, and increase mortality to a serious extent. The most common complications of scurvy are dysentery, diarrhœa, and malarial fever, which some regard as epiphenomena of the disease. Hemeralopia and nyctalopia have a like origin with scurvy, and the pathological annals of navigation of the last two centuries are filled with the disastrous associations of the forementioned diseases.

If properly treated an uncomplicated case of scurvy leaves no trace. Many ex-soldiers are, however, borne on the Invalid Pension List on account of the results of scurvy incurred in the late Civil War. In these cases the chief sequelæ are loss of teeth, scars from extensive ulcers, and occasional lesions of one or more of the thoracic or abdominal organs.

Simple, uncomplicated cases of scurvy often disappear, as if by magic, on removal of the cause; but the reparative process is ordinarily slow, and severe cases require two months' treatment. The patient may be considered out of danger if, after several days of treatment, he regains the use of his limbs and has no dysentery, chest complication, or bleeding at the nose. An improved state of the skin is also a favorable indication. The prognosis, however, depends on the intensity of the symptoms; upon previous or concomitant diseases, such as fevers and lesions of the digestive organs; upon prolonged treatment for syphilis; upon malarial poisoning; upon the fact of a previous attack; and upon atmospheric and climatic conditions.

The diagnosis of scurvy is a matter of no difficulty. Perhaps some distinction should be made between it and purpura and Alpine pellagra, in order to avoid nosological confusion. The only morbid conditions with which scurvy is likely to be confounded are the different anæmias and spanæmias, hæmatophilia, beriberi, and the cachectic condition brought about by dirt-eating. (See Appetite.)

No disease is more easily prevented, and none is more amenable to treatment than scurvy. The means of its prevention are now so well understood that an outbreak of scurvy among soldiers, sailors, prisoners, or the inmates of an asylum, or among any other persons subjected to discipline or restraint, is, in most cases, presumptive evidence of neglect on the part of somebody. The law takes cognizance of this neglect, as is shown in Sections 4,569 and 4,570 of the Revised Statutes.

The prophylaxis of scurvy is so apparent, after its causes are known, that to particularize the details would be to repeat unnecessarily.

Regarding the prevention of scurvy, the most efficacious hygienic precepts are now a matter of common knowledge. The principal ones that bear emphasizing are the enforcement of dryness and cleanliness, especially on the berth-deck or forecastle of a ship, and the use of so-called antiscorbutics. We have no rational explanation of the power of the latter as a preventive; their use being in the large and true sense purely empirical. New Bedford whalers cruising in the Pacific Arctic provide themselves with a sufficient supply of live pigs, cocoanuts, pickled cabbages, onions, and potatoes. From the captain of a Russian fur-trading vessel I learned of an excellent antiscorbutic in the use of cranberries, especially the little ones that grow in Alaska and the Aleutian Islands. Lime-juice, in great renown with the English, has won for them the sobriquet of "lime-juicers" from Yankee sailors. It is, however, very unpopular among many sailors, because they think the use of lime-juice causes impotency; and it is doubtful whether it be as effective as a liberal allowance of potatoes, onions, sauerkraut, and condensed milk, or the occasional issue of beer, cheap light wine, or even wine of absinthe, the three latter being regarded by Lind as antiscorbutics of the first order. The same authority also recommends eating a bit of raw onion every morning before exposure on deck. When practicable, cider may be added to the dietary, and

the daily use of lemonade at dinner is to be highly commended.

The curative treatment of scurvy being almost entirely hygienic, but little is to be done in a therapeutic way. Admirable results may be obtained from a good dietary consisting chiefly of milk, vegetables, and fruit. (See Grape Cure.) A chlorinated or an antiseptic mouthwash; an alcoholic or a camphorated lotion for the purpuric spots; the administration of brandy or quinine to overcome adynamia and cardiac insufficiency; and rest in a horizontal or sitting position, in order to avoid possible syncope, are the salient and essential therapeutic points to be observed in ordinary cases. The treatment of complications and sequelæ should be mainly directed against the asthenic condition, and so the economy should be fortified against a return of the disease, which may happen on the slightest provocation.

For the future observer there still remains much to be done in clearing up points of disagreement and in filling up the gaps left in the pathological anatomy of scurvy. To this end the newer experimental methods of investigation—chemical, clinical, and histological—should be made to take the place of the old hypotheses and sterile reasonings of our forefathers. In spite of numerous efforts, much remains to be done in the way of investigations bearing upon the component elements of the *blood*, such as a rigorous enumeration of the red globules, the amount of hæmoglobine in the corpuscles, and the chemical analyses of the globules themselves. In addition, it is desirable to know the proportions of iron and potassium, as well as of the principal substances eliminated by the excretions, particularly the urine. A better and more extended study of the state of the capillary system in the principal organs and tissues is a desideratum, and the same may be said of the study of the pathological anatomy of the principal viscera of the abdominal cavity. On the side of the nerve-centres almost nothing has been pointed out up to the present in the pathological anatomy of scurvy, and we are equally ignorant of the anatomical changes that occur within the organs of sight. *Irving C. Rosse.*

SEAL, GOLDEN (*Hydrastis*, U. S. Ph., Yellow Puccoon, Yellow Root, etc.). The rhizome and rootlets of *Hydrastis canadensis* Linn.; order, *Ranunculaceæ*. This is a low perennial herb, with a tuberculated, crooked, yellow rhizome, marked along its upper surface with frequent scars (seals) of fallen stems, and bearing numerous wiry, wavy, or crooked, yellow roots. The aërial stem, situated at the extremity of the rhizome, and surrounded at the base by a few brown scales, is upright, from two to three decimetres long, and bearing two unequal five- or seven-lobed leaves. The lower of these is the larger, and petiolate; the upper is sessile; flower solitary, terminal, about as large as a buttercup; it consists of three fugacious, greenish-white sepals, numerous stamens, and about a dozen pistils; fruit a raspberry-like cluster of red berries. Hydrastis grows abundantly in the northern and western parts of the United States and in Canada. In New England, and the Middle and Southern States it is more scarce. It was originally used by the Indians as a dye and medicine, and has been known to us about a hundred years.

Description.—It comes in pieces four or five centimetres long, slightly branched, or simple, covered with rather numerous rootlets, yellowish-gray outside, bright yellow within; the rhizome is slightly wrinkled longitudinally; odor strong; taste very bitter. The principal active derivatives of Hydrastis are the alkaloid *berberine*, the same as that found in Barberry Bark and other plants, and *hydrastine*. This latter substance, discovered about 1852, crystallizes in brilliant, white, four-sided prisms, soluble in alcohol, chloroform, and ether, but scarcely at all in water. No odor; taste, in solution, bitter. A third alkaloid, *xanthopuccine*, appears to exist in the drug, but is less fully known than the others. The proportion of hydrastine in the dried root is about one and a half per cent. An *odorous principle* and a *resin* have not yet been isolated.

Action and Use.—It is difficult to find in Hydrastis anything more than the usual tonic qualities of the *berberine*-yielding drugs; in small doses they all are thought to improve the appetite and promote assimilation; in large ones they derange the stomach. It is given in intermittent and other fevers, and for the various uses to which quinine is put—sweating, typhoid, diarrhœa, etc. Locally used, Hydrastis is in considerable favor as an ingredient of urethral and vaginal injections, as well as for washes for other surgical cases—ulcers, hæmorrhoids, vegetations, etc.

Administration.—Hydrastis is not often given in substance; the dose would be from three to ten grams. A Fluid Extract (*Extractum Hydrastis Fluidum*) and Tincture (*Tinctura Hydrastis*, $\frac{1}{5}$) are officinal. An infusion may be also made. For a wash or injection hydrastine and berberine are both to be had; doses from two to ten decigrams. "Hydrastin" is an impure preparation obtained in the usual way for "resinoids;" it is a combination of the three alkaloids and some resinous substance. Dose about three decigrams.

Allied Plants.—See Aconite.

Allied Drugs.—Coptis, Barberry, Columbo, etc.

W. P. Bolles.

SEA-SICKNESS. The assemblage of morbid symptoms denominated sea-sickness, or more properly sea-illness, is too well known to require formal definition, since there are but few that have not had both subjective and objective experience of the malady.

In spite of the distressing character of sea-sickness it fails to elicit much pity from others. It is also strange that the unpleasant phenomena of sea-sickness have been so little elucidated; such little advancement having been made in the study of the subject that it is practically a fresh one with an unlimited field of observation, and he that succeeds in working it will reap the reward of a public benefactor. The great medical writers of antiquity scarcely allude to sea-sickness, and the published observations of sea-going surgeons are most meagre. The majority of writers on the subject have been landsmen who knew but little of the sea, and sailors who knew less of medicine. In fact, the subject has been so little scrutinized by physicians, that it presents the remarkable anomaly of the existence of an ailment almost without a medical bibliography, the two hundred or more references to this subject consisting chiefly of a few theses or inaugural dissertations and short journal articles. It is rather to general literature that one must turn to find illustrations of the subject. Plutarch appears to be the first author to describe its symptoms and treatment. The malady is also mentioned by Suetonius and Juvenal, and every school-boy knows of Cicero's desperate resolve to fall into the hands of his executioner rather than endure longer the horror of sea-sickness. In Burton's "Anatomy of Melancholy" sea-sickness is mentioned as being very good at times; in Boswell's "Johnson" the great doctor recommends the salutary effects of a smart sea-sickness; Goldsmith interested himself to the extent of attempting to invent a machine for its prevention; in "Tristram Shandy" the cerebral effects of the malady are felicitously described; and so citations might be extended indefinitely from the "quite, quite down" of Shakespeare to Browning's "swooning sickness on the dismal sea," not to mention the comments of Rabelais and Montaigne.

Most of the attempted explanations of sea-sickness are pure figments of the mind, that of the greatest German *savant* being, in point of fact, but little above that of the humblest fisherman. It is, however, generally conceded that the symptoms are owing to the influence of the motions of the ship, which admit of infinite variation, as anyone may observe while sitting on the quarter-deck, or

when lying in a bunk, during rough weather. In endeavoring to balance or right itself, the ship rolls, pitches, seems to pause, and then darts with a side motion fore-and-aft, or, in more precise language, a variety of oscillations take place around both the transverse and the longitudinal axes of the ship. These motions alone are the cause of sea-illness, and bad smells, heat, sight of the waves, fear, "biliousness," and other alleged causes are mere accessories. The same idea, aphoristically expressed more than two thousand years ago, does not admit of greater refinement, notwithstanding the advanced knowledge of the day.

There are, however, certain unusual and disorderly movements that may cause phenomena similar to those of sea-illness, such as the trembling of the earth during a volcanic eruption or an earthquake, experiences of the kind having been common during the late seismic disturbances at Charleston and Mentone. Riding backward in a railway train, going up and down in a lift or in a balloon, the act of swinging, riding a camel or a dromedary, rapid gyratory movements of the body, the concussion experienced by workmen in riveting boiler-plates, or, in short, any series of unusual and disorderly shocks that disturb the cerebro-spinal or the ganglionic nervous system may bring on this peculiar functional disturbance.

It is estimated that of those who go to sea about three per cent. are never sick, and three per cent. are never well. Others, after temporary illness, recover rapidly; a few are prostrated for weeks, and, in rare instances, some delicate or susceptible persons may never recover. There is also much that is odd and enigmatical regarding individual susceptibility to sea-sickness. Although women are more subject than men, it sometimes happens that a delicate, hysterical girl will escape illness, while a strong man is prostrated. Champion pugilists during a voyage at sea have been overcome, while many of the weaker passengers were exempt. One of the greatest sufferers I have ever known was a celebrated member of the London Athletic Club. The liability to illness is much affected by the class of ship and by certain motions. Many persons will cross the Atlantic with impunity, and yet get ill on a Channel steamer. The sensibility of others is such that travel on a comparatively smooth river or lake causes unpleasant sensations. As a rule, navigation is easiest on a sailing-ship; the tendency to illness is increased on board a paddle-wheel steamer, and it is greatest on board a screw steamer. If the force of the wind should cause a list in the steamer to one or the other side, the tendency to become ill is greater. I have often noticed, in a transatlantic steamer, that passengers who had recovered from an illness incurred during a fore-and-aft motion of the ship, with the wind astern or off the quarter, would invariably become ill again when the wind shifted so as to cause a beam-sea, which changed the direction of the ship's oscillations. Owing to the greater amplitude of the oscillations experienced in going aloft, I have often seen boys become ill on board a training-ship, who kept well as long as they remained on deck. After staying ashore for some time, the inuring process of getting one's sea-legs has often to be repeated, even in "old sea-dogs." Some years since, in a gale on the Pacific, just after quitting the Golden Gate, I was a fellow-sufferer with an old Nantucket whaling captain; and though having personal claims to being something of a sea-rover, I lately became squeamish on board a steam yacht while witnessing a race. Nothing dampens enthusiasm like sea-sickness. Men full of military ardor start on an expedition, and after a day or two at sea on board a transport suddenly come to the conclusion that there is really no cause for war. History tells how Bonaparte's sea-sickness paralyzed and brought to naught his grand enterprise of invading England.

Many professional sailors suffer greatly from sea-sickness, and even Nelson was a martyr to this cause. I know of several naval officers who are great sufferers; one, a fleet captain, tells me that he often, in his cabin, suffers agony on this account. With many persons the susceptibility is so great that the sensorial perversions continue for days after going ashore, and in others anything suggestive of the sea causes unpleasant sensations. I have known such to be caused by a boatswain's whistle. A naval officer of my acquaintance, who is sorely troubled by this form of illness, has all the premonitory symptoms on the reception of his orders for sea duty; and I know an old lady in New Bedford who is unable to look at the heaving figure of a ship on the face of an old-fashioned clock without becoming ill. Another instance, in which the mere recollection of the occurrence caused renewal of the nausea, is that of the late Henry Ward Beecher, who relates that, many years after his first voyage across the Atlantic, he heard some sailors in a Brooklyn dock singing the same old "chanty" song that he had heard when ill at sea, and that the mere listening to this song produced symptoms of sea-sickness.

That something less than perverted sensation may arouse the unpleasant associations of sea-sickness is evidenced by the effects upon a highly susceptible person on reading one of Clark Russell's novels, say, "Wreck of the Grosvenor" or "Sailor's Sweetheart." Carried almost beyond the realms of fancy, one sees a complete nautical picture in his mind's eye; he hears the thud of the sea and the sounds of the running rigging; smells the tarred rope and bilge, and feels the close atmosphere and nauseating roll of the ship.

The cerebral action which recalls such phenomena can hardly be said to exist in the lower order of animals—such as birds, dogs, sheep, horses, and elephants—who often suffer greatly from sea-sickness. It is easier to look for a mechanical or physical cause in the disturbance of the cerebro-spinal fluid from the effects of a centrifugal force, analogous to the change that takes place in such a liquid substance as milk when placed in the tubes of a whirling machine for testing.

Similar effects of cerebro-spinal disturbance appear in a tumbler-pigeon, which seems lifeless after being whirled around for a few moments with the head under its wing; gulls, Mother Carey's chickens, and other aquatic birds, when placed on a ship's deck become nauseated from the rolling and pitching, that is to say, from the great oscillations of the ship around its axes; and many persons have observed the phenomena of sea-sickness in children who have ridden too long on a merry-go-round.

The many explanations that are offered to account for the symptoms of sea-illness differ one from another, and are all more or less objectionable. One of the causes assigned to account for the nausea is neither the motion in itself nor the appearance of motion, but the violation of the habitual conceptions of contrasted effects of motion, which may obtain not only in those having sight, but in the blind. The motions of the ship cause mental concepts totally at variance with the ordinary experience.

Dr. William James, of Boston, states that deaf-mutes, as a class, are exempt from sea-sickness, and for that reason it is suggested that the malady does not occur in the case of destruction either of the auditory nerves or of their labyrinthine terminations, and that the semicircular canals are the probable starting-point of the affection. An illustrative instance is mentioned in which a person much subject to sea-sickness was entirely cured after receiving a blow on the head which crushed the mastoid process and caused deafness.

That there is some connection between aural defects and certain symptoms simulating those of sea-illness appears to be the fact. Such symptoms are at times observed when the Eustachian tube is obstructed, and still more commonly when there has been concussion of the labyrinth, or when the structures contained within this cavity have undergone pathological changes as the result of cerebro-spinal meningitis.

Whether the nausea be owing to irritation in certain states of defective aural mechanism; to irritation of the nerves of the eye caused by the apparent instability of all surrounding objects; to agitation of the abdominal viscera; to the continuity of the muscular contractions necessary for the maintenance of the equilibrium; to the pumping motion of the liquids of the body, analogous to the rise and fall of the mercury in a barometer; to reflex

action disturbing the medulla, the spinal cord, the solar plexus, and the splanchnic nerves, or to concussive impact resulting in cerebral anæmia and diminution of the brain mass, we are not in a position definitely to say. These are questions too subtile and problematical, but it is possible that there is more or less truth in each, and that the symptoms vary accordingly as the cerebral, the spinal, or the visceral contents are most acted on; so that in some, whose cerebro-spinal system is less resistant, the trouble experienced is headache, giddiness, and unsteadiness, rather than the vomiting and loss of appetite of others, whose organic nervous system is principally affected.

No illness is less harmful and sooner forgotten than is this. Ordinarily it passes off in a few days, leaving the patient none the worse for his experience. In fact, it is highly beneficial in many ailments, as affections of the liver and digestive organs, melancholia, certain kinds of mental alienation, and obstinate intermittent fever, which I have known to be broken up by this curative means alone when all others had failed; and were it not for the rare occurrence of death in persons suffering from some antecedent malady, and the alarming weakness and erethism produced in other delicate subjects, the matter of deciding whether there is any effective prophylactic or any infallible treatment that may ward off, alleviate, and abate the ravages and woes of this unpleasant adjunct of sea-travel, would scarcely occupy the serious attention of the physician.

As a rule, sea-sickness is dangerous in organic disease of the stomach, brain, heart, or lungs, and to pregnant women. All such should avoid sea-voyages. Hæmorrhages and hernia may occasionally result from the straining caused by the frequent vomiting, and defective nutrition may bring about great wasting of the body. Obstinate constipation, marked diminution of the urine, and occasional spasmodic contraction of the urethra, are among what may be called the complications of sea-sickness. In addition to these, sugar is sometimes found in the urine, owing to irritation of the diabetic centre in the medulla; convulsions may occur in some cases, and instances of temporary insanity from this cause are reported. I have seen one such case in a Frenchman in crossing the English Channel from Dieppe. Dr. Reynolds states that he has seen three cases.[1]

Pretended specifics for sea-sickness have not been wanting from the earliest times, and most of them, from old women's remedies down to the sort of liver-pad praised by Bacon, are as worthless as they are foolish. We do not know the contents of the box of which Shakespeare says, "If you are sick at sea, a dram of this will drive away distemper" ("Cymbeline," act iii., scene 4.) Nor was it perhaps so effective as the rope's-end formerly used on green midshipmen in the British navy; or the bucket of cold water that is usually dashed over sea-sick men on board whaling-vessels; or the treatment pursued in the case of boys on training-ships, who are supported by two other persons, if necessary, and made to walk the deck and swallow occasional spoonfuls of hot soup until they get well. Such heroic measures, of course, cannot be resorted to when dealing with delicate, susceptible people, invalids, and pregnant women, who make up the larger part of the passenger list of an ocean steamer; so recourse is often had to such drugs as chloral, opium, chloroform, amyl nitrite, and numerous other sedatives, most of which are of little more value than the colored spectacles, supposed to prevent sea-sickness, which were sold in large quantities, a few years since, by an enterprising individual in Cadiz to Spanish soldiers embarking for Cuba.

Although like advising a sufferer from toothache to be philosophical, it is best, if one must go to sea, to exercise his courage and force of will. He must keep up and show his stoicism by remaining in the open air, and eating at usual hours, regardless of the fact that the food is vomited. The vomiting, which, by the way, is not one and the same thing with sea-sickness, is often allayed by lying down and by swallowing crushed ice or small quantities of iced champagne. According to Dr. Coniat, of the Compagnie Générale Transatlantique, the rebellious vomiting is arrested with "prompt and evident success" after faradization of the epigastric region, combined with the external employment of a solution of atropia, the intensity of the current being graduated according to the susceptibility of the person and the obstinacy of the vomiting.[2] The debilitated stomach is soonest brought back to its normal state after drinking a little bitter beer, or eating an orange, a lemon, or other bland and delicate food; but, as a rule, all spirits, liquids, and sweets should be avoided, as they disturb the stomach and irritate the gastric mucous membrane to the extent of causing a predisposition to illness. A teaspoonful of Worcestershire sauce is often excellent in the earlier stages; and fat bacon, smoked herring, and curry will often stay down when other things are vomited.

Mechanical contrivances against sea-sickness, as tight belts, swinging beds, the Bessemer saloon, and the project of affording greater amplitude by connecting two or four vessels after the manner of a catamaran, have proved inoperative.

A course of exercise in a swing, with a view to preparing for a voyage, has proved as futile as the habit of taking medicine previously to embarking. No malady, in fact, has afforded a more ample field for polypharmacy, and none is more rebellious to treatment. In fact, there is no remedy for sea-sickness, and as long as men go to sea, so long will they be liable to suffer from this distressing malady. *Irving C. Rosse.*

[2] Archiv. Méd. Navale, November, 1868.

SEBACEOUS CYST, or "wen," as it is popularly called, appears as a variously sized, firm or soft, roundish tumor, seated in the skin or subcutaneous connective tissue. The skin covering the tumor is natural in color, or whitish from stretching. The tumors may occur singly or in great numbers, and may vary from the size of a pea to that of a walnut, or larger. They are usually firm, but sometimes doughy, and are generally freely movable and painless. Their usual seat is upon the scalp, face, back, and scrotum, though they may be met with anywhere, even on the soles, it is said. They may last for years unchanged, but sometimes break down and ulcerate. They may degenerate into epithelioma in old persons. Some sebaceous cysts are flat, with a minute hole in the centre, others tend to rise above the surface of the skin and become semiglobular. The latter are those commonly found upon the scalp, when they are devoid of hair.

The contents of sebaceous cysts may be milky or cheesy in consistence, and are often decomposed and fetid. The tumors are, in fact, nothing more than enormously distended sebaceous ducts and glands, the walls of which have become hypertrophied until they form a tough sac.

The treatment of sebaceous cyst is excision. The cyst-wall should be carefully dissected out, as otherwise the disease is apt to recur. *Arthur Van Harlingen.*

SEBORRHŒA. A disease of the sebaceous glands of the skin, characterized by an increase in the quantity of sebum poured out; and also, in most cases, by an alteration in quality of the secretion. There are two varieties—*seborrhœa oleosa* and *seborrhœa sicca.*

Seborrhœa oleosa appears in the form of an oily coating upon the skin, giving it an unctuous and greasy feel. Its most common seat is on the scalp and about the face, particularly the nose and forehead, where it appears as a greasy coating, containing more or less dust and dirt, and looking as though the skin had been smeared with a dirty ointment. In the scalp it collects on the hair, giving it a dark, limp look, as if it had been freely oiled, or, when the scalp is bald, looking as if oil had been poured over it.

Seborrhœa sicca, or dry seborrhœa, occurs in infants as *vernix caseosa*, or smegma of the new-born. Here it is almost physiological, and is usually soon removed. If it remains it becomes a diseased condition, and as such is often seen upon the scalp. Dry seborrhœa shows

itself on both the hairy and non-hairy portions of the body as a more or less greasy mass of scales, of a dirty yellowish color, and somewhat adherent to the skin. On the scalp these masses are larger and oilier, tending to cling to the skin in thick plates, and leaving, when picked off, a smooth, grayish, moist or oily surface beneath. In old persons the scalp, and sometimes the region of the beard, is covered to a greater or less extent with a brown, adherent greasy coating, which is essentially seborrhœic in character.

Seborrhœa of the scalp, like pityriasis, with which it is sometimes confounded (see *Pityriasis simplex*), is sometimes followed in the young by premature baldness. If taken in time, however, baldness from this cause can be prevented, and it is desirable in all cases to remove the seborrhœic condition, even if it gives rise to little or no annoyance.

Seborrhœa of the foreskin and glans penis is an abnormal flow of the normal secretion of this part, known as *smegma præputii*. If not attended to, it leads to balanitis, from the irritation of its rapidly decomposing sebaceous products.

Seborrhœa is induced by a variety of causes, prominent among which is the chlorotic or anæmic state. It is more apt to occur about puberty or in early adult age. It may occur in persons otherwise healthy. In such cases it is usually curable by local measures.

The diagnosis of seborrhœa is usually not a matter of much difficulty, the evidently sebaceous character of the products of disease pointing out its nature with sufficient certainty. The treatment of seborrhœa should usually be both constitutional and local. Fresh air and exercise, especially in the case of young women, is to be insisted upon. Attention should also be paid to diet. The history should be looked into, and any functional irregularities corrected when possible. Success in treatment often depends upon ascertaining and meeting the exciting cause in the individual. Cod-liver oil, iron, and arsenic are the most generally useful remedies. Iron may be given in the form of the tincture of the chloride alone, or with phosphoric acid. Arsenic is best given as Fowler's solution, in the dose of four or five minims, thrice daily, in wine of iron. Cod-liver oil is particularly beneficial in cases in which oily seborrhœa is accompanied by acne, particularly acne indurata in strumous subjects.

The local treatment of the disease is very important. In seborrhœa of the scalp the scales and crusts must first be removed. If they are hard and caked, as is sometimes the case in old people, the scalp should be soaked in olive- or almond-oil overnight. Hot water and soap will then remove the softened crusts.

An excellent means of removing the crusts and scales is by means of the spiritus saponis kalinus, an alcoholic solution of Hebra's green soap. A tablespoonful of this may be applied to the scalp with a sponge and a considerable quantity of warm water added, so as to make a lather. After vigorously shampooing the scalp for a few minutes, the soapy matters are to be washed away with an abundance of clear warm water, and the scalp dried quickly with a soft towel, when it is ready for the application of the more strictly remedial agents, usually in the form of medicated oils. An excellent formula is the following:

℞. Acidi carbolici	Gm.	3 (gr. xlv.)
Ol. ricini	Gm.	4 (f ʒ j.)
Ol. limonis	Gm.	2 (f ʒ ss.)
Aq. cologniensis ......ad	Gm.	64 (f ℥ ij.)

On the bald scalp and other places where there is no hair an ointment of one part of sulphur to eight parts of cosmoline may be employed.

The prognosis of seborrhœa is generally favorable. The oily variety is that which is most apt to be stubborn under treatment. *Arthur Van Harlingen.*

SECRETION, PHYSIOLOGY OF. Secretion in general may be defined as the separation of certain products from the blood, usually in a liquid form, which are poured out on the free epithelial surface of the secreting organ. When the secreting surface happens to have a somewhat complicated structure it is usually spoken of as a gland. Simple epithelial membranes, such as the pleura or peritoneum, may, and often do, form secretions from the blood, and though not ordinarily described as glands, there is, nevertheless, no fundamental distinction between the process of secretion in them and in the more complicated secreting organs, such as the salivary glands. That is, in both cases we have to deal with secretions, as defined above, and though the secondary differences between the two are many, they are, perhaps, not more numerous than those which exist among the glands, usually described as such, in the body. Indeed, the phenomena shown in the action of the different glands are often so diverse that some physiologists are inclined to doubt whether any general theory of secretion will ever be obtained; but these differences, as well as the resemblances, will be better appreciated after the action of the various glands has been described.

Defining a gland as a secretory organ, the simplest form of gland that we have to consider consists of three essential parts, viz., (1) a simple basement-membrane, or membrana propria, supporting on one side a layer (2) of secreting cells, nucleated epithelial cells, and on the other side (3) a network of blood-capillaries, as shown in the diagram (Fig. 3417).

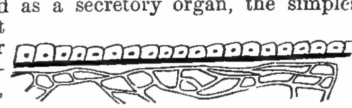

FIG. 3417.—Typical Secreting Surface. *a*, Basement-membrane; *b*, secreting cells; *c*, capillary network.

All the secreting organs of the body are constructed essentially on this plan; and the serous, mucous, and synovial membranes furnish examples of this simplest form of secreting apparatus. It is obvious, however, that if all secreting organs were constructed exactly in this way, as plain surfaces, the extent of the secreting surface would be greatly limited. The various complications of structure that we meet with in the different glands seem to have for their primary purpose economy of space.

A plain secreting membrane, such as that described, may have its surface increased, without occupying more space, in one of two ways. First, by protrusion in the form of folds. These folds or processes may be either simple or compound, according to the extent of surface demanded, as shown in Fig. 3418. Examples of this

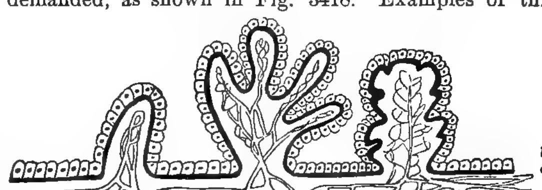

FIG. 3418.—Increase of Secreting Surface by Protrusion. *a*, Basement-membrane; *b*, epithelial cells; *c*, network of blood-vessels.

method of increasing the surface are found in the villi of the mucous membrane of the small intestines, and in other places, though this method seems to be one that is not generally used. Second, by a denting in of the surface to form a crypt or follicle. The cavity thus formed may be either tubular or saccular. Most of the glands of the body are formed on this plan, and may, therefore, be divided into two great classes—the tubular glands and the saccular, or, as they are more commonly called, the racemose glands (from *racemus*, a cluster of grapes). The invagination of the membrane may form only a simple tube or sac, making what is known as a simple tubular or racemose gland—as in the crypts of Lieberkühn of the small intestine, the sweat-glands, and some mucous crypts. Diagrams of this form of gland are shown in Fig. 3419. The increase in the extent of surface in these cases is not very great, unless, as in the sweat-ducts, the simple tube is very much elongated and twisted into a compact knot. The invagination, however, instead of

being a simple tube or sac, may be variously compounded, forming what are called compound glands, of which again we have two kinds—compound tubular and compound racemose glands—diagrammatic representations of which are given in Figs. 3420 and 3421.

In the compound racemose gland the separate little

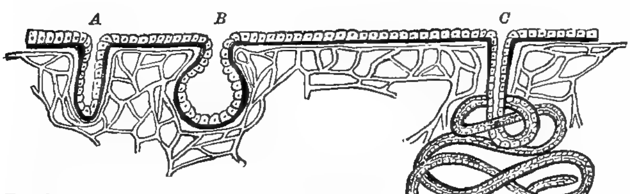

Fig. 3419.—Increase of Secreting Surface by Invagination. *A* and *C*, forms of simple tubular glands; *B*, simple racemose gland.

sacs are spoken of as alveoli or acini, and they open into canals or ducts which finally unite into one or more common secretory ducts. The salivary glands and pancreas are good examples of this type of gland, the secreting surface being enormously increased without any great loss of space. The different alveoli are united into lobules, and these, bound together by connective tissue, form the gland. The actual secreting cells are found in the alveoli, while the epithelial cells lining the ducts have, probably, simply a protective function. Examples of the compound tubular glands are found in the kidneys and testes, and to a less marked extent in the gastric tubules of the stomach. In the kidney and testes, by this subdivision of the tubular gland, a really vast extent of secreting surface is obtained within a very limited space. In such glands we can also distinguish a portion in which the epithelial cells have an active secretory function, from that known as the duct of the gland, in which the epithelial cells seem to form simply a protective covering.

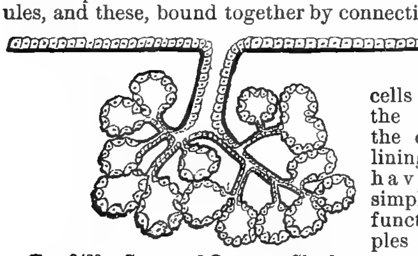

Fig. 3420.—Compound Racemose Gland.

It was formerly customary to divide the secretions into two great classes, viz., excretions and secretions proper. Johannes Müller, in his "Physiology," defined these two classes in this way · Excretions are substances which exist already formed in the blood, and are merely eliminated by the gland without being changed in the process—the urea of urine, for instance; while the secretions proper are substances which do not previously exist in the blood, but are first manufactured from it by the cells of the secreting gland—a good example of this type is found in the milk produced by the mammary gland.

It has as yet been found impossible, however, to establish any such distinction as this. Even in the case of urea it has long been doubted whether the kidneys simply eliminate this substance from the blood after it has been formed in other tissues, many contending that the cells of the uriniferous tubules take part in the formation of the urea. Indeed, the question may still be regarded as an open one, needing further investigation before decisive statements can be made.

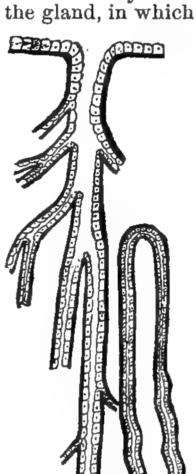

Fig. 3421. — Compound Tubular Gland.

The more usual conception of an excretion as a product, formed in a gland, which is of no further use in the animal economy, and is simply eliminated from the body as waste matter, while sometimes a convenient expression, is also inadmissible from a scientific standpoint. In the first place, we have secretions, such as the bile, which contain both waste products, of which no further use can be made, and also true secretory products of great functional importance in the body. In the second place, the method of formation of these so-called excretions—the urine, for instance—cannot be clearly separated from the processes of ordinary secretion. It will be better, then, to abandon any attempt to make a distinction between secretions and excretions, and to describe the processes in both cases under the general term of secretion, as is done in the best text-books of physiology at the present time.

Another classification of secretions that has been suggested divides them into transudations and secretions proper. By transudations we mean those secretions which can be conceived as derived from the blood by the simple physical processes of filtration and diffusion. Examples of this are found in the secretions formed on serous membranes—the pericardial liquid, or that in the tunica vaginalis of the scrotum, for instance. These liquids contain no specific elements, such as we find in most secretions, but have a chemical composition similar to that of the blood from which they are derived. It would seem very probable, then, at first glance, that such secretions are formed as the products of filtration and diffusion. The plasma of the blood in the capillaries is under greater pressure than the lymph impregnating the tissues, so that we should expect a steady filtration of the plasma through the capillaries into the lymph of the tissues, and, in turn, a transudation of this lymph upon the free surface of membranes, such as the ordinary serous membranes. According to this view the epithelial cells of such a membrane take no active part in the formation of the transudation or secretion, whichever we choose to call it. Since in all secretions, even those in which we have a specific element characterizing the secretion, and undoubtedly formed *de novo* by the metabolic activity of the gland-cells, we have also certain products, the water and salts, which may be considered as derived directly from the blood by the physical processes mentioned, it will be necessary to distinguish in each secretion two kinds of substances—one manufactured by the cells of the gland from nutritive material furnished by the blood, or, more correctly speaking, the lymph; and one derived from the lymph by filtration and diffusion—that is, transudation-substances—whose formation is not dependent upon the life-processes of the gland-cells. Some such distinction is actually made at present by physiologists, as we shall see when describing the secretion of the salivary glands. But the distinction is not usually drawn as sharply as indicated above, for the reason that many facts are known which seem to show that the formation of even the water and salts of secretions is in some way connected with the activity of the secreting cells.

To illustrate the difficulties encountered in explaining transudations by referring them to the physical processes of filtration and diffusion, some recent experiments of Tigerstedt and Santesson[1] may be quoted. These experimenters found that while filtration takes place readily through dead animal membranes, nevertheless, when living membranes were used, such, for instance, as the lung of a frog, and filtration was attempted under the same pressure, with serum or normal salt solution, no filtrate at all was obtained. If the living lung-tissue that allowed no liquid to filter through it was killed by heat, or by any other means, filtration quickly commenced. Similar results were obtained with the frog's intestines and abdominal wall; and if we were justified in applying these results to the other membranes of the body, it would be necessary to explain transudations by something more than simple physical laws. The authors cite many facts to show that even the formation of lymph, which has always been regarded as caused by the filtra-

tion of blood-plasma through the thin walls of the capillaries, is apparently independent of the blood-pressure, in many cases at least; for, if produced by filtration, the amount of lymph obtained ought to increase with increase of blood-pressure. They conclude from their experiments that the transudation of the blood-plasma to form the lymph is caused by the activity of the cells composing the capillary walls, and this conclusion, if correct, will apply *à fortiori* to transudations of the lymph through the basement-membrane and epithelial covering of glandular walls. Investigations like this compel us to be cautious in explaining the simplest phenomenon of the animal body by physical laws obtained from the study of dead matter. It may be convenient to speak of transudations as opposed to secretions proper. The distinction has some basis in the fact that in transudations the chemical constituents are qualitatively the same as those of the blood or lymph from which the transudation is derived, while the secretions proper are characterized by the presence of certain constituents not normally contained in the blood, but manufactured in the glandular cells in consequence of their metabolic processes; nevertheless it would be gratuitous, at present, to assume that in transudations the epithelial cells act simply as a filter or membrane through which certain things pass in consequence of a greater pressure on one side. It is certainly possible that the epithelial cells may take an active part in the production of the water and salts of a secretion, as well as in the formation of mucin or specific ferments. As long as the word transudation has the significance it possesses at present, a division of the secretions into transudations and secretions proper has, perhaps, as little right to acceptance as the old separation into excretions and secretions.

The facts known and the theories maintained, with regard to secretion, can be best presented by a description of the physiology of the salivary glands and the pancreas, from the study of which most of our knowledge on this subject has been obtained. But before passing on to the physiology of these glands it will be well to review briefly the principal theories of secretion held by physiologists from the time of Haller, since the relative importance of the facts which we now possess can be more clearly emphasized by such a comparison. Though Haller is credited with being one of the chief opponents of the old mechanical school of physiologists, the physiology of secretion as given by him is almost entirely mechanical. He divided the secretions into four classes, and held that the substances composing these secretions all pre-existed in the blood, from which they were separated by various mechanical means. The alveoli of the glands were supposed to be formed of "arteries and veins, divided and subdivided," and the arteries were connected directly with the ducts of the glands by pores or canals of varying sizes. This belief in the connection between the arteries and ducts was a deduction from the heroic injections of those days, or what Haller calls "the superlative art of great anatomists," by which wax injections were forced from the arteries into the gland-ducts. The fact that the different secretions, although derived from the same source, the blood, possess marked and constant differences of composition was explained by supposing that the pores or canals connecting the arteries and ducts were of different sizes; none of them were large enough to allow the unchanged blood with its corpuscles to pass through, but some were smaller than others and allowed only the lightest and most volatile particles of the blood to pass, while the larger pores gave passage to the grosser particles. Additional factors in causing the differences in the different secretions were found in the angle, whether acute or a right angle, which the artery supplying the gland made with the main trunk, and also in the difference in velocity of the blood-stream in the secreting arteries, depending on the width of the artery, distance from the heart, etc. Similar mechanical views were held well into the nineteenth century, until the masterly work of Johannes Müller, on the structure and physiology of secreting glands, laid a true foundation for modern views.

Müller proved that no pores of communication exist between the arteries and ducts of the gland; he described the anatomy of the glands and the relations of the blood-vessels to them, and showed that the nature of the secretion was not dependent on the gross structure of the gland, nor on the way in which its vascular supply was obtained. "The nature of the secretion depends solely on the peculiar vital properties of the organic substance which forms the secreting canals," is his final conclusion, and he states his belief that "the variety of secretion is due to the same cause as the variety of the formation and vital properties of organs generally; the only difference being that, in nutrition, the part of the blood which has undergone the peculiar change is incorporated with the organ itself, while in secretion it is eliminated from it."[2] The extensive researches of modern times have added very much to our knowledge of the histology and chemistry of secreting tissues; but, as Heidenhain remarks, if we substitute the term "cells" for "living substance," or "organic substance," the words of Müller just quoted express the conclusion to which modern physiologists have come, and but little can be added to them.

The most important advances made since Müller's work have been connected with the cell-theory of Schwann, and the discovery of the laws of diffusion through membranes by Dutrochet. Schwann's conception of the cellular structure of the animal body was followed by careful histological investigations of the structure of glands as well as of other organs. The glandular epithelium was described, though the physiology of secretion was not at first directly benefited by this discovery. The laws of diffusion of liquids through membranes seemed to promise great things for the physiology of secretion, and investigations upon this basis were eagerly taken up by some of the best physiologists. As a consequence of this, the physical theories of secretion again came to the front, and have since occupied an important position in the explanation of secretory phenomena. Ludwig, in his "Physiology" (vol. ii., 1861), develops in detail the conceptions of filtration and diffusion in their application to the processes of secretion. According to him, the forces concerned in the production of secretions are filtration, diffusion, and also the action of stimulated nerves, though he was careful to say that other forces still might contribute to this result. Ludwig knew, of course, at the time of the publication of his "Physiology," that the organic material found in the secretions of the salivary gland, etc., was not obtained directly from the blood, but was made in the gland itself; but it is important to notice that, by the aid of the simple physical phenomena of diffusion and filtration, he was able to build up a theory of secretion that to a large extent accounted for the specific differences found in the secretion of different glands. The discovery by Ludwig that some of the glands—the submaxillary gland, for example—give a secretion when the nerve-fibres going to them are stimulated, was an extremely important addition to our knowledge of secretion, and has played a large part in recent theories of the physiology of glands. The researches of the same distinguished physiologist proved that the secretion in this case is not owing to simple filtration from the blood, even if the water and salts alone of the secretion are considered; for it was found that in some cases the pressure in the gland might rise to nearly double the mean pressure of the blood in the carotid artery. An equally important observation, also made by Ludwig, was that the temperature of the gland and of its secretion increases during the act of secretion, a fact which would seem to indicate that active chemical changes take place.

At about this same period, also, Claude Bernard found that during stimulation of the nerve going to the submaxillary gland the blood-flow through the gland is greatly increased, suggesting again an increased nutritive activity of the gland in secretion. If Ludwig, at the time his "Physiology" was published, laid too much emphasis on the purely physical factors in secretion, it is nevertheless mainly owing to the important discoveries made by

himself and his pupils that these physical forces have been found to be insufficient. The numerous researches of the last twenty years have shown that, in many of the glands we have true secretory nerves, comparable in their functions to the motor nerves of muscles. Just as stimulation of the nerve of a muscle causes the muscle to enter into functional activity, to contract, so the stimulation of the secretory nerve causes the gland to enter into functional activity, and form its proper secretion. Chemical examination of these secretions has shown that, in some glands at least, the most distinctive constituents of their secretion do not exist at all in the blood, but are formed within the gland.

This dependence of secretion on nervous influences, and the undoubted chemical changes which take place in the gland during its period of activity, have forced us back again to the position held by Müller, that the nature of the secretion depends upon the properties of the living substance which forms the glands. This living substance we now know consists of glandular epithelium cells, and it is to-day the most difficult problem in the study of secretion to understand the properties of these secreting cells. As Müller pointed out, it is only a particular case of the wider problem of nutrition shown by all living cells. A satisfactory theory of secretion must give us some conception of the metabolic changes undergone by the gland-cells at rest and during activity, and the way in which nervous influences affect these changes. We are indebted to no one more than to Heidenhain for what we know at present with regard to the action of the nerves on secretion, and the histological changes shown by the gland cells during rest and activity. His study of the cells of the glands, together with similar work by Kühne, Langley, and others, forms the most important contribution of recent times to this difficult problem. We are far, as yet, from having sufficient data for the construction of a general theory of secretion applicable to all glands, but a large number of facts tending in this direction have been accumulated, especially in the case of the salivary glands and the pancreas. A detailed account of the physiology of secretion in these glands, therefore, will best show the nature and importance of the views now held. The knowledge that has been gained of the physiological processes involved in the secretion of these glands is more complete than for the other glands of the body, though the views presented may be, and are, looked upon as the foundation for a general theory of secretion. But the application of the views derived from the study of these glands to the secretions formed by other glands, is in many cases simply a matter of inference, and lacks any experimental basis.

Salivary Glands.—We can take it for granted that the gross anatomy of these glands is sufficiently well known, and that we may pass at once to a description of their histology, as far as it is necessary to an understanding of their functional activity. Heidenhain distinguishes in the salivary glands two different types of secreting cells, characterized both by the nature of the secretion formed and by the histological appearances of the cells. Glands containing cells of the first type give a thin, watery secretion containing, in addition to the water, only albuminates, salts, and, in some cases, a diastatic ferment. He speaks of them as *albuminous* (or *serous*) *glands*, and examples of this class are found in the parotid gland of man and the mammalia generally, and in the submaxillary gland of the rabbit. Glands of the second type he names *mucous glands;* the secretion which they form is thicker and more mucilaginous, containing mucin as its principal constituent, in addition to a certain amount of salts and albuminates. The submaxillary gland, in most mammalia, and the sublingual belong to this type. The submaxillary gland of man is of a mixed character. Most of the alveoli contain only granular albuminous cells; some contain only mucous cells, and others have partly albuminous and partly mucous cells. The sublingual of man is also a mixed gland, but approaches more nearly the type of mucous glands than the submaxillary.

The alveoli of the albuminous glands consist of a basement membrane, or tunica propria, covered with the glandular epithelial cells. The basement membrane itself is formed of a number of flattened and branched connective-tissue cells, the branches fusing with one another to form a network, while the spaces between the branches are filled up by a structureless membrane or matrix. The gland-cells are of a polygonal or cuboidal shape, and are characterized by their very granular structure. On this account the boundary line between the different cells is seen with some difficulty. Each cell shows a distinct nucleus often of an irregular shape, and a number of dark granules in the body of the cell, which are colored by the different staining reagents, such as borax carmine and Heidenhain's hæmatoxylin. An example of this type of gland is shown in Fig. 3422. The alveoli of the mucous glands have a

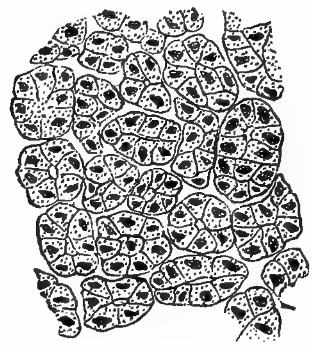

Fig. 3422.—Albuminous Gland (Resting). Parotid of the Dog. (After Heidenhain.)

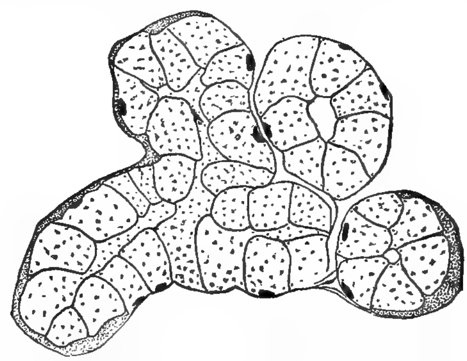

Fig. 3423.—Mucous Gland. Submaxillary of Dog. Resting stage. (From a camera-lucida drawing of a gland stained in Heidenhain's hæmatoxylin.)

basement membrane of the same structure as in the albuminous glands, but the secreting cells upon it are of quite different appearance, as shown in Fig. 3423. They are large, clear, and possess few granules; each has a

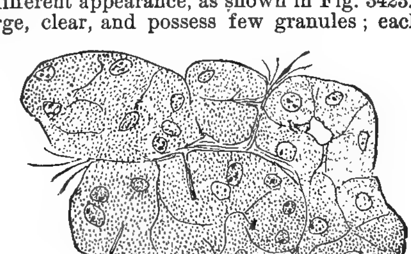

Fig. 3424.—Human Submaxillary Gland. (From a camera-lucida drawing of a gland stained in Heidenhain's hæmatoxylin.)

distinct nucleus which lies toward the base of the cell. The clear substance making up the body of the cell does not stain, and gives the micro-chemical reactions of mucin. In perfectly typical mucous glands there are often

found cells of another character, granular protoplasmic cells, lying between the mucous cells and the basement membrane. These cells are usually spoken of as the *demilune cells of Giannuzzi*, and play an important part in the functional activity of the gland. (See Fig. 3425.)

The secretory ducts in both types of glands show about the same structure. The larger ducts are lined by a

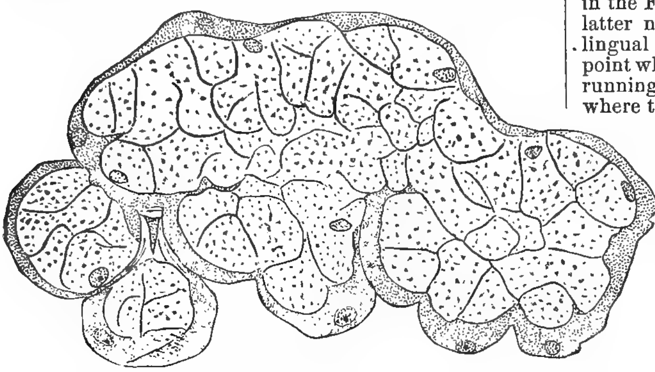

FIG. 3425.—Submaxillary Gland of Cat, showing the Demilune Cells. Camera-lucida drawing.

simple columnar epithelium, which, in all probability, has only a protective function, and cannot be considered as a secreting surface. The smaller ducts leading to the alveoli have also a layer of columnar or cuboidal epithelial cells, which show toward the base, where they sit upon the basement membrane, a striking longitudinal fibrillation. These small ducts are united to the acini by what are known as the "intermediate piece"—ducts of the finest calibre—which in the mucous glands are lined by short cuboidal cells, that, at the junction of the tube with the acinus, pass suddenly into the large, clear, secreting cells of the gland. The cells of the intermediate piece in the albuminous glands are said to be more elongated and spindle-shaped, and project some distance into the alveolus. The salivary glands are supplied with nerve-fibres from the sympathetic and cranial nerves, and histological examination of the gland shows a rich network of nerve-fibres and ganglia between the lobes and acini. Some of these fibres are vasomotor, and are distributed to the blood-vessels of the glands; others are undoubtedly secretory, and in some way connected with the secreting cells. The way in which the secretory fibres end in the cells has not yet been determined satisfactorily. Some years ago Pflüger published several papers in which he described in detail how the nerve-fibres penetrated into the cells of the alveoli and ducts, and the axis-cylinder broke up into fibrils which were lost in the cell. But these results have not been confirmed by later histologists, so that we are not justified in accepting them, although the facts known with regard to the physiology of secretion seem to demand some such connection between the cells and nerve-fibres as that described by Pflüger.

Influence of the Nerves on the Secretion of the Salivary Glands.—In 1851 Ludwig discovered that after continuous stimulation of the chorda tympani nerve going to the submaxillary gland, in the dog, the saliva secreted suffered a change in its chemical composition of such a nature that the percentage of solid constituents, especially of the organic substances, was diminished. Heidenhain afterward took up the same line of experiments, and to his thorough and thoughtful work we owe most of our knowledge on this subject. An account of his experiments may be found in *Pflüger's Archiv für die gesammte Physiologie*, vol. xvii., p. 1, from which the following account is chiefly taken. His experiments were made upon the submaxillary gland of the dog, and the parotid gland of the dog and the rabbit. The submaxillary gland of the dog derives its nerve-fibres from two sources: First, cerebral fibres which originate in the facial nerve, but afterward leave this nerve in the Fallopian canal to join the chorda tympani; this latter nerve, after running for some distance with the lingual branch of the fifth cranial nerve, leaves it at the point where the lingual crosses the duct of the gland, and running along the duct reaches the gland. At the point where the chorda tympani leaves the lingual there is a small ganglion—the submaxillary ganglion. Second, sympathetic fibres which leave the sympathetic trunk above the first cervical ganglion, and pass to the gland along the two branches of the facial artery which supply the gland with blood.

If the chorda tympani is stimulated by weak induction shocks the gland almost immediately begins to secrete, and this secretion, by proper regulation of the stimuli, may be kept up for hours. The secretion obtained in this way is comparatively thin and watery, and contains not more than one or two per cent. of solids when evaporated to dryness. If the sympathetic fibres are stimulated in the same way, quite a different result is obtained. The secretion in this case is relatively small in amount, and flows very slowly. Instead of being thin and clear, like that obtained by stimulating the chorda, it is thick and turbid, and may contain as much as six per cent. of total solids after evaporation to dryness. The results of stimulation of the two sets of fibres show other differences, especially in the circulatory changes in the gland. During stimulation of the chorda the abundant flow of saliva is accompanied by a greatly increased flow of blood through the gland; the whole gland becomes of a reddish hue; the veins passing off from it are distended by the increased flow of blood through them, and, if they are cut, the blood flows from them in a much stronger stream than in the resting gland, of a redder color, and often with a decided pulse. We must suppose, then, that the chorda contains, in addition to secretory fibres belonging directly to the gland, also vaso-dilator fibres passing to its blood-vessels. During stimulation of the sympathetic

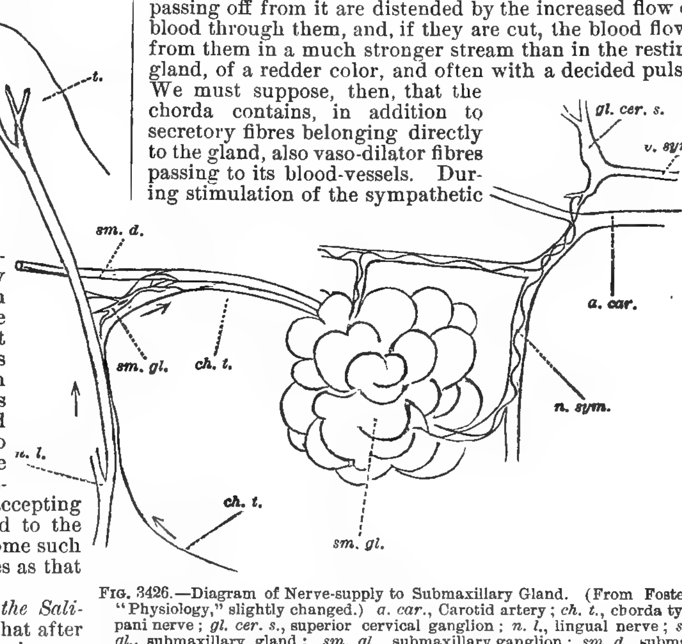

FIG. 3426.—Diagram of Nerve-supply to Submaxillary Gland. (From Foster's "Physiology," slightly changed.) *a. car.*, Carotid artery; *ch. t.*, chorda tympani nerve; *gl. cer. s.*, superior cervical ganglion; *n. l.*, lingual nerve; *sm. gl.*, submaxillary gland; *sm. gl.*, submaxillary ganglion; *sm. d.*, submaxillary duct; *t.*, tongue; *v. sym.*, vago-sympathetic trunk; *n. sym.*, sympathetic branches to the gland.

we get an opposite set of phenomena, the gland becomes pale, and if the veins returning from it are cut the blood flows out in single drops, or ceases altogether. The sympathetic branches, in other words, contain, in addition to secretory fibres proper, also vaso-constrictor fibres going to the blood-vessels.

Influence of the Strength of the Nerve Stimulation upon the Chemical Composition of the Secretion.—If the stimulus applied to the chorda be gradually increased in strength, care being taken not to exhaust the gland, the chemical composition of the secretion is found to change with regard to the relative amounts of the water, the salts, and the organic constituents. The water and salts of the secretion increase with increased strength of stimulus up to a certain maximal limit, although the increase in the two does not run along exactly parallel lines. After the maximal percentage of salts has been reached, further increase in strength of stimulus has no effect, the percentage remaining practically constant, as shown in the accompanying diagram (Fig. 3427).

It is of special importance to notice that these results are obtained from the gland in all cases, no matter what its previous condition was—whether it had been formerly stimulated, or whether it had been in a state of rest. With regard to the organic constituents the results are different. If previous to the stimulation the gland was in a resting condition and unfatigued, then increased strength of stimulation is followed at first by a rise in the percentage of organic constituents; and, indeed, this rise is in the beginning more marked than in the case of the salts. But as the gland becomes more and more fatigued, the relative increase in the organic constituents becomes

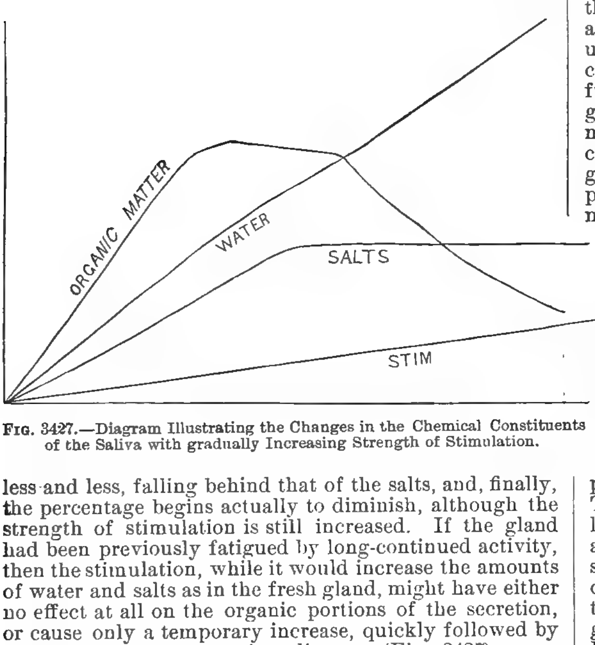

FIG. 3427.—Diagram Illustrating the Changes in the Chemical Constituents of the Saliva with gradually Increasing Strength of Stimulation.

less and less, falling behind that of the salts, and, finally, the percentage begins actually to diminish, although the strength of stimulation is still increased. If the gland had been previously fatigued by long-continued activity, then the stimulation, while it would increase the amounts of water and salts as in the fresh gland, might have either no effect at all on the organic portions of the secretion, or cause only a temporary increase, quickly followed by a fall. The accompanying diagram (Fig. 3427) represents the relative increase in these three components of the secretion, in an unfatigued gland, as the stimulation is made stronger. An examination of the diagram shows that the water and salts, though not increasing in exactly the same ratio, have much in common, whereas the curve of increase of organic constituents runs an entirely independent course. These facts lead us to believe that the conditions determining the secretion of the organic substances are different from those affecting the water and salts, and this view is confirmed by the results of stimulation of the sympathetic fibres. Stimulation of the sympathetic fibres going to the submaxillary gland causes a vaso-constriction of the blood-vessels and a flow of saliva. But the stream of saliva is very different from that obtained by stimulation of the chorda tympani; it is very slow, and the saliva, instead of being clear and watery, is thick and turbid. Chemical analysis of the saliva secreted after stimulation of the sympathetic shows that it contains a much larger percentage of organic matter than that following stimulation of the chorda tympani. This also indicates that the secretion of the organic constituents and that of the water and salts depend upon different conditions. This difference is brought out even more distinctly in Heidenhain's experiments upon the parotid gland.

The parotid gland, like the submaxillary, is supplied by nerve-fibres which are derived from the cerebral nerves, and by sympathetic nerve-fibres. The cerebral fibres have a complicated course; arising first in the glosso-pharyngeal nerve, they leave this trunk by the tympanic branch of the petrous ganglion, or the nerve of Jacobson; from this nerve they branch off in the small petrosal nerve to reach the otic ganglion, and from the otic ganglion they pass to the parotid gland through branches of the auriculo-temporal nerve. Stimulation, then, either of the nerve of Jacobson while in the tympanic cavity, or of the auriculo-temporal nerve, will enable us to determine the effect of these fibres on the parotid secretion. The sympathetic fibres of the parotid reach the gland along the branches of the carotid artery, and may be stimulated while still in the cervical sympathetic.

When the cerebral fibres of the parotid are stimulated, results are obtained similar to those given for the submaxillary gland: the saliva begins to flow at once in large quantities, and is of a clear, watery appearance, while at the same time the circulation through the gland is increased. If the strength of the stimulation is increased, the velocity of the secreted saliva becomes greater, and along with this there is an increase in the quantity of soluble salts, up to a maximal limit. This happens in all cases, whether or not the gland had previously been in functional activity. As in the case of the submaxillary gland, the amount of organic constituents present in this more abundant flow of saliva depends on the previous condition of the gland. If before the stimulation the gland had been secreting actively for some time, then the percentage of organic constituents, instead of increasing, may, on the contrary, begin to fall; while, if the gland had been resting, the organic constituents at first increase, but soon begin to decrease, showing, as in the case of the saliva, that the conditions governing their secretion are different from those under which the water and salts are formed.

This difference is made still more striking by the following observations. If the sympathetic fibres of the parotid gland are stimulated, usually no secretion at all is produced; although the stimulus may be applied for hours, the column of saliva in the cannula placed in the parotid duct remains stationary, provided, of course, the nerve of Jacobson is first cut to prevent any possible reflex stimulation of the gland by this means. Though no secretion flows from the cannula, nevertheless stimulation of the sympathetic has a very important action on the gland, for if shortly afterward, or at the same time, the nerve of Jacobson is stimulated, the saliva obtained differs markedly from that obtained by stimulation of the nerve of Jacobson alone, inasmuch as the organic constituents are greatly increased. In some cases Heidenhain stimulated at the same time the cerebral fibres going to each of the parotid glands, and on one side stimulated simultaneously the sympathetic fibres going to one of the glands; as a result of this the secretion from the latter gland was found to be very much richer in organic constituents. While the organic substances are thus largely increased by stimulation of the sympathetic fibres—the secretion sometimes containing tenfold the amount of organic matter—nevertheless the percentage of salts in the secretion is not affected by the action of the sympathetic fibres. Very weighty evidence is thus obtained showing that the nerve-fibres which cause the formation of the organic portion of the secretion are distinct from those which bring about the separation of the water and salts. Heidenhain's theory to account for these facts is as follows:

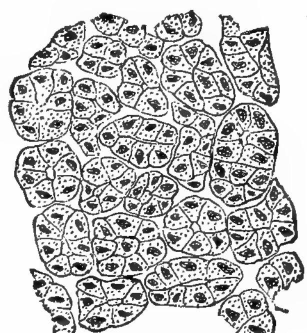
Theory of Secretory and Trophic Nerve-fibres.—The fact that the increased flow of saliva in both the submaxillary and parotid glands of the dog, when the cerebral fibres are stimulated, is accompanied by active vaso-dilatation of the blood-vessels of the gland, while the diminished secretion in both cases from stimulation of the sympa-

thetic fibres is associated with strong vaso-constriction of the blood-vessels of the gland, would lead one naturally to the supposition that the amount of secretion in each case was dependent on the quantity of blood flowing through the organ. On the hypothesis that the secretion is the result of filtration and diffusion from the blood, the increased flow in one instance, and the diminished flow in the other, would seem to find a sufficient explanation in the changes in the blood-supply. But we possess very complete proofs that this supposition is erroneous, and that the secretion is independent of any increase or diminution in the quantity of blood flowing through the gland.

Ludwig first showed that if a mercury manometer is connected with the duct of the submaxillary gland, and the chorda tympani is then stimulated for a certain time, the pressure in the ducts of the gland, as shown by the manometer, may become much greater than the blood-pressure of the animal, the excess of pressure in the gland being in some cases as much as 100 mm. of mercury. This pressure in the ducts is, of course, continued backward into the alveoli, and it is not possible to conceive, under these circumstances, that the secretion is a filtration product from the blood and lymph of the gland, since the filtration stream always proceeds from a place of higher to one of lower pressure. So it has been observed that if the blood-supply is completely shut off from the gland by clamping the arteries, stimulation of the chorda will still excite a secretion for a short time. The neatest and most conclusive experiments that have been brought forward to demonstrate that the flow of saliva is independent of the changes in the quantity or pressure of the blood, are those obtained from the action of atropine and the hydrochlorate of quinine upon the gland. Kenchel (Dorpat, 1868, "Das Atropin und die Hemmungsnerven") showed that atropine injected into the blood, or directly into the gland, completely prevents the secretory action of the chorda tympani; nevertheless stimulation of the chorda[3] causes vaso-dilatation of the arteries of the gland, just as it does without the previous administration of atropine. That is, the atropine paralyzes the secretory fibres of the chorda, while it does not affect the vaso-motor fibres, and the gland in this case will not secrete a drop, although the quantity of blood flowing through it is largely increased, and the pressure in the capillaries is much greater than in the resting gland. The action of quinine is even more conclusive. Heidenhain found (Hermann's "Handbuch der Physiologie," vol. v., p. 45) that if he mixed 10 c.c. of saliva, secreted under stimulation of the chorda tympani, with 2 c.c. of a saturated solution of hydrochlorate of quinine, diluted this neutral mixture to 20 c.c., and then injected a few cubic centimetres into the duct of the salivary gland, he got a greatly increased flow of blood in the gland, but no trace of a secretion. Nevertheless, if the chorda was stimulated a rich flow of saliva was obtained. In this experiment the secretory fibres were not paralyzed, but remained perfectly irritable, while the strong vaso-dilatation caused by the quinine, without simultaneous stimulation of the secretory fibres, was powerless to produce any secretion. From these experiments we are forced to conclude that, as far as the submaxillary gland is concerned at least, the secretion is not caused by a simple increase in the quantity and pressure of the blood in the gland capillaries. On the contrary, we must recognize the existence of true secretory fibres, which exert their action upon the gland-cells directly, and not indirectly by alterations of the blood-stream.

From the experiments upon the parotid and submaxillary glands given above, Heidenhain concludes that we can divide these secretory fibres into two classes, one of which he calls trophic fibres and the other secretory fibres; stimulation of the latter causes the secretion of water and salts, while stimulation of the trophic fibres causes the formation of soluble organic products in the protoplasm of the gland-cells, and these products are then dissolved in the water of the secretion. Upon this hypothesis we can explain the action of the secretory nerves upon the parotid and submaxillary glands in the following way: The sympathetic nerve-branches going to the parotid gland (of the dog) contain only trophic fibres, so that stimulation of this nerve, while it causes important changes in the gland, and the formation of the organic constituents of the secretion, gives no perceptible secretion, because there is no stream of water to dissolve and carry out these products. The nerve of Jacobson, on the other hand, contains mainly secretory fibres, and but few trophic fibres, so that stimulation of this nerve will give an abundant flow of saliva, which, however, will be poor in organic material. In the same way, the chorda-tympani nerve may be considered as composed mainly of secretory fibres, while the sympathetic branches to the submaxillary contain many trophic fibres, together with a sufficient number of secretory fibres to give a slow flow of saliva, rich in organic products, when these nerves are stimulated. Granting that we have two such classes of fibres, how can we conceive their action to take place? In what way do the secretory fibres bring about the secretion of water and salts, and the trophic fibres cause the formation of the organic material of the secretion? These are difficult questions to answer, and it is impossible, with the knowledge we now possess, to give any really satisfactory explanation of these phenomena. The action of the trophic fibres is perhaps better understood, so that we may consider them first. Our ideas of the way in which the trophic fibres act rest partly upon the chemical changes caused by their stimulation, and partly upon the simultaneous morphological changes which can be detected in the gland. The former have been mentioned already; the changes in the histological appearance of the gland have been described by Heidenhain from preparations of the hardened gland, and by Langley from observations upon the living gland. The most important results may be briefly stated as follows:

Histological Changes in the Active Gland as Evidence for the Existence of Trophic Fibres.—If a resting albuminous gland—the parotid of the dog, for instance—is har-



[Fig. 3422.—Albuminous Gland (Resting). Parotid of the Dog. (After Heidenhain.)]

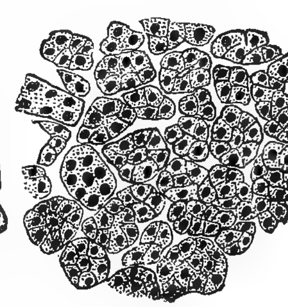


Fig. 3423.—Albuminous Gland, after Strong Secretion. Parotid of the Dog. (After Heidenhain.)

dened in alcohol and then stained in carmine, or, better still, if stained in Heidenhain's hæmatoxylin, we see that the cells are more or less compactly filled with fine granules, which receive a stain from the hæmatoxylin, and are embedded in a clear ground-substance which does not stain. The nucleus of each cell, according to Heidenhain, is small and of irregular outline. If, now, the nerve of Jacobson is stimulated in another gland, and the gland is then hardened in alcohol and stained, very little, if any change will be observed in it, unless the stimulation has been very strong and continued for many hours. But if, at the same time, the sympathetic fibres had been stimulated also for a comparatively short time, very marked changes will be noticed. The cells are distinctly smaller, the nucleus becomes rounder and shows nucleoli, while the cells present a more granular appearance, owing to the diminution in the amount of clear ground-substance contained in them. The diminution in the size of the cells, and the different relative quantities of clear substance and granules, show that the organic ma-

terial of the secretion, which, as we have seen in the case of the parotid, is so largely increased by stimulation of the trophic fibres in the sympathetic, must have been derived from the substance of the cells. In some way the action of these fibres causes metabolic changes in the cell protoplasm and the formation of the organic portion of the secretion. If the gland is again allowed to rest, the proportion of clear substance to granular material increases, and the cells become larger. Heidenhain concludes, therefore, that the clear substance is the material from which the organic products of the secretion are directly formed, and that during secretory activity it is converted into these products and washed out of the cell by the stream of secreted fluids; while in periods of rest the protoplasmic substance of the cell is first regenerated from the food-material given by the blood, and then converted into this clear ground-substance; the latter may be looked upon, not as the organic material of the secretion, but as the substance from which this material is formed, in consequence of metabolic changes set up in it at the moment of secretion by the action of the trophic nerve-fibres.

Langley's experiments upon the changes during secretion in the albuminous glands[4] yielded him somewhat different results. His experiments were made upon the fresh living gland, either by cutting out bits of the gland during rest and activity, or, in the case of the parotid of the rabbit, a portion of the gland, while still in the body, was placed under the microscope, and its appearance observed while the blood was circulating freely through it. He found that, when the animal was in a fasting condition, the cells of these glands had a granular appearance throughout their substance, the outlines of the different cells constituting an alveolus being faintly marked by light lines. When, however, the gland was made to secrete, by giving the animal food, by injecting pilocarpin, or by stimulating the sympathetic nerve-fibres going to it, the granules began to disappear from the outer borders of the cells—that is, from the border turned toward the basement membrane—so that each cell now showed an outer clear border and an inner granular portion. After prolonged secretion very few granules were left in the cell, and these formed a thin layer at its inner portion bordering upon the lumen, and stretched outward for a greater or less distance along the sides of the cells. During secretion, also, the cells separated slightly from one another at the lumen, and this, with a distinct diminution in the size of the individual cells, caused the lumen in each alveolus to become more manifest. He found that these appearances could not be preserved by hardening the gland in alcohol or osmic acid, so that probably Heidenhain's observations on the hardened gland do not accurately represent the changes that take place in the living gland.

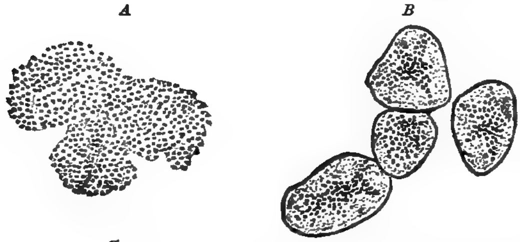

Fig. 3429.—From Langley's paper. *A*, Cells of parotid gland of rabbit in resting condition; *B* and *C*, after strong secretion, showing the disappearance of the granules.

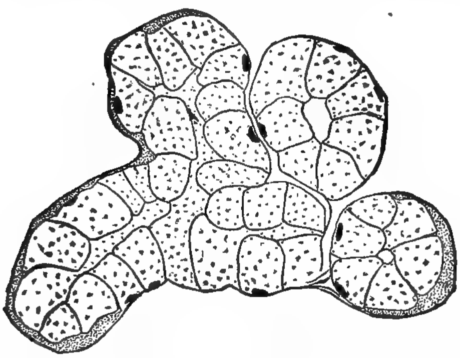
From these results we must believe that in the albuminous glands, as we shall find to be the case in the pancreas, the granules represent the substance from which the organic constituents, and especially its specific ferment, are formed, and that stimulation of the trophic nerves causes the expulsion of these granules. It is not believed that the granules are forced out as such in the secretion-stream, but that they represent the material from which the organic products of the secretion are formed, at the moment of secretion, under the influence of the trophic nerves. Following the analogy of the pancreas, this preliminary material may be spoken of as a zymogen. It is formed from the protoplasmic contents of the cells, and deposited in the form of granules, which, in turn, are dissolved and changed into ptyalin and the organic products of the secretion during the period of glandular activity. We know nothing of the chemical reactions that occur in this process; but from analogy with what we know to take place when other tissues—muscles, for instance—enter into functional activity, it is most probable that these chemical changes are of the nature of destructive metabolisms or katabolisms. The term trophic, which Heidenhain has used to characterize the nerve-fibres causing these changes, is, as Gaskell has pointed out, somewhat unfortunate. Trophic or nutritive nerves are usually understood to be those whose action leads to a constructive metabolism or anabolism in the tissue to which they are distributed. A better designation for these gland-nerves, then, would be that suggested by Gaskell, viz., katabolic nerves. However, Heidenhain believes that the nerves in question, when stimulated, cause changes in the gland-cells of a twofold character. On one hand, the zymogen—the substance from which the ptyalin and organic products in the secretion are directly formed, and which in this case is stored up in the cells in the form of granules—undergoes katabolic changes, with the production of the characteristic elements of the secretion; while, on the other hand, active constructive metabolisms are in progress, which result in the formation of new material in the cell from the food furnished by the lymph. This new material can be recognized in the living cell as the clear non-granular substance, which in the active gland makes a distinct zone at the base of the cell. This, in turn, is changed into the granular material, but whether this change is katabolic or anabolic cannot be determined with certainty. We must recognize that these two processes go on simultaneously in the cell, and the diminution in size of the cell during activity is from the excess of the destructive over the constructive changes, while the growth of the cell during the period of rest is owing to the greater constructive metabolisms. If these processes all result from the action of the gland-nerves, then these nerves are, in part at least, truly trophic or anabolic; but the change which we know most definitely to be the result of their influence, the final change from the zymogen to the organic material found in the secretion, is most probably of a katabolic nature, and Gaskell's term would seem, therefore, to be the most appropriate.

In presenting the theories of the action of the trophic fibres, the phenomena shown by the albuminous or serous glands have alone been considered, but we have equally strong evidence that similar changes occur in the mucous glands. In some respects, indeed, the changes in these glands are more decided, and, fortunately, we have good observations upon both the hardened and the fresh gland in its different conditions of rest and activity. Most of our information is derived from Heidenhain's and Lavdovsky's work upon the hardened glands. According to their descriptions, the mucous cells of the alveoli in the resting gland are large, clear, with flattened nuclei well toward the base of the cells. The demilune cells of Gianuzzi, placed between the basement membrane and the mucous cells, are smaller and of a granular, protoplasmic nature. The clear substance of the mucous cells has all the micro-chemical reactions of mucigen, and seems to be undoubtedly the substance from which the mucus of the secretion is directly formed. When the gland becomes active, from stimulation of the nerve, for instance, the nuclei of the mucous cells become more spherical, show distinct nuclei, and advance more toward the middle of the cells. The cells meanwhile become smaller, because of the transformation of

the mucigen into mucus and its elimination from the cells. If the stimulation is strong and continued for a long time, more important changes take place. According to Heidenhain, the mucous cells break down completely, and are carried off in the secretion, while the demilune, or border cells, grow and form new mucus-secreting cells similar to those destroyed. Such results are obtained, of course, only from excessive artificial stimulation, but Heidenhain believes that this represents a normal physiological process. The individual mucous cells may continue for a time to secrete mucus, and then be regenerated by the formation, first, of protoplasm from the food of the lymph, and the transformation of this into mucigen, but sooner or later the cell is destroyed, and its place is supplied by one of the demilune cells. That we do not see any evidence of this in sections of mucous glands, not submitted to artificial stimulation, is owing to the fact that the change only affects individual cells, and would necessarily be inconspicuous under normal



[FIG. 3423.—Mucous Gland. Submaxillary of Dog. Resting stage. (From a camera-lucida drawing of a gland stained in Heidenhain's hæmatoxylin.)]

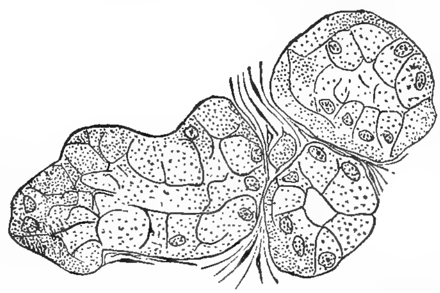


FIG. 3430.—Submaxillary Gland of Dog after eight hours' Stimulation of the Chorda Tympani. (From a camera-lucida drawing.)

conditions, since probably only a few cells in the gland would be undergoing this change at the same time.

More recently Langley [6] has made experiments upon the fresh gland with regard to its histological appearance during rest and activity, using the submaxillary and the sublingual glands of the dog. He finds that in the resting gland, when treated with dilute solutions of neutral or alkaline salts, he could detect, along with the hyaline material in the cells, a number of granules, both inclosed in a network stretching throughout the cell. The granules extend through the cell, and during secretion both the hyaline substance and the granules are "turned out of the cells; after prolonged secretion the cells consist of an outer zone, chiefly of freshly formed substance, and of an inner zone of network, hyaline substance, and granules." Langley does not agree with Heidenhain and Lavdovský in believing that the mucous cells disintegrate during secretion and are replaced by the demilunes. On the contrary, he thinks that the demilunes are secreting cells of a different nature, belonging to the albuminous type, and that the mucous cells, after their period of activity is over, grow again to their original size in a way closely comparable to that described as occurring in the parotid gland and the pancreas.

Action of Secretory Fibres.—The term secretory fibres is applied here in a restricted sense to those fibres whose stimulation excites a secretion of water and salts. This name also seems somewhat unfortunate, as it would be more convenient to speak of all the glandular nerve-fibres as secretory, as, indeed, is usually done. It has been suggested that transudatory fibres would be a better designation, and it would certainly be a more convenient one, inasmuch as it would enable us to speak of two different things by different names. The term, however, is not entirely free from objection. By transudations we are accustomed to understand fluids formed by filtration or diffusion through membranes in the body. It is more than doubtful whether the action of the fibres in question can be considered of this character—that is, as simply increasing or permitting the filtration and diffusion of water and salts from the lymph through the basement-membrane and cells into the lumen of the alveolus. As was shown in the beginning of this article, there seems to be an accumulation of evidence forcing us to the belief that transudation through living membranes is quite a different thing from filtration or diffusion through dead membranes. If we use the word transudatory simply to indicate the fact of the production of water and salts in the secretion, without any reference to the manner in which they are formed, the term will be a useful one; but inasmuch as this conception of filtration and diffusion is generally attached to the word, it will be better for us to use the non-committal term secretory, in the sense in which it is employed by Heidenhain.

How the water of the secretions is formed has always been a difficult question to decide. Quite a number of theories have been proposed from time to time, but none of them are really satisfactory, and on this point, as on many others in physiology, we must await future histological and physiological researches. We know that at bottom the stream of water in secretion is caused by chemical and physical agencies, but what the nature of these phenomena is remains to be discovered. We have abundant proof, part of which has already been given, that it is not a case of simple filtration or diffusion from the blood in the capillaries; we know that changes in the pressure in the capillaries have no direct effect on the quantity of water in the secretion. Gianuzzi divided the process of water-secretion into two different and independent stages: First, the filtration of the water through the blood-capillaries into the lymph-spaces; second, the transference of this water from the lymph to the lumen of the alveolus through the activity of the cells. Heidenhain has shown that this hypothesis, the first part of it at least, is contradicted by facts, and it introduces a new difficulty in the way of understanding how these two processes are regulated with respect to each other. Another theory, suggested by Hering, is that —in the submaxillary gland, for instance—stimulation of the secretory nerves causes the formation within the cells of a colloidal substance, mucin, which has a great attraction for water, and that, as a result of the imbibition-power of this mucin, water is carried into the cells, and there forms with the mucin a solution which makes the secretion. If this theory were correct, then those glands which contain the most mucin ought to show the most active secretion. As a matter of fact, this is not the case—the sublingual is richer in mucin than the submaxillary, but the secretion-stream in the former is much less rapid than it is in the latter; so also the organic substances in the parotid saliva may sink to a very small percentage, and yet the secretion may be very active.

Heidenhain's own theory to account for the production of the water as the result of nerve-stimulation is also far from conclusive. He starts from the fundamental fact that no more water leaves the blood-capillaries than appears afterward in the secretion—that is, no matter how long the secretion continues, the gland is never œdematous, nor is the velocity of the lymph in the lymphatics of the gland increased. This being the case, we must suppose that the water-stream is regulated by the secretion—that is, by the activity of the cells of the gland. If, now, we conceive that the substance of these cells, or some constituent of them, has an attraction for water, then while the gland is in the resting state water will be absorbed first from the basement-membrane;

this membrane makes good its loss by subtracting water from the lymph of the tissue, and this, finally, from the blood of the capillaries. The water in the cells increases, and its tension becomes greater, until, finally, the endosmotic power of the cell-substance is held in equilibrium, and the diffusion-stream between the blood in the capillaries and the cells comes to a stand-still. The water held in the substance of the cells cannot escape into the lumen of the alveolus, which would be the natural path for it to take, since there the water is under little or no pressure, because the border of the cell-protoplasm is so constructed as to offer a great resistance to filtration. So the water may be held in the cell under great tension, and yet not be able to filter through this limiting layer into the lumen. The action of the nerves consists in so changing the structure of this resisting layer that it may offer little resistance to filtration, and the water of the cell then filters out into the ducts; its own endosmotic power, no longer held in equilibrium, again draws water from the lymph, etc., and a filtration-stream is started, the moving force of which is this endosmotic power of the cell-substance. In what way the nerves cause a change in the nature of the resisting layer of the cell can only be a matter of speculation. The author of the theory thinks that there is a molecular change or rearrangement in its structure, of such a character that it no longer offers a resistance to the passage of water from a point of high pressure within the cell to one of lower pressure outside of the cell. It is possible, also, that active contractions of the cell-substance may facilitate the secretion of liquid. The whole theory goes far beyond the facts which are known; but it is, perhaps, the best that has been offered, and may be adopted provisionally until future researches give us more data to speculate upon.

Heidenhain says little about the secretion of salts independently of the water in which they are dissolved. Presumably, on his theory, the salts are carried directly in the diffusion-stream, passing from the blood of the capillaries to the cells of the alveoli, and depend no more for their secretion upon metabolisms in the cells than the water does. In accordance with this view, Heidenhain found that the maximum amount of inorganic salts in the submaxillary saliva lay between 0.5 and 0.6 per cent., or, according to the later experiments of Werther, may reach 0.77 per cent.; increased velocity of the secretion-stream beyond this point caused no increase in the percentage of salts. This percentage of salts is still below that of the blood, and calls for no especial secretory activity of the cell to explain its production. In other glands of the body, however, we meet with what seems to be a true secretion of salts—that is, the salts cannot be considered as filtering or diffusing through the gland-cells with the stream of water, but exist in such quantities that they must have been collected from the blood by the secreting cells in some way, and are the direct products of the metabolic activity of these cells. In the mammary gland, for instance, Bunge[6] finds that the salts of the milk not only differ widely in percentage-value from the same salts in the blood, from which they are ultimately derived, but exist in the same percentage by weight as in the ash of the sucking animal for whose food the milk is intended—that is, the epithelial cells pick out from the blood certain salts in the quantities needed for the growth of the young animal. For the proof of this interesting statement Bunge submits the following table of analyses:

100 parts of ash contain:	Sucking animal. Rabbit.	Sucking animal. Dog.	Sucking animal. Cat.	Dog's milk.	Dog's blood.	Dog's serum.
K_2O	10.8	8.5	10.1	10.7	3.1	2.4
Na_2O	6.0	8.2	8.3	6.1	45.6	52.1
CaO	35.0	35.8	34.1	34.4	0.9	2.1
MgO	2.2	1.6	1.5	1.5	0.4	0.5
Fe_2O_3	0.23	0.34	0.24	0.14	9.4	0.12
P_2O_5	41.9	39.8	40.2	37.5	13.2	5.9
Cl_2	4.9	7.3	7.1	12.4	35.6	47.6

There can be no question of simple diffusion and filtration in this case. While the blood of the mother contains in its ash less than one per cent. of CaO, the milk holds over thirty-four per cent., and, on the other hand, the blood contains a large percentage of Na_2O and Cl, while the ash of the milk contains very much less.

Similar results have been obtained from the kidney by Munk.[7] This observer experimented upon kidneys of dogs taken from the body and kept alive by an artificial circulation of defibrinated blood, usually diluted with one-half to one volume of water or normal salt solution. Under these conditions the kidney continued to secrete urine steadily, and the characteristic salts of the secretion always existed in a higher percentage in the secretion than in the blood which was circulating through the gland. The NaCl, for instance, was found without exception to be greater in the secretion than in the blood, the excess varying between eighteen and sixty-seven per cent. Even when by addition of NaCl to the circulating blood the percentage of this salt was raised to 2.28, the weight of NaCl found in the secretion was always from twelve to sixty per cent. higher. The same results were obtained with Na_2SO_4 and Na_2HPO_4, and here, again, the secretion of the salts is undoubtedly connected with the activity of the secreting cells, and is not a passive phenomenon. Munk's success in getting a true secretion of urine from a kidney with artificial circulation is opposed to the experience of other observers, and his results need corroboration before they can be fully accepted.

Stricker and Spina have advocated a different theory of secretion, founded upon some observations made upon the simple racemose glands contained in the skin of the frog.[8] In these simple glands the lining epithelium forms a more or less flattened layer upon the alveolar wall, leaving a relatively large lumen. When the gland is stimulated by electricity, either directly or through nerves, two things happen. In the first place, the whole gland becomes smaller, from a contraction of the external surface, and, secondly, the cells of the alveolus dilate and completely close up the lumen. After the stimulation has ceased, the cells and gland return again to their former condition. As far as the first of these phenomena is concerned, it is probably owing to the contraction of muscular elements in the periphery of the gland. The enlargement of the gland-cells that follows stimulation may be explained either as an active dilatation, or as a passive dilatation from the imbibition of water. The authors hold to the first of these views; they see no reason why nerve-stimulation should not lead to an active dilatation of the cells as well as to a contraction, and believe that the object of the dilatation is twofold. On the one hand, by obliterating the lumen the cells drive out the secretion which was standing in it, and, on the other, their enlargement creates a negative pressure within the cells, in consequence of which water is drawn into them from the surrounding lymph. When the stimulation ceases the cells return to their normal size and squeeze out this water into the lumen. According to this theory the cells act both as a mechanical force-pump and as a suction-pump, drawing the water into themselves, and again forcing it out into the duct. Stricker and Spina have attempted to apply this theory to similar glands—the salivary glands, for instance—but the attempt is hardly worthy of serious consideration. As Heidenhain says, the enlargement of the cells in these glands during secretion, which undoubtedly takes place, is in reality a secondary phenomenon; the stream of water which results from the stimulation causing changes in the cells is the primary phenomenon, and the cells swell up from imbibition of this water. Why stimulation of the nerves should set up a secretion-stream through the gland is the same problem that we have discussed already with reference to the salivary glands, and Heidenhain's hypothesis applies as well in one case as in the other.

Action of Atropine and Pilocarpine on the Salivary Glands.—The action of a number of different poisons on the salivary secretion has been determined more or less

completely. Of these poisons, atropine and pilocarpine, from their decided and antagonistic effects, have always been regarded with peculiar interest. It has long been known that when atropine in minimal doses is injected either into the blood or directly into the gland through its duct, the secretion of the gland very quickly stops, and in the submaxillary gland, upon which most of the experiments have been made, stimulation of the chorda no longer has any effect upon the gland-secretion, although the dilatation of the blood-vessels follows as in the unpoisoned gland. This action of the atropine is not exerted upon the nerve-centres in the cerebro-spinal system, but directly upon the glands. The same effects may be obtained when all nervous connections between the glands and the nerve-centres are severed. The atropine must act either upon the secreting cells directly, or else upon the termination of the nerves in the gland. The second of these views seems to be the probable one, for the reason that when atropine is injected into the blood of a dog the chorda-fibres going to the submaxillary gland are completely paralyzed—no amount of stimulation will cause them to excite a secretion. But even very strong doses will not paralyze the action of the sympathetic fibres of the same gland. Hence the gland-cells themselves must be capable of functional activity. What the atropine has done is to prevent the action of the chorda-impulses on these cells. The connection between the nerve-fibres and gland-cells is unknown, and it remains an open question whether the atropine affects this connection, or possibly acts upon the local centres, small ganglia, which exist in the substance of the gland, and with which, presumably, the chorda-fibres are first connected before passing to the secreting cells. The action of pilocarpine is of the opposite kind. Very small doses (0.001 Gm.), injected into the blood, cause an active secretion of the gland (submaxillary), a secretion which may be increased by simultaneous stimulation of the chorda-fibres. If, however, the dose of pilocarpine is too strong, the gland is paralyzed, as in the case of atropine-poisoning.

Most of our knowledge of the action of these drugs is derived from Langley's work.[9] With regard to their antagonistic action, he states that they have an imperfect mutual antagonism. As long as the dose of pilocarpine is sufficiently small to cause secretion of the gland, the antagonism of atropine for it is perfect—that is, the secretion of the gland can be stopped by injection of atropine. The antagonism of pilocarpine for atropine, however, is less perfect, and is more complete the smaller the dose of atropine—that is, the paralyzing action of the atropine, if the dose is not too great, may be removed by injection of pilocarpine. While the atropine may be regarded as acting upon the peripheral nerve-endings in the gland in such a way as to paralyze them, the pilocarpine in small doses may be supposed to stimulate these nerve-endings, and in larger doses to paralyze them. These facts give us but little aid in understanding the physiological mechanism of secretion, though any theory that is proposed must take them into consideration.

The Secretion-centre.—The salivary glands in the normal relations of the body are set into action, not by direct stimulation of the secretory nerves supplied to them, but reflexly from stimulation of sensory nerves of the tongue, of the buccal cavity, of the alimentary canal in general, etc. The position of the secretory centre through which these reflexes are made has been placed in the medulla, at about the nuclei of origin of the facial and glosso-pharyngeal nerves. Bernard attempted to show that the little submaxillary ganglion placed in the angle between the lingual and chorda-tympani nerves might serve as a reflex centre for stimulation of the endings of the lingual in the tongue. Experiments made by other observers have discredited this theory, and we cannot at present state what the function of this ganglion is with reference to the submaxillary gland. The secretory centre in the medulla can be excited by stimulation of the sciatic or the splanchnic nerve, and can also be stimulated directly by mechanical or electrical means. In strong dyspnœa this centre is usually thrown into action by the stimulating action of the venous blood in the medulla. The secretory centre may also be stimulated by impulses descending from the higher centres in the brain. As is well known, the mere thought of pleasant food may cause a reflex secretion of saliva. On the other hand, the action of this centre may be inhibited either by afferent impulses from various nerves of the body, or by impulses descending from higher centres in the brain. The well-known fact that terror, anxiety, etc., frequently stop the flow of saliva is sufficient proof of this latter statement.

Paralytic Secretion.—Claude Bernard discovered, in 1864, that if the chorda-tympani fibres of the submaxillary glands are cut, the gland ceases to secrete, because the efferent path from the secretory centre is now cut off. Nevertheless, from one to three days after the section of the nerve a slow secretion begins in the gland, and keeps up continuously for several weeks. As a final result of the section, the gland undergoes complete atrophy unless the chorda-fibres again grow out. The cause of this paralytic secretion is very obscure. Heidenhain thought that it was owing, perhaps, to the stagnation of saliva in the ducts, certain products being formed which stimulated the gland. Langley has recently studied the subject with more success than other observers.[10] He has both added new facts to those already known with regard to the results of this section, and has suggested a plausible theory of the cause of the paralytic secretion. Section of the chorda tympani in the cat, according to Langley, is followed by a continuous secretion of watery saliva from the submaxillary gland on both the cut and the uncut side, that on the cut side being the more abundant. The secretion of the gland on the side on which the nerve was cut he calls the paralytic secretion, and that from the gland on the other side, the antiparalytic or antilytic secretion. The primary cause of these secretions he considers to be an increase in the irritability of the cells of the secretory centre. When the chorda on one side is cut, the central secretory nerve-cells become more irritable, and finally the blood flowing through the centre, which is normally somewhat venous, but not enough so to stimulate the centre, becomes now a sufficient stimulus to this more irritable centre, and the impulses pass to the gland on the cut side through the sympathetic fibres which remain uncut, thus exciting the paralytic secretion; while on the other side the impulses descend through both the chorda and the sympathetic, causing the antilytic secretion. Confirmatory of this view he finds that the paralytic secretion may be stopped in its first stages by section of the sympathetic fibres of the same side. In later stages, however, section of the sympathetic fibres, while it may slow the secretion, will not stop it altogether. Langley explains this by supposing that now the local centres in the gland itself have become affected, that is, become more irritable, and are being stimulated continually by the blood flowing through the gland, so that it is possible to get a paralytic secretion from the gland after all nervous connection with the medullary centre is cut off; the secretion in this case would probably take a longer time to develop, as the local centres undergo this change in irritability more slowly than the general centre in the medulla. As a confirmation of this view, Langley points out that in the sweat-glands, in which no peripheral nerve-cells, local centres, are known to exist, no paralytic secretion can be obtained when the nerves of the glands are cut; while in the salivary glands and the pancreas, in which these peripheral nerve-cells have been found, a paralytic secretion is obtained when all the nerves supplying the gland are cut. This theory seems to meet all the facts in the case, and is certainly a great advance on any hitherto offered, though it is somewhat difficult to see why section of the chorda should be attended by an increase in irritability of the central nerve-cells of the medulla.

Secretion in the Pancreas.—In some respects the study of the process of secretion, as exhibited in the pancreas, has been of more service in throwing light upon the phenomena of secretion in general than the study of the salivary gland. This is especially true with respect to the histological changes undergone by the cells during

secretion. Observations upon the hardened gland, in different stages of activity, by Heidenhain, and confirmatory experiments upon the living pancreas of the rabbit, by Kühne and Lea, have given us a pretty clear conception of the mechanism of the secretion of the organic constituents. In other respects, however, the work upon the pancreas has been less successful. Little or nothing is known of the effect of direct nerve stimulation upon the character of the pancreatic secretion, so that the evidence for the presence of different kinds of secretory nerves in this gland is not so direct as in those already described. An account of the physiology of secretion in the pancreas will add, then, but little to the data already given, as far as any general theory of secretion is concerned. But it will serve to show that in many points the process exhibits a fundamental similarity in the two sets of glands, giving us some hope that certain general statements with regard to gland activity may yet be formulated. From what has been said of salivary secretion it is very evident that our knowledge of the real nature of the process is very fragmentary and insufficient, and this is even more conspicuous in the case of the pancreas. The theories in the one case, as far as they have been developed, apply fairly well in the other; but in neither case are the facts sufficient for the construction of a theory of secretion that does not force us to use hypotheses for the truth of which there is little positive proof. Glands so similar in structure as the pancreas and salivary glands must function in essentially the same way, and it seems allowable to supplement the facts known with regard to one by the results obtained, under more favorable conditions, from experiments upon the other. What we have to say about pancreatic secretion, then, will be made as brief as possible, since the general deductions that might be made from its study alone have already been presented in speaking of the salivary glands.

The pancreatic secretion, as obtained from a temporary fistula in the duct of a dog, is a clear, thick, sticky liquid that coagulates in the cold, and shows an alkaline reaction. It contains a large percentage of organic material, which appears to consist chiefly of albuminous bodies, alkali albuminate, and the usual salts, among which the sodium salts are especially abundant. Owing to its large amount of albuminous material the secretion gives a strong precipitate or coagulum when heated. What especially characterizes the secretion, however, is the presence of at least three unformed ferments, or enzymes, which have the power of causing digestive changes in the three chief classes of alimentary principles. These three enzymes are, (1) A diastatic ferment capable of converting starch into sugar; (2) a ferment capable of converting albumins into peptones and amido-acids; (3) a ferment capable of splitting neutral fat into glycerine and the corresponding fatty acid. The physiological action of these ferments does not interest us in this connection; we are concerned only with the way in which they are formed within the cells of the gland, together with the other products of secretion, and with the mechanism by which they are forced out of the cells into the secretory ducts. In cases of permanent pancreatic fistula, where the secretion has been long continued, its characters differ in degree from those given above; the secretion becomes much thinner, and the percentage of solid constituents may sink to a very low level, one or two per cent., while in the fresh gland it may be nine to ten per cent. So all gradations may be obtained according to the condition of the gland. It is evident that the chemical constitution of this secretion places the gland in the albuminous type, and the morphological changes in its structure during rest and activity also suggest strongly the appearances found in salivary glands of this type, *e.g.*, the parotid.

The secretion of pancreatic juice in the dog is not continuous, but intermittent. After the reception of food and the commencement of gastric digestion the pancreatic juice begins to flow out of the duct into the intestine, and continues to be secreted with varying velocity for several hours. By making a pancreatic fistula, and measuring directly the amount of pancreatic secretion that flowed from it, Bernstein,[11] and afterward Heidenhain,[12] have been able to determine the variations in the secretion in the hours following digestion. The curves given by the two investigators agree very well, and the general result, as stated by Heidenhain, is as follows: Immediately after the reception of food the secretion begins, and increases in velocity up to a certain maximum, which it reaches from the first to the third hour after digestion has begun. The velocity then falls quickly un-

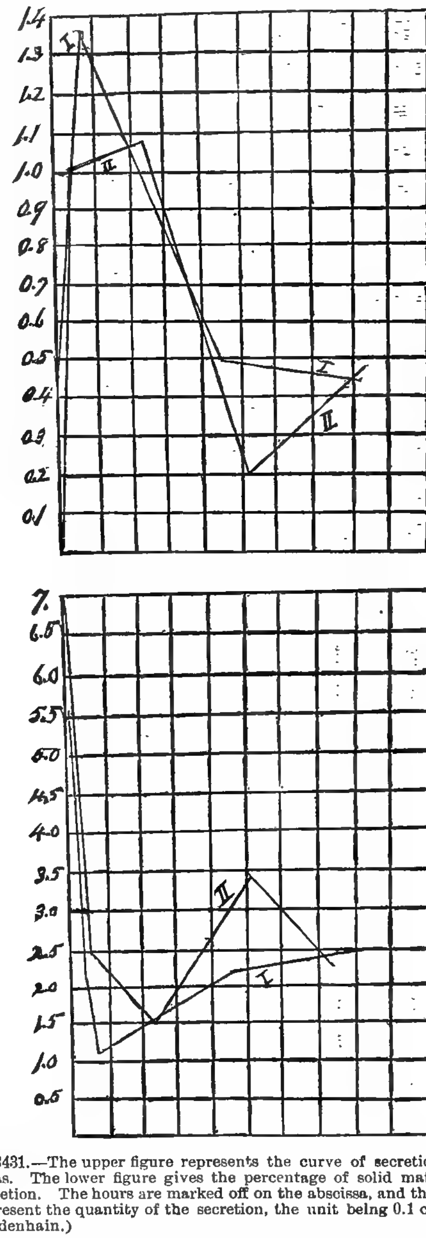

FIG. 3431.—The upper figure represents the curve of secretion of pancreas. The lower figure gives the percentage of solid matter in the secretion. The hours are marked off on the abscissa, and the ordinates represent the quantity of the secretion, the unit being 0.1 c.c. (After Heidenhain.)

til the fifth or sixth hour, after which there is a second increase of velocity up to the ninth or the eleventh hour. This second increased velocity is never so great as that which occurs in the first few hours. The flow of secretion then diminishes slowly until the sixteenth or seventeenth hour after digestion, when it again comes back practically to zero. Two of the curves obtained by Heidenhain are given in the upper portion of the accompanying figure. Heidenhain determined at the same

time the percentage of solid constituents in the secretion at the different hours, and the results are represented in the lower curves of the figure. An examination of these curves shows that as the velocity of the secretion increased the percentage of solid matter decreased, in this respect differing very much from the salivary secretion. The solid matter of the secretion is composed partly of organic constitutents and partly of salts; the variations given here are presumably variations in the organic material chiefly, though no analyses are given, so that the external characters of the secretion change during the hours of its flow; at first thick and coagulable, it becomes afterward thinner and more like the weak secretion from long-established fistulas, while toward the end of its flow—when the velocity is again very small—the percentage of organic constituents increases, giving again a secretion like that usually described as normal.

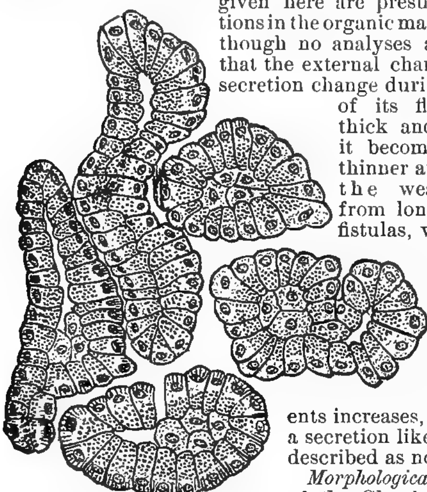

FIG. 3432.—Pancreas of Dog. (From Heidenhain.)

Morphological Appearance of the Gland in Rest and Activity. — Together with these changes in the flow of the secretion certain well-marked differences in the histological appearance of the gland have been noticed. A resting gland from a dog that has fasted for twenty-four hours or more, if hardened in alcohol and stained in carmine or Heidenhain's hæmatoxylin, shows in sections appearances represented in Fig. 3432. The cells of the alveoli show two distinct zones—an outer non-granular zone, which stains readily and contains the nucleus, and an inner granular zone facing the lumen; the matrix containing these granules does not stain at all, and is differentiated clearly from the stained outer layer. Heidenhain has shown, also, that in the outer non-granular zone the cells show a distinct striation, the lines disappearing at the commencement of the granular portion. If, now, the pancreas from a dog recently fed is treated in the same way within the first six or ten hours after digestion, marked changes in the relations of the two zones will be found to occur. The non-staining granular inner zone becomes smaller and smaller during this period, until in some of the alveoli it may entirely disappear. Together with this disappearance of the granular zone there is a corresponding increase in the staining non-granular portion, which becomes wider and wider, and may finally extend over the whole cell from basement membrane to lumen. The increase of the outer zone, however, does not quite keep pace with the consumption of the granular zone, so that during this period the cells and the alveoli or tubes of the gland become decidedly smaller, a condition of things represented in Fig. 3433.

During the second stage of digestion, within the tenth to the twentieth hour after feeding, the gland again comes back gradually to its resting condition. The cells increase in size, the inner granular zone is regenerated, and the outer clear zone of staining protoplasm forms now only a thin layer on the outer or basement membrane side of the cells.

The observations of Heidenhain on the hardened pancreas of the dog have been confirmed and extended by experiments of Kühne and Lea [13] upon the pancreas of a living rabbit. The secretion of the pancreas in the rabbit appears to be continuous, owing to the different character of the food and the time required for its digestion. When a portion of the pancreas in the living animal is examined under the microscope, two different kinds of alveoli or tubes may be seen, either in one field or in different parts of the specimen. In one represented in *A*, Fig. 3434, the outlines of the alveolus are smooth and even, the individual cells are not clearly distinguished from one another, and two zones can be seen—a clear homogeneous outer zone toward the basement membrane, and a granular inner zone toward the lumen. In the other, represented in *B*, Fig. 3434, the outlines of the

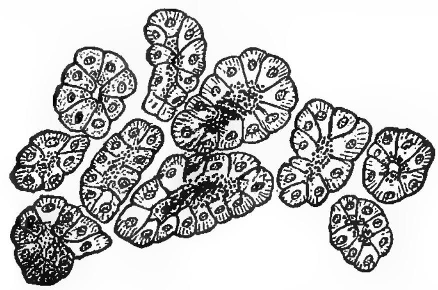

FIG. 3433.—Pancreas of Dog; six to ten hours after digestion has begun. (From Heidenhain.)

alveolus are notched or indented, and the division between the individual cells becomes more or less distinct in consequence of spaces or lines which appear between them. In the alveoli, also, the granular layer or zone is less conspicuous and the outer zone relatively greater. Kühne and Lea were able to show that this latter appearance represents the condition of activity, while the former, *A*, shows the resting state. When the gland was actively secreting, the notched alveoli were most numerous; and, furthermore, drugs which excite the secretion, jaborandi, *e.g.*, caused the alveoli to assume this shape, while atropine, which inhibits the secretion, brought about the smooth outline. When indifferent solutions, like normal salt solution or defibrinated blood, were forced into the duct of the gland under a low pressure, the liquid could be followed back, in the latter case, by the blood-corpuscles, into the small ducts and lumens of the alveoli; if the pressure was now taken off, the secretion of the cells forced back the defibrinated blood from the lumens, and in cases in which this occurred the alveoli assumed the notched appearance. For these reasons this latter condition may be considered as the state of activity. They saw alveoli pass from a state of rest to one of activity, and were able to determine that there was a movement of the granules toward the lumen. In the state of activity it was noticed, also, that the external zone of the cells, the non-granular zone, became distinctly striated, and if the striæ were seen during the resting stage they became more distinct in the state of activity. These experiments, together with those of Heidenhain, leave no doubt that the organic material of the secretion

A *B*

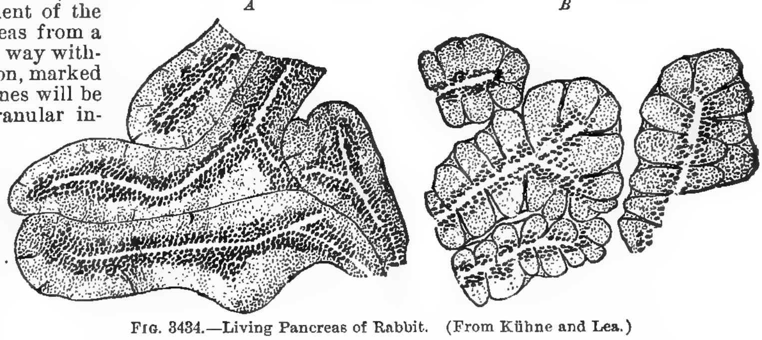

FIG. 3434.—Living Pancreas of Rabbit. (From Kühne and Lea.)

is formed from the granules of the inner zone, and that these in turn are derived from the protoplasmic material of the outer zone directly or indirectly; while during the act of secretion active changes of form take place in the cells, owing either to a contraction of the substance of the cells themselves or of some other element of the alveoli or tubes composing the gland.

Some recent experiments of Ogata[14] have given the same results with regard to the changes in the granular zone and size of the cells during rest and activity. Ogata's chief results, however, relate to the changes in the nucleus of the cell during rest and secretion, and the way in which the pancreatic cells that may be destroyed during the secretory process are replaced. Briefly presented, his results are as follows: He distinguishes in the nucleus of the resting cell two kinds of nucleoli—one staining with hæmatoxylin, like the nuclear membrane which he calls karyosmen, and of these there may be one or several; the other kind, usually a single nucleolus, he calls a plasmasoma, and it stains readily with eosin. In the cell outside of the nucleus he describes the two layers, granular and non-granular, already spoken of. In the inner granular layer the zymogen-granules are embedded in a clear, structureless matrix, which also extends throughout the non-granular zone, and forms what he calls the cell-stroma. In the external zone of the cell this cell-stroma contains granules of another kind from those of the inner zone; they are very fine and stain readily in nigrosin, and Ogata speaks of them as protoplasm. When the gland is stimulated in any way—by feeding, by stimulation of the medulla, or, best of all, by the injection of pilocarpin—very marked changes take place in the cell. The zymogen-granules disappear and the cells become smaller, as already described, but in addition to this a new body appears in the cell just outside of the nucleus; this he calls a "Nebenkern" (accessory nucleus) after Gaule, and he finds that it is formed by the passage of the plasmasoma out of the nucleus into the cell-body. One of two things may happen to this "Nebenkern." It may grow and finally be converted into zymogen-granules, to replace those used up in secretion, or it may develop an entirely new cell, with granules, nucleus, nucleoli, etc., and thus indirectly furnish new zymogen-granules. As the new pancreas-cell develops from the "Nebenkern," which in this case is a veritable cytoblast, the old cell dies away and finally disappears. These experiments of Ogata on the development of the new cell are in the line of recent researches on cell-growth and the function of the nucleus, but are too new to be accepted at present without further confirmation.

Formation of the Pancreatic Ferments.—Though the experiments just given indicate clearly that the ferments are derived from the granular material of the cells, we know that these granules do not themselves contain the ferments, but are composed of a material which probably at the moment of secretion suffers changes that result in the production of the ferments and other organic substances. This mother substance, from which the ferments or enzymes are formed, is spoken of usually as zymogen, but it is not easy to prove its existence. If a dog which has fasted for twenty-four hours—at which time, from what has been said, we know that the gland contains a large proportion of the granular material in the inner zone of the cells—is killed, and immediately after death a glycerine-extract is made of the pancreas, very little or no trypsin will be obtained from it. But if the gland is first allowed to remain in the air, in a warm place, for twenty-four hours, or treated with dilute acetic acid, then a glycerine-extract will be found to have a powerful tryptic action. The fresh gland then contains no trypsin ready-made, or only very small quantities of it, but a substance (zymogen) which can be readily converted into trypsin. The zymogen of the fresh gland is readily extracted by glycerine, and the zymogen of this extract can then be easily changed to trypsin by any one of a number of different methods—by simple dilution with water, by the passage of a stream of oxygen through it, by shaking with finely divided platinum-black, etc. The amount of trypsin or zymogen contained in the pancreas is found to vary according to the number of hours that have elapsed after digestion before the extract is made, and these variations are in the direction we should expect if the zymogen is contained in the granular material of the gland. Heidenhain has made a number of such experiments upon dogs, using in all cases a glycerine-extract of the gland, and has found that immediately after digestion the amount of zymogen or trypsin begins to sink, and reaches its minimum from the sixth to the tenth hour after the food has been taken, just the time at which, according to microscopical examination, the granular material of the inner zone is least abundant. After this the amount of ferment that can be extracted begins to increase, together with the increase of granular material that has been shown to take place in the gland, reaches its maximum at about the sixteenth hour, and then remains practically constant until the next meal is taken. Similar results have been obtained with the diastatic and fatty acid ferments. Grützner[15] found that both reached their minimum at about the sixth hour of digestion, and then slowly increased, the diastatic ferment reaching its maximum at the fourteenth hour, while the fatty acid ferment gradually increased in quantity until the fortieth hour. In the pancreatic gland, then, we are able to trace the genesis of the ferments, by microscopical and chemical means, more satisfactorily than in the salivary glands. The similarity in the appearance of the resting and active conditions of the living pancreatic and the living parotid gland lead us to believe that what has been ascertained for the former will hold good for the latter. On the contrary, what we know of the action of the nerves on the secretory activity of a gland has been derived almost entirely from a study of the salivary glands, and can be applied only by inference to the pancreas.

Action of the Nerves on the Pancreatic Secretion.—The secretion of the pancreas is, under normal conditions, probably a reflex act; it begins as soon as food has been received into the stomach, but the path of the reflex has not been determined. The centre for the reflex probably lies in the medulla, since direct stimulation of this organ increases the velocity of the secretion, and, furthermore, the secretion may be inhibited by the stimulation of certain afferent nerves, the vagus, for instance. Nevertheless the pancreas seems to be, to a large extent, an automatic organ, even more so than the salivary glands. The ganglia found in its substance act as local centres, which excite secretion in the gland after all nervous connection with the higher medullary centre has been severed. This secretion of the pancreas, after as complete section as possible of all nerves going to it, is of the nature of a paralytic secretion, and the views of Langley as to the mechanism of the paralytic secretion in the salivary gland will doubtless apply to the pancreas also. It is difficult to remove the pancreas from all nervous influence, since its nerve-branches are derived from the plexus hepaticus, lienalis, and mesentericus superior, and reach the gland along the walls of its blood-vessels, and are therefore less easily isolated than in the case of the salivary gland. For the same reason no satisfactory experiments, comparable to those given for the submaxillary and parotid glands, have yet been made upon the effect of direct stimulation of the secretory nerves of the pancreas. The best that can be done is to stimulate the secretory centre in the medulla and observe the effects. Experiments of this kind have shown that not only is the velocity of the secretion increased as the result of stimulation, but there is also an increase in the percentage of organic matter contained in it. These results indicate that here, as in the salivary glands, we have to deal with two kinds of nerve-fibres—secretory fibres, which regulate the velocity of the secretion, that is, the amount of water which passes out in a given time; and trophic fibres, whose business it is to form the organic materials of the secretion from the zymogen-granules, and at the same time start constructive metabolic processes in the cell, which result in the formation of new protoplasm and new zymogen-granules to take the place of those secreted.

The experimental evidence for the existence of these fibres is not very conclusive, though there is nothing to oppose such a view, and the analogy of the salivary glands, as before stated, leads us to believe that the nervous mechanism is essentially the same in both cases.

SECRETION IN OTHER GLANDS.—The most important outcome of modern researches on the phenomena of secretion, as illustrated in the salivary glands and pancreas, relates to the part taken by the extrinsic nerves of the gland in regulating and modifying the flow of the secretion, and to the histological changes which can be observed in the gland during its periods of rest and activity. It will be interesting to summarize briefly our knowledge of these two processes in some of the other glands of the body.

Stomach.—As far as the nervous mechanism of the secretion in the stomach is concerned, the results of investigations are very meagre. There is some evidence that the secretion of the gastric gland is under the influence of extrinsic nerves. For instance, it is stated that in cases of gastric fistula the mere sight of food has been observed to start the secretion of gastric juice. Unfortunately this observation has not been satisfactorily confirmed, and the flow of gastric juice, if it took place under such circumstances, might be an indirect result of reflex movements of the stomach, so that it cannot be considered as conclusive proof that the stomach can be reflexly excited to secretion. The well-known observation of Richet, who found that, in a man with a completely obstructed œsophagus, the chewing of sapid substances, sugar, citron, etc., caused a reflex flow of gastric juice, is also unsatisfactory, especially as similar experiments upon dogs have given negative results. On the other hand, direct stimulation of the vagus, or of the sympathetic branches to the stomach, has given only negative results. So, also, section of all the extrinsic nerves going to the stomach seems to have no direct influence on the secretion, and we are forced to believe that the intrinsic nervous apparatus, plexuses of Auerbach and of Meissner, are sufficient to regulate the normal secretion of these glands.

With regard to the histological changes in the gastric glands during secretion, our knowledge is much more satisfactory. From the microscopical study of glands taken from dogs in different stages of digestion, and hardened in alcohol, Heidenhain has been able to show that certain definite changes in the size and appearance of the cells can be observed. More detailed and trustworthy observations upon the living glands have been made by Langley and Sewall,[16] and Langley.[17] The experiments of these investigators were made upon the œsophageal and gastric glands of the frog and related animals. As is well known, the pepsin of the gastric secretion in the frog is chiefly formed in the œsophageal glands, and it has been found that these glands suffer changes during secretion which are very similar to those already described as occurring in the parotid gland and the pancreas. If these glands are made to secrete, either by mechanical stimulation or by the action of food, the cells, which in the resting condition were granular throughout, begin to lose their granules. The disappearance takes place from the periphery inward, so that soon the cells show an outer non-granular, and an inner granular, zone, owing to the fact that the granules toward the exterior travel inward to the lumen, as those formerly occupying that position are used up in making the secretion. The secretion of pepsin goes on as long as digestion continues, and Langley has proved that during the latter half or two-thirds of the digestive period the granules begin to increase in number, showing that two processes are going on simultaneously, viz., the conversion of the zymogen granules into pepsin and its discharge into the duct of the gland, and the manufacture of new zymogen granules from the protoplasm of the cell. It may be assumed that these two processes go on throughout the whole period of activity, and that in addition there is a continual formation of new protoplasm in the cell from the food offered by the lymph, this being a necessary preliminary step to the formation of new zymogen granules. In the first stages of digestion it is probable that the conversion of zymogen, or pepsinogen as it is called in this particular case, to pepsin overbalances the other processes, and the cells therefore diminish in size. The other two processes, however, soon equalize this loss of substance, and in the later stages of digestion lead to an actual increase in the size of the cells. The cells, therefore, do not have to wait until the period of activity is passed to make up the loss of substance suffered during secretion, but the restorative processes go on simultaneously with the secretion, so that at the end of digestion the gland-cells are nearly or quite as large as the resting cell.

Kidney.—We have no satisfactory evidence of the existence of secretory nerves in the kidney. Eckhard held such a view,[18] and thought that these fibres have their origin from a secretory centre in the medulla, pass down the cord, and reach the sympathetic chain by the communicating branches in the upper thoracic region. Their path from the sympathetic trunk to the kidneys was not definitely known, but Eckhard supposed it to be through the circumvascular plexus around the aorta. He was led to this conclusion chiefly from the fact that, after separation of all the nerves going to the kidneys, as far as they could be distinguished anatomically, stimulation of the medulla still caused an increased secretion of urine. The explanation of this he found in the stimulation of secretory nerves, since the only other theory which could account for it, namely, variations in arterial pressure from the stimulation of the vaso-motor centre, was shown by him to be insufficient, the variations in arterial pressure not being constant.

As far as Eckhard's work has been repeated by later observers, the result has been to weaken his theory of special secretory nerves. The results obtained from section of the cord, stimulation of the medulla, etc., find a simpler explanation in the vaso-motor changes which follow such experiments, and the variations in the quantity of secretion are now usually believed to be the result of the increased or diminished blood-flow through the kidneys.

With regard to the mechanism of the secretion of urine, at least two different views are held at present among physiologists. According to the theory of Ludwig, the secretion of urine is the result of simple filtration and diffusion. In the blood-vessels of the glomeruli the conditions are such that not only is there a filtration of water and salts, but also of the specific elements of the secretion from the blood into the kidney tubules, and this diluted urine in its passage along the uriniferous tubules, by diffusion with the surrounding lymph, becomes concentrated to its normal strength. According to the other theory, first advocated by Bowman, and since upheld by Heidenhain, the secretion of water and salts takes place in the glomeruli, while the specific elements of the secretion are eliminated from the blood by the epithelial cells of the tubules. According to Heidenhain, we have to deal in both cases with a functional activity of the epithelial cells of the kidney, a true secretion as opposed to Ludwig's idea of a simple physical process in which the cells take no active part. The question of the truth or error of Ludwig's view seems to turn mainly on the effect of variations in arterial pressure in the kidneys on the quantity of the urine formed. According to his theory an increase in the arterial pressure should always be accompanied by an increased secretion, and *vice versa*. Heidenhain contends that this is not true, that in some cases increased pressure in the kidney-vessels is not followed by increased secretion, that all the numerous experiments made by Ludwig and his pupils to demonstrate this point simply show that the quantity of the secretion (quantity of water secreted) depends, not on variations in pressure in the arteries of the kidney, but upon variations in the velocity of the blood-flow, an increased velocity of the blood being accompanied invariably by a greater secretion. The labors of Heidenhain, especially his well-known experiments on the secretion of indigo-carmine, have pretty well established the second part of Bowman's theory, that the secretion of the specific elements of the urine takes place through the action

of the cells of the uriniferous tubules; and there is a continually increasing amount of evidence, from various sources, which goes to support the first part of the theory as modified by Heidenhain, viz., that the secretion of the water is also the result of the functional activity of the epithelial cells, most probably those of the glomeruli. There is no evidence of any histological changes in the appearance of the gland-cells during rest and activity of the kind described for the salivary glands, the pancreas, and the glands of the stomach.

Mammary Glands.—Without going into the details of the discussion as to the action of nerves in the production of the mammary secretion, it can be stated that we have abundant evidence that this secretion is, to some extent, capable of being influenced by the nerves. But whether the effect of the nerves is a direct one upon the secreting cells, making them true secretory nerves, or whether it is an indirect effect through modifications of the blood-flow, as in the kidney, is an entirely unsettled question, and we have no positive evidence one way or the other.

Well-defined histological changes of the glandular epithelium, in different stages of activity, have been described by Heidenhain. The changes, however, seem to lie chiefly in the direction of variations in the size of the cells lining the alveoli, and in the amount of fat present in them; so that, while we are justified in believing that the organic products of the secretion, at least, are the result of metabolic changes in the gland-cells, there is nothing in the mechanism of the formation of these products, such as the production of zymogen granules, which would bring this process into close relation with the metabolic changes in other glands. The inorganic constituents of the mammary secretion, as already stated from the analysis of Bunge, differ very widely from those of the blood in percentage proportion, the difference being most marked in the proportion of CaO, P_2O_5, and Na_2O. In the ash of dog's blood there is 45.6 per cent. Na_2O, 0.9 per cent. CaO, and 13.2 per cent. P_2O_5; while in the ash of dog's milk there is 6.1 per cent. Na_2O, 34.4 per cent. CaO, and 37.5 per cent. P_2O_5—a difference which would seem to indicate an active secretion on the part of the gland-cells.

Sweat-glands.—It has been demonstrated beyond doubt that the sweat-glands are provided with proper secretory nerves. Stimulation of the sciatic or brachial plexus in the lower animals causes drops of sweat to form on the balls of the feet. It has been clearly shown that this is not owing to vaso-dilatation, or to any contraction of the tissue simply pressing out the sweat from the gland-ducts. The secretion may be obtained as long as twenty minutes after amputation of the leg, or after clamping the femoral artery, and Luchsinger has shown that the glands may be made to secrete continuously from nerve stimulation for many hours. The nerves of the glands may be stimulated either directly, or reflexly through the central nervous system, and it has been found that pilocarpine and atropine act upon the secretion of these glands just as they do upon the salivary glands.

The precise path of the secretory fibres for the balls of the feet, in cats and dogs, has not been determined. It seems most probable that—for the lower limbs—they leave the spinal cord through the rami communicantes of the three lower dorsal and four upper lumbar nerves, and reach their destination through the sympathetic system. Whether or not there is a general secretory centre for all the sweat-secreting nerves of the body, is unknown; according to Luchsinger the evidence at hand indicates a number of spinal centres as the points of origin of the secretory nerve-fibres. According to Ott [19] the cells show histological changes, after profuse secretion, similar to those found to occur in the salivary glands. From the study of specimens hardened in alcohol after stimulation for two hours and a half, he states that the cells are smaller, more granular, and stain more readily in carmine than those of the resting gland. The increase in the number of granules, as in the case of the salivary glands after hardening in alcohol, is probably the result of the action of the alcohol, and it is possible that if these glands were studied while fresh, the production of secreting material in the form of granules which dissolve and disappear during secretion, as in the pancreas and salivary glands, might be demonstrated. A general survey of the action of the glands of the body, other than the salivary glands and pancreas, teaches us, in fact, that the general theory of secretion, as obtained from the study of these glands, which has been presented in some detail in this article, is not generally applicable. After a careful comparison of the physiology of the different glands, as far as is known, one is forced to the conclusion of Heidenhain, that a general theory of secretion cannot be made at present, if indeed it is possible at all. As he points out, we can make a general theory of the physiology of muscular or contractile substance. Some of the common properties upon which such a thing can be based may be mentioned briefly. When stimulated, a contraction or shortening always results, never a dilatation, as might seem theoretically possible. The chemical changes which accompany the contraction are doubtless closely related. The metabolic changes in voluntary and involuntary muscles, if not identical, must be very similar, and it is not going too far, perhaps, to say that the chemical changes in the substance of the contracting amœba are of essentially the same character as those in the voluntary muscles. So, too, we have theories of the ultimate structure of contractile substance, such as that of Engelmann, and of the mechanism of its action in contraction, which are applicable to the contractile material in protoplasms wherever found. If we seek for any such common properties among the secreting tissues, the search will be in vain. As far as the secretions of our own bodies go, the two most general characteristics that have been established are, that the secretion is the result of metabolic changes in the gland-cells, as shown by chemical and histological examination of the secretion and of the cells; and furthermore, that the action of the cells is under the influence of the nerves. But as we have already seen in some of the glands, we cannot prove the existence of secretory nerves, or perhaps the evidence is entirely against their existence; while, on the other hand, the generous definition of secretion includes certain liquids, such as the serous transudations or the lymph, the formation of which, according to general belief, is not dependent upon any functional activity of epithelial cells, although evidence has been given in this article to show that this general belief may be erroneous. Indeed, the very definition of secretion as given in the beginning of this article, the definition generally accepted, is an artificial one, which does not clearly characterize or differentiate secretion from other physiological processes. The second part of the definition, viz., that the secreted substance, after its separation from the blood, is poured out on a free epithelial surface, seems to be an arbitrary distinction. In the liver, for instance, we have an example of a gland which forms a true secretion, bile, according to the definition. The materials for the secretion are prepared in the liver-cells, and poured out on the free epithelial surface of the bile-ducts. But the liver-cells also prepare another substance, glycogen, which is finally poured out into the blood-vessels, and the processes in the two cases would seem to be essentially the same, though no one speaks of the latter as a secretion. If it be urged in this particular case that the glycogen is of direct nutritive value to the body-cells, food-matter, in fact, while the bile is only of secondary value in its action on the food-stuffs in the intestine, such a distinction cannot be accepted as general. For in some of the undoubted secretions, such as saliva and pancreatic juice, we have albumins present which must finally be absorbed from the alimentary canal, and serve as nutritive material.

The formation of the organic products of the secretions, whenever such products occur, is essentially similar to the ordinary nutritive processes in all the cells. The food-material given by the lymph is assimilated into new protoplasm of the kind characteristic of the cell, and this then undergoes retrograde changes of a katabolic nature, which result finally in the production of the zymogen material. Perhaps an essential difference between the metabolism in gland-cells and the nutritive changes

in the cells of the tissues generally, may lie in the fact that, whereas in the cells generally the end products of katabolism are CO_2, H_2O, and some simple nitrogenous residue, in the gland-cells the series of katabolic changes, at least in those glands which are distinguished by the formation of organic material in their secretions, ends in the formation of these more complex products ; the oxidations or dissociations are less complete. In those glands, like the kidney, in which the cells seem only to pick the secreted material out of the blood, we have no theory at all of the means by which this is accomplished, nor do we know whether or not the process is associated with any metabolic changes in the cells themselves. With regard to the active secretion of water and of salts by gland-cells, or epithelial cells of any kind, no satisfactory theory is yet offered. Heidenhain's view of the action of the secretory fibres in the salivary glands, to account for this process, will not apply at all to the similar process of water formation in the kidney, nor to the formation of lymph by the endothelial cells of the capillaries, if this is demonstrated to be true. *W. H. Howell.*

SEDATIVES. There is a class of remedies called sedatives, or depressants, the action of which is to quiet overexcitement of an organ or group of organs. Like all other divisions of therapeutic agents, that of the sedatives cannot be strictly defined, as it embraces many remedies which exert a sedative action only in certain cases and upon certain organs. Thus digitalis is a vascular sedative, while at the same time it is a powerful cardiac tonic. Again, a remedy may be either an excitant or a sedative, according to the dose, or to the length of time that has elapsed since its administration. Opium, for example, may be employed as either a stimulant or a sedative, according to the dose, or the condition or idiosyncrasy of the patient.

The group of remedies which may be given to produce sedation is a very large one, and may be divided into subclasses according to the mode and degree of action of the medicaments comprised therein, or to the special organ or group of organs acted upon. Thus we have nervous sedatives, emollients, analgesics, anæsthetics, anaphrodisiacs, hypnotics, etc. We shall here consider briefly the nervous, respiratory, circulatory, gastric, urinary, and local sedatives. For a further consideration of the remedies embraced in this class, the reader may consult the articles Anodynes, Antispasmodics, Anaphrodisiacs, Anæsthetics, and Hypnotics, in the earlier volumes of this HANDBOOK.

NERVOUS SEDATIVES.—These remedies are employed to quiet abnormal excitability of the brain and spinal cord, either directly by their action upon the nervous centres, or indirectly by stilling pain or removing any other cause of the exalted nervous state. Among the general sedatives may be mentioned rest, warm baths, alcohol in small doses, especially in the form of malt liquors, tobacco smoke in moderate quantity, for those who are habituated to its use, valerian, camphor, hyoscyamus, the bromides, chloral, opium, and all the hypnotics and anodynes. Among spinal sedatives gelsemium and calabar bean are familiar examples.

RESPIRATORY SEDATIVES.—These are remedies which serve to relieve dyspnœa and quiet cough. These effects may be obtained by removing the cause, whether it be in the lungs, the liver, the heart, the larynx, or the ear, by obtunding the respiratory centre, or by reducing the irritability of the terminal nervous filaments. Belladonna, opium, oxalate of cerium, quebracho, and the expectorants generally, may be mentioned as examples of the respiratory sedatives.

CIRCULATORY SEDATIVES are agents which reduce the frequency and the strength of the cardiac action, and diminish the volume of blood in the vessels. Some remedies, like digitalis, increase the strength of the cardiac pulsations, while they reduce the flow of blood in the vessels. These are called vascular, as distinguished from cardiac, sedatives. The principal circulatory sedatives are cold, veratrum viride, aconite, ergot, digitalis, and opium.

GASTRIC SEDATIVES are employed to relieve pain and vomiting. They act by reducing local irritation in the stomach itself, or by a direct effect upon the vomiting centre. The most important are cold, opium, bismuth, oxalate of cerium, chloroform, creasote, atropine, hydrocyanic acid, and ipecac, calomel, or arsenious acid in minute doses.

URINARY SEDATIVES.—These are agents which render the urine bland and unirritating, or which lessen pain and irritability of the bladder. Alkalies, water in large amounts, copaiba, thymol, belladonna, opium, and warm sitz-baths are some of the remedies of this class.

LOCAL SEDATIVES.—In this class are all those remedies which act directly upon the terminal nerve-filaments in any locality, diminishing their sensibility. Many of the gastric and urinary sedatives, already referred to, are examples of this class of agents; but the term, in its more commonly understood application, refers to remedies acting upon the skin and accessible mucous membranes. These agents are employed to relieve pain and itching of the parts to which they are applied. Aconite, belladonna, opium, chloral-camphor, carbolic acid, hydrocyanic acid, chloroform, lead-water, cocaine, and cold, in the form of ice or evaporating lotions, are familiar examples of this class of remedies. *T. L. S.*

SEGMENTATION OF THE BODY. As stated in the article Fœtus, vol. iii., p. 177, the segmentation of the body depends primarily upon the divisions of the muscles to which the segmental divisions and arrangements of the other parts are secondary. The evidence we at present possess in regard to the evolution of vertebrates indicates that they were derived from forms allied to the segmented worms (Annelida). These animals are, in fact, the only ones besides the vertebrates whose bodies have a segmentation. In the annelides all the segments are decidedly similar, and though we see, here and there, a group of them modified, all in a like manner, as for instance in the clitellus of the earth-worm, yet we do not see anything strictly comparable to the division of the segments in vertebrates into two main groups, one comprising the segments of the head, the other the segments of the rump. Consequently, we must say that the possession of a head developed by the condensation of a number of segments is a feature exclusively pertaining to vertebrates. This involves the corollary that no invertebrate possesses a true head, if we take the definition of that term from vertebrates. The homologous parts, or, to be more precise, the segments homologous with those of the vertebrate head were, of course, present in the invertebrate ancestral form.

These considerations render it evident that to elucidate the segmentation of the higher types we have to determine, *first*, the primitive character of the segments; *second*, the number and modifications of the segments in the head; and *third*, the number and modifications of those in the rump. It is impossible to enter here upon a full discussion of this abstruse problem. We can only state briefly the essential results at present known.

First. As to the primitive arrangement. We must assume that in the ancestral type of vertebrates the body cavity was continuous ventrally throughout both the region of the head and of the rump. The dorsal portion of the body cavity was divided into the muscular segments or myotomes. Each pair of myotomes, of course,

represented a single segment. For each segment there were four nerves, two on each side; of these two, one sprang from the ventral side of the nervous system and passed to innervate the myotome of that side; this nerve persists, in man, in the series of spinal nerves as the anterior motor root; the other nerve of the same side sprang from the dorsal part of the central nervous system, passed outside of the myotome, and innervated both the walls of the body cavity and also an epidermal sense-organ upon the surface of the segment. This nerve is represented in man by the sensory root of a spinal nerve.

The evolution of a heart upon the ventral side of the body may be regarded as having been, presumably, the first definite step toward the evolution of the head, because the heart lay a little distance behind the mouth, so that there were a few segments in front of the heart and an indefinite series behind it. But the heart was so constructed that it pumped the blood forward; it must have been advantageous for the blood to be purified before it reached the tissues to which it was forwarded by the heart; certainly the purifying apparatus *was* actually developed in the segments in front of the heart, for they only were gill-bearing. These respiratory needs were satisfied by the development of gill-clefts, which permitted a freer circulation of water and an increased exposure of the superficial blood-vessels of the branchiæ, and so effected a more perfect aeration of the blood. The division of the body into a gill-bearing and a not gill-bearing region may be designated as the second step in the evolution of the head. In fact, the branchiate segments are the head segments. The presence of gill-clefts has led to many modifications of the primitive segmental arrangements, and these complications have been greatly increased by the extreme condensation of the head segments and also by the displacement of certain parts, as well as by the disappearance of others, and, finally, through the annexation by the head of three or four segments properly belonging to the rump.

Second. Number and characteristics of the cephalic segments. The determination of the number of segments in the vertebrate head has long occupied the attention of naturalists. In the beginning of this century the vertebræ were usually taken as the means of counting segments, for at that time the fact that segmentation depends on the myotomes, and that therefore the vertebræ are parts of the inter-segmental structures, had not been ascertained. Hence, in this period, we find discussion turning upon the number of supposed vertebræ in the head. The earliest suggestion of a vertebral theory of the skull, known to me, is that of Burdin, independently made about the same time by Heilmeyer. These authors compared the skull to a single complex vertebra. The first to announce the modern theory of there being several segments in the head, was Oken, who conceived that there were four cranial vertebræ. Goethe adopted this hypothesis with some infelicitous modifications of his own. He counted six vertebræ, of which three belonged to the facial apparatus. As to the number of vertebræ, there is a very extensive literature, which possesses an interest purely historical. Let it suffice, therefore, to state aphoristically that three vertebræ were advocated by Spix, Meckel, Burdach, and Carus; four by Oken, Bojanus, and Owen; six by McClise; and seven by Geoffroy.

The discovery of the real segmentation was started by Gegenbaur, continued by Balfour, and elaborated by Marshall, Spencer, Dohrn, van Wijhe, Froriep, Beard, and others. Gegenbaur recognized the segmental arrangement of the cranial nerves, and endeavored to ascertain their primitive number and arrangement. This was a great step in the right direction. Subsequent writers have studied in more detail the development of the cranial nerves, giving especial attention to their relation to the primitive segments or myotomes, which embryology shows to be temporarily present in the head. These researches have led to the conclusion that the two nerves, on each side of each segment, have remained distinct, whereas in the rump they are transformed into roots which unite into one nerve. The dorsal or sensory nerve in the head runs to a sensory organ in the integument, which organ is situated just above the opening of the branchial cleft of the same segment. This nerve also possessed three branches, one running above the cleft, one in front of it, and one behind it. The ventral or motor nerve ran to the myotome of its segment. The number of myotomes, in at least all the higher vertebrates, to be found in the head of the embryo is twelve, and there is some reason for thinking that there may once have been a thirteenth in front of those which we can still detect. Now, the majority of these myotomes disappear very early, and the nerves which belong to them have disappeared also. In fact, no trace of the nerves of several of the myotomes has been observed. We see that the majority of the branchial sense-organs are also only temporary embryonic structures. But the sensory nerves, as they have other branches than those to the branchial sense-organs, are left with functions to perform, and accordingly are preserved in the adult. It is a misnomer to call the ventral cephalic nerves sensory only, because they carry motor fibres likewise, which supply the muscles developed in the gill-arches independently of the myotomes. A brief explanation is requisite in regard to the three posterior segments of the head, and in regard to the seventh, eighth, ninth, and tenth segments. These two sets of myotomes have each a single nerve only. The seventh to tenth segments correspond in our enumeration to the sixth to ninth myotomes, one myotome being supposed to have been lost in front. The nerve of these segments is shown by its development in the embryo to be the product of the fusion of four nerves; it is known to anatomists as the vagus. The nerve of the eleventh to thirteenth segments (tenth to twelfth myotomes) is the hypoglossus, which is produced by the fusion of three distinct nerves, each of which has two roots, and possesses in the embryo all the essential features of a true spinal nerve. It follows that the three corresponding segments are not truly cephalic, but have been annexed from the region of the rump by the head, and added to the occipital region. Since the differentiation of the head commenced with the evolution of branchial clefts, it has resulted in the evolution of the head preceding that of the vertebræ; hence there is no trace whatever of vertebræ in the head, except in the hypoglossal region.

The table on the next page presents, in a compact form, all the essential facts yet gathered in regard to the segmental disposition of the organs of the head.

The characteristics of the head segments are, first, the development of gill-clefts; second, the fact that the dorsal and ventral nerves do not become roots, but remain distinct; third, the absence of vertebræ. There are many other peculiarities which might be signalized, but the three named seem to me the most essential. There are *very* numerous secondary modifications, which are in large part indicated in the following table.

Third. Rump segments. The number of segments in the rump is very variable. In man there are thirty-seven or thirty-eight, of which four or five constitute the temporary tail, and disappear during the second month of fœtal life. The characteristics of the rump may be said to be the conversion of the nerves into roots; the development of true vertebræ; the great development of myotomes, which produce the skeleton muscles; and, finally, the segmental organs or excretory tubules, which constitute the primitive kidney or so-called Wolffian body, and of which there is, at first, at least one pair in each segment. It must be added that not every rump segment appears to necessarily have segmental organs.

† Dohrn and Beard regard the facial nerve as double, and think that one myotome and one cleft are lost between the mouth and hyoid cleft.

Charles Sedgwick Minot.

SEGMENTATION OF THE OVUM. There follows upon the impregnation of the ovum a remarkable process known as the segmentation. This term is used to designate the series of divisions of the impregnated ovum into a number of cells, of which all the cells of the future animal are the direct descendants. Common usage applies the term only up to the time of development, when the two primitive germ-layers are clearly differentiated and the first distinct organs are beginning to appear. The word was introduced before the masses into which the ovum divides were known to be cells. The cleavage of the ovum was described by Prevost and Dumas, and again by Rusconi in 1836.[27] Since then it has been investigated very frequently. The cell doctrine dates from 1839.

As stated in the article on Impregnation (vol. iv., p. 5), *the nucleus of the impregnated ovum is formed by the union of the male and female pronuclei.* Van Beneden had affirmed that there was no real union in the eggs of Ascaris, but Carnoy[13] has shown that Van Beneden's observations were incomplete, and Zacharias[26] states that they were so very defective as to be fundamentally erroneous, and that in reality the eggs of Ascaris offer another proof of the actual union of the pronuclei. It seems to me safe to accept the generalization just made as to the origin of the first or *segmentation nucleus.*

The position of this nucleus is determined, first, by the form of the egg; second, by the distribution of the formative (ectodermal) and nutritive (entodermal) yolk. In *round* eggs, with very little yolk—alecithal ova—such as those of Echinoderms, the nucleus lies nearly in the centre. It is commonly stated to lie *exactly* in the centre, but I must question the accuracy of such statements. When there is an evident differentiation of nutritive and formative yolk—telolecithal ova—the nucleus is always eccentric and its eccentricity increases with the amount of yolk, for it always tends to approach the so-called "animal" pole, where the protoplasmatic or formative yolk is accumulated. In *oval* eggs with little yolk the nucleus lies in the middle of the long axis, as in Nematod eggs, but whenever there is differentiation of an animal pole the nucleus tends to approach it. In brief, we may say that the *segmentation nucleus takes the most central position possible with regard to the protoplasm of the ovum.* The vitelline granules are not regarded as protoplasm, hence, when they accumulate they may increase the bulk on one side of the nucleus without otherwise disturbing the radial distribution of the protoplasm around it.

After the segmentation nucleus is formed there occurs a pause, which lasts, according to observations on several invertebrates, from half to three-quarters of an hour. During this period the yolk gradually expands again (having contracted during impregnation), and also acquires a radiating appearance starting from the nucleus as a centre. The radiation is due to the arrangement of the protoplasmatic network, and the conforming distribution of the yolk granules. The physiological mechanism is unknown which causes this radiation and the other radiations of protoplasm which appear during cell divisions. Morphologists often speak loosely of nuclear attraction as the cause, but it need hardly be pointed out that this notion is, physiologically speaking, vague and crude. The monocentric radiation soon disappears and is replaced by a dicentric radiation, which marks the end of the period of repose, and the commencement of the first division of the ovum. For figures see Hertwig's memoirs.[18, 19]

The external appearances of segmentation in the living ova vary, of course, especially according to the amount and distribution of the yolk material. The appearances in holoblastic ova with very little yolk are well exemplified by Limax campestris. Mark's description[22] is, nearly in his own words, as follows: In Limax, after impregnation, the region of the segmentation nucleus remains more clear, but all that can be distinguished is a more or less circular, ill-defined area, which is less opaque than the surrounding portions of the vitellus. After a few moments this area grows less distinct. It finally appears elongated. Very soon this lengthening results in two light spots, which are inconspicuous at first, but which increase in size and distinctness, and presently become oval. If the outline of the egg be carefully watched, it is now seen to lengthen gradually in a direction corresponding to the line which joins the spots. As the latter enlarge, the lengthening of the ovum increases, though not very conspicuously. Soon a slight flattening of the surface appears just under the polar globules; the flattening changes to a depression (Fig. 3435), which grows deeper and becomes angular. A little later the furrow is seen to have extended around on the sides of the yolk as a shallow depression, reaching something

more than half-way toward the vegetable or inferior pole, and in four or five minutes after its appearance the depression extends completely around the yolk. This annular constriction now deepens on all sides, but most rapidly at the animal pole; as it deepens it becomes narrower, almost a fissure. By the further deepening of the constriction on all sides, there are formed two equal masses, connected by only a slender thread of protoplasm, situated nearer the vegetative than the animal pole, and which soon becomes more attenuated, and finally parts. The first cleavage is now accomplished. Both segments undergo changes of form; they approach and flatten out against each other, and after a certain time themselves divide.

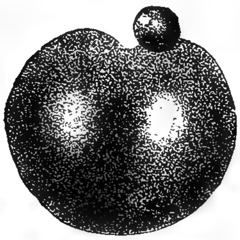

FIG. 3435. — Ovum of Limax Campestris during the First Cleavage. Magnified 200 diameters. The envelopes are not drawn in. (After E. L. Mark.)

The division of *all* ova, so far as at present known, is indirect (karyokinesis, mitosis), there being nuclear spindles, amphiasters, etc. The dicentric radiation just mentioned marks the appearance of the first amphiaster.

The plane of the first division determines those of the subsequent divisions, and also of all the axes of the embryo; * it is itself determined by the position of the long axis of the first amphiaster or nuclear spindle, to which it is at right angles. It, therefore, is a matter of great interest to ascertain what factors determine the position of the first spindle, or, in other words, the axis of elongation of the segmentation nucleus. So far as at present known, there are two factors: 1, Relation to the axis of the ovum; 2, position of the path taken by male pronucleus to approach the female pronucleus. The axis of the ovum is fixed before impregnation; it passes through the centre of the animal, and that of the vegetable pole. Usually the nuclear spindle which leads to the formation of the polar globule has its long axis coincident with that of the ovum, hence the point of exit of the polar globule marks one end of the ovic axis. *The first amphiaster or spindle is always at right angles to the ovic axis.* This, however, leaves the meridian plane undetermined. Roux,[24] from a series of interesting experiments on frogs' ova, concludes that the plane is fixed by the path of the spermatozoon. So far as I know, this idea was first suggested by Selenka, in 1878, in his paper on "The Development of Toxopneustes Variegatus;" compare also Mark, *l. c.*,[22] p. 500. In the frog's egg the path of the male pronucleus is marked by a line of pigment, as was first described by Van Bambecke,[28] and has been well figured by O. Hertwig.[29] The pigment renders it easy to ascertain the position of the male road, even after the first cleavage of the ovum. This Roux has done in sectioned ova, and from his experiments and observations reaches this result: *The long axis of the first segmentation spindle lies in a plane, which passes through the axis of the ovum and the path of the male pronucleus.* If Roux's conclusion is confirmed, it will become of fundamental importance. Yet there must be other factors which can at least replace the male pronucleus in this special rôle, since the development of parthenogenetic ova, in which there is no male pronucleus at all, is equally determinate. It is probable that the distribution of the protoplasm is the real cause determining the position of the nucleus; thus in oval eggs the spindle lies in the direction of the long axis; it is quite probable that if the male pronucleus has the effect ascribed to it by Roux, it produces it indirectly by altering the distribution of the protoplasm within the ovum; that such alteration takes place is indicated by the occurrence of the male aster.

After the spindle is formed it divides, and the daughter nuclei form the centres of two segmentation spheres or cells. Each of these cells again divides in the meridional plane at right angles to the first. The third cleavage is at right angles to both the first. If an egg is placed with its axis vertical, the planes of the first and second divisions both will be vertical, but that of the third will be horizontal.

Segmentation occurs with many variations, according to the manifold modifications of ova, and these varieties we must now briefly consider.

It has long been customary to describe the various modifications of segmentation as belonging to three types: 1, *regular* or *equal*; 2, *unequal*; 3, *partial*. It has become traditional to state that the first type is found in the Echinoderms, etc., and is characterized by the regular and uniform division of the cells (segments), so that there are first two, then four, eight, sixteen, thirty-two, sixty-four, and so forth, cells. But this statement is fundamentally erroneous. The frog's ovum is taken as the example of the second type, and the bird's ovum of the third. This classification is most unfortunate, for it leads attention off from *the essential* feature of the process of segmentation, as first pointed out by Minot in 1877. Minot[23] established the generalization that *in all animals the yolk undergoes a total segmentation, during which the cells of the ectoderm divide faster and become smaller than the cells of the entoderm* (Fig. 3436). There are, however, a small, and it seems diminishing, number of cases where the process of segmentation and the formation of the germ-layers is imperfectly understood, and which cannot yet be shown to conform to this generalization. "All the known variations in the process of segmentation depend merely upon: 1, The degree of difference in size between the two sets of cells; 2, the time when the difference appears; 3, the mode of development, whether polar or by delamination,* either of which may or may not be accompanied by axial infolding. In Gasteropods, Planarians, Calcispongiæ, Gephyrea, Annelida, fish, birds, and Arthropods the difference is great and appears early. In Echinoderms, most Cœlenterates, some sponges, in Nematods, Amphibians, etc., it is less marked and appears later" (Minot, *l. c.*).

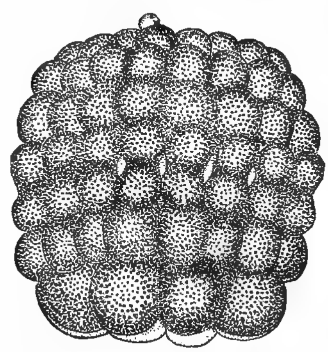

FIG. 3436.—Ovum of Amphioxus Lanceolatus during Segmentation; stage with 88 cells. Magnified 280 diameters. (After Hatschek.) One pole is occupied by large, the other by smaller, cells.

In most cases the entodermic cells are very decidedly larger and less numerous than those of the ectoderm. This distinction is obviously necessary on account of the mutual relations of the two primitive layers. The ectoderm has to grow around the entoderm, which it can do only by acquiring a greater superficial extension—this the ectoderm accomplishes by dividing very quickly at first into small cells. After the entoderm is fully enveloped it may then continue to grow until its superficies is much greater than that of the outer layer, within which, however, it still finds room by forming numerous folds; thus is gradually reached the condition in the higher adult animals, where the intestine sometimes has an enormous surface, but is nevertheless contained in body-walls covered by ectoderm presenting much less surface. It is, therefore, only during the early stages of segmentation that we find the entoderm expanding more slowly than the ectoderm.

The degree of difference in size between the ectoderm and

* In certain cases, notably in birds, as described below, the segmentation is irregular; and it is therefore not known yet whether the scheme of arrangement of the cleavage planes here given can be applied to *all* ova or not. We may say, however, that the scheme is the primitive one, from which any modifications arose phylogenetically. The best discussion of the subject is by Whitman.[1]

* There is not a single satisfactory description of the process of delamination known to me, and one cannot avoid hesitating to accept it as an actual occurrence. It is certainly at most a very rare, and probably secondary, modification of segmentation. It does not occur among vertebrates.

entoderm cells depends upon the amount of yolk present. The yolk-granules are *situated*, not quite exclusively but almost so, in those parts of the ovum out of which the entodermal cells are formed. Hence, when there is a great deal of yolk, the *Anlage* of the entoderm in the ovum becomes bulky, and the entodermal cells correspondingly big, as may be seen very plainly in amphibian ova. On the other hand, when the amount of yolk is very small, as in the eggs of echinoderms, the difference in size of the two kinds of cells is very slight at the start of segmentation; but, as the cleavage process continues, the ectodermal cells, in consequence of their more rapid divisions, become markedly smaller than their entodermal fellows. The same may be said in regard to mammalian ova, the segmentation of which is described more fully below. Besides its effect upon the volume of the entoderm, the yolk matter seems to actually retard the development of the inner germ-layer, by impeding the division of cells. This effect was pointed out many years ago, and is one of the familiar principles of embryology.* This is well exemplified in the bird's egg, in which the nuclei divide in the entoderm, but only gradually gather distinct cell-bodies about themselves, and in consequence the ventral side of the primitive entodermic cavity is bounded by a mass of protoplasm with scattered nuclei and numerous yolk-granules; and as these last are transformed into protoplasm, the cells are completed as separate individualities. The proliferation of the nuclei without *pari passu* separation of the cells occurs in similar manner in elasmobranchs, and comparable phenomena occur in many invertebrates, notably among the arthropods (Fig. 3437), with the so-called superficial segmentation.

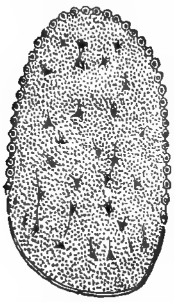

FIG. 3437.—Section of the Egg of a Moth. (After Bobretzky.) Nuclei are seen scattered through the yolk.

The terms *holoblastic* and *meroblastic* are applied to ova according to their manner of segmentation. The first is employed for those ova in which there is either very little or only a moderate amount of yolk, so that the whole of the ovum splits up into distinct masses (cells), which enter into the composition of the embryo. The second designates ova with a very large amount of yolk, so that while the protoplasm from which the ectoderm arises divides rapidly into distinct cells, the entodermal portion merely develops nuclei at first, with the result that while one portion of the egg is "segmenting," another portion (the entodermal) remains unsegmented, so far as the external appearances are concerned. Eggs, then, with much yolk undergo the so-called partial segmentation; hence the adjective *meroblastic.*

The result of segmentation is to produce two kinds of cells, ectodermal and entodermal; the latter are the larger and contain most of the yolk-granules; the entodermal cells may be represented for a certain period, partly or wholly, by a mass of yolk with scattered nuclei (Fig. 3437). The cells are arranged so as to form, each kind, a layer of epithelium. The two epithelia are joined at their edges; the line of junction is the *ectental line.* (See Fœtus.) Between the two layers, ectoderm and entoderm, is a space known as the *segmentation cavity*, and which varies in form and size according to the species of ovum. Among radiates it approaches a spherical shape, and the two epithelia make a hollow sphere; this arrangement is known as the *Blastula* form, and by some writers has been considered the primitive type of structure resulting from segmentation. In other cases the segmentation cavity is a mere slit between the entoderm distended with yolk and the ectoderm. (See the figures in the article on the Blastoderm.) Ultimately, the segmentation cavity is invaded by cells, which enter into the composition of the mesoderm (see Germ-layers, Gastrula, and Fœtus, development of), and by which the cavity is ultimately filled up. The body cavity arises subsequently in the mesoderm. (See Cœlom.) The segmentation cavity is very much reduced in amniote ova, and in birds is obliterated so early by the precocious thickening of the ectoderm that it scarcely can be said to appear.

The best-known example of a meroblastic ovum is the hen's egg. Its segmentation commences while it is passing through the lower part of the oviduct, and shortly before the shell has begun to be formed.

Viewed from above, a furrow is seen to make its appearance, running across the germinal disk, though not for its whole breadth, and dividing it into two halves; this furrow is developed in accompaniment with the division of the first segmentation nucleus. The primary furrow is succeeded by a second, nearly at right angles to itself. The surface thus becomes divided into four segments or quadrants (Fig. 3438, A), which are not at first separated

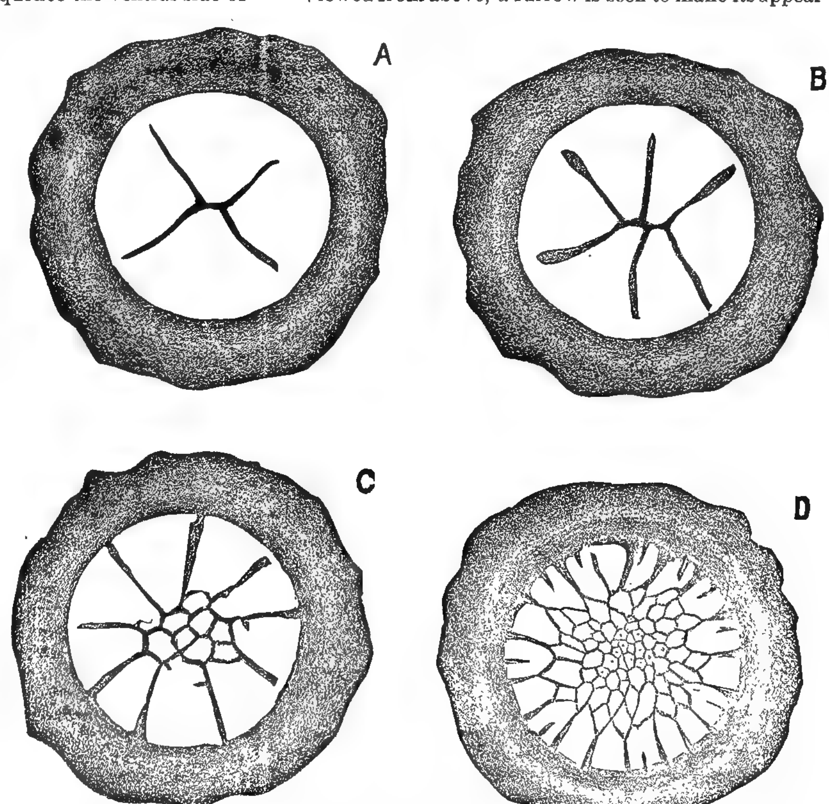

FIG. 3438.—Four Stages of the Segmentation of the Hen's Ovum. Only the germinal disk, seen from above, and part of the surrounding yellow yolk are represented. (After Coste.)

* It is not a little curious that two embryologists have recently discussed this principle as if it were quite a new discovery of their own.

from the underlying substance. The number of radiating furrows, of which there are now four, increases to from seven to nine, when there occur a series of cross-furrows by which the central portion of each segment is cut off from the peripheral portion, giving rise to the appearance of a number of small central segments surrounded by more external elongated segments. Division of the segments now proceeds rapidly by means of furrows running in various directions. Not only are the small central segments divided into still smaller ones (Fig. 3438, D), but also their number is increased by the addition of more segments cut off from the peripheral ones. Sections of the hardened blastoderm show that segmentation is not confined to the surface, but extends through the mass, there being also horizontal furrows, *i.e.*, furrows parallel to the surface of the ovum. According to Duval,[15] whose account of the segmenting hen's ovum is, on the whole, the most satisfactory, when quite a small number of cells are separated off there is a small space between them and the yolk, as shown in his Figs. 2, 3, 4, 5, and 6 of Pl. I.; this space he calls the segmentation cavity; but this can hardly be, as the cells formed below it make part of the ectoderm (primitive blastoderm); the cells referred to are those marked *in* in Fig. 8 of the same plate; the space there lettered *cg* is the entodermal cavity. We can now speak of the primitive blastoderm (compare the article Blastoderm, vol. i., p. 528). The several-layered mass of cells represents the ectoderm; it has only traces of the segmentation cavity. The yolk represents the entoderm. At this stage the ectoderm is not completely separated off, but still receives peripheral accretions from what may be called the segmenting zone around the blastoderm. For the further history see Blastoderm, and the first section of the article Fœtus, where the differentiation of the cellular entoderm is described.

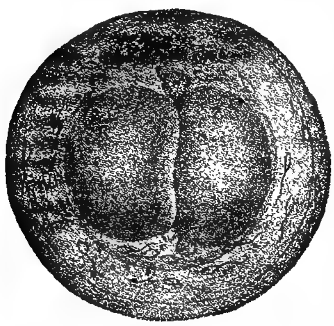

Fig. 3439.—Ovum of a Rabbit of Twenty-four Hours; the first cleavage has been completed. (After Coste.)

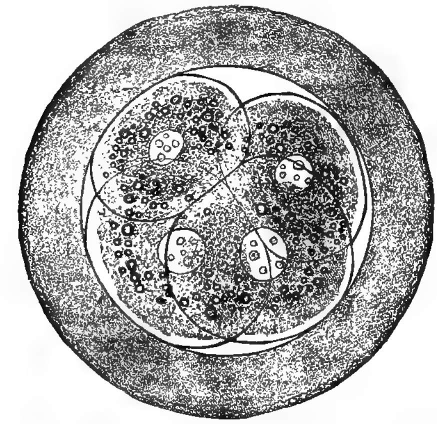

Fig. 3440.—Ovum of Vespertilio Murina, with Four Cleavage Spheres. (After Van Beneden and Julin.)

The ovum of the placental mammalia is called holoblastic, because it contains very little yolk and undergoes "total" segmentation. Its segmentation was first clearly recognized by Bischoff, though it had been previously seen and misinterpreted by Barry.[2] Very beautiful figures are given by Coste.[14] A number of more recent writers have dealt with the subject, among whom Hensen[17] deserves especial mention. Reference may also be made to Heape's observations on the mole;[16] to Kupffer's on rodents; to Selenka's on rodents and the opossum in his "Embryologische Studien;" to Van Beneden and Julin's on bats,[6] and to Van Beneden's on the rabbit;[3, 4] but of these last the entire accuracy may be doubted. The ovum is discharged from the ovary surrounded by the so-called *corona radiata*, which is composed of cells of the *discus proligerus*. It passes quite rapidly through the first half or two-thirds of the oviduct, and during this period is impregnated and loses the *corona radiata*. In the lower half, or third, of the oviduct segmentation begins, and may be wholly or only partially completed when the ovum passes into the uterus. The ovum spends about seventy hours in the oviduct in the rabbit, and about eight days in the dog. The first cleavage plane passes through the axis of extrusion of the polar globules (Fig. 3439); the two segmentation spheres flatten out against one another. The second cleavage plane is probably also meridional, as is indicated by Selenka's observations on the opossum; and there are four equivalent cells as the result. Van Beneden asserts, however, that the cells are unlike, two being smaller than the others (Fig. 3440). These smaller cells he regards as the representatives of the ectoderm. The successive cleavages have never been followed accurately, but after a time there appear an outer layer of cells (Fig. 3441), *Ec.*, forming an epithelium under the zona pellucida, *Z*, and an inner mass of cells, *im.*, of darker appearance, which at first completely fill the space within the epithelium. During all these early stages the cells (segmentation spheres) are all naked, *i.e.*, without any membrane: the nuclei, when not in karyokinetic stages, are large, clear, and vesicular; the yolk granules are small, highly refractile, and more or less nearly spherical; they show a marked tendency to lie in the egg, half-way between the nucleus and zona, or, when the cells are large, around the nucleus, but a little distance from it. The outer layer of cells is not complete, but interrupted at one point, where the inner mass (Fig. 3441, *im.*) comes through to the surface. By the continued division of the cells of the subzonal layer, that membrane forms a larger vesicle, and there arises a space between the outer epithelium and the inner mass, as shown in Fig. 421, Vol. I. The cavity, I think, is probably the true segmentation cavity; the outer layer is the entoderm, and not the ectoderm, as commonly described; and the inner mass is the true ectoderm. For the reasons of this interpretation see Blastoderm.

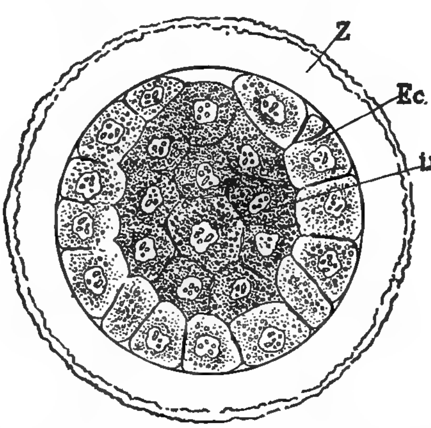

Fig. 3441.—Rabbit's Ovum in an Advanced Stage of Segmentation. *Z*, zona pellucida; *Ec.*, ectoderm of authors; *im.*, inner mass of cells.

Literature.

The literature upon Segmentation is very extensive. I cite a few of the principal articles, giving the majority of those which deal with the mammalia. There is no research published on mammalian segmentation which meets the present requirements of embryology.

Charles Sedgwick Minot.

SELTERS is a village in the province of Hesse-Nassau, Prussia, near which is a spring which is the source of the well-known Selters or Seltzer-water. The following is the composition of this water. In one thousand parts of water there are:

Sodium bicarbonate	1.021
Calcium bicarbonate	0.550
Magnesium bicarbonate	0.210
Ferrous bicarbonate	0.030
Sodium sulphate	0.150
Sodium phosphate	0.040
Sodium chloride	2.040
Potassium chloride	0.001
Silica and aluminium	0.050
Total	4.092

Selters-water is exported in large quantities, very little use being made of it at the spring itself. It is recommended in the treatment of dyspepsia and catarrhal troubles of the respiratory organs. Its chief employment, however, is as a beverage. *T. L. S.*

SELTZER SPRINGS. *Location and Post-office,* Mendocino County, Cal.

ACCESS.—By San Francisco & North Pacific Railroad to Cloverdale; thence by stage.

ANALYSIS (H. G. Hanks).—One pint contains (61° Fahr.):

	Grains.
Carbonate of soda	7.598
Carbonate of magnesia	10.118
Carbonate of lime	1.938
Carbonate of iron	0.567
Chloride of sodium	1.478
Alumina	0.075
Silica	0.729
Total	22.503
Gas.	Cub. in
Carbonic acid	45

G. B. F.

SEMINAL INCONTINENCE. DEFINITION.—By this is meant the involuntary loss of seminal fluid, whether one is asleep or awake, by ejaculations or passive flow. The term *spermatorrhœa* has commonly been applied to this condition, but not with uniform significance. By some writers this word is made to signify only the passive flow of semen, according to its etymology (σπέρμα, semen, and ῥέω, I flow); and losses accompanying erections, spasmodic ejaculations, and orgasms, are styled pollutions. Some make a distinction between nocturnal and diurnal pollutions, or those in sleeping and waking hours, and so have three forms of the malady. Those who apply the term spermatorrhœa to all forms of seminal incontinence, speak of *true* and *false* spermatorrhœa, but here the distinction is not uniform. With some the *true* variety means emissions with erection and orgasm, while others restrict its use to cases in which the emissions contain spermatozoa. This last distinction is lacking in both precision and convenience, for the presence of spermatozoa must be determined by microscopical examination, and in the same case they may at one time be present, and at another time absent, according to frequency of emissions. In this article *seminal incontinence* will express all forms of involuntary seminal emission; the word *spermatorrhœa* will be restricted to that form in which erection, spasmodic ejaculation, and orgasm are absent; and other forms will be styled *nocturnal* and *diurnal pollutions*, according as they occur in sleeping or in waking hours.

NATURAL HISTORY.—It is to be premised that seminal incontinence may be physiological or pathological. Most men in vigorous health, who do not indulge in sexual intercourse, have occasional nocturnal emissions, and they may occur once in two weeks, once a week, or even oftener, without any impairment to health. It is only when they are followed by a sense of muscular exhaustion, pain in the head and back, mental hebetude, and depression of spirits, that they become morbid and require measures for their arrest. In health the testicles, prostate gland, and seminal vesicles are in the constant exercise of their functions, from the period of puberty to the decay of old age, and their secretions are commonly redundant, that is to say, more than the absorbents can take up and carry off in the general circulation. This redundancy is relieved by a due amount of sexual intercourse, or by occasional involuntary emissions. Excessive stimulation and use of these organs result in seminal incontinence, and later in impotence. It is unnecessary to repeat here what is described in other articles about the anatomy of the male sexual organs and their functions.

Most cases of morbid seminal incontinence begin with nocturnal pollutions, which become more and more frequent unless the exciting causes be discontinued. In neglected cases the malady is aggravated, gradually the pollutions become more frequent, they begin to occur in waking hours from indulgence in libidinous thoughts, from the friction of the clothing, especially in horseback-riding, from toying with women, from perusal of indecent books or pictures, and frequently during defæcation and urination. The erections and orgasm diminish, until the complaint runs into the third stage, when they cease,

and the flow is passive, sometimes intermittent and sometimes constant. There are instances, however, in which the emissions are passive from the beginning, but these result from gonorrhœa and are exceptional. As the pollutions become more frequent, they contain fewer spermatozoa, which are immature, have little or no motion, and finally are absent. In consequence of catarrh of the prostate gland and seminal vesicles the spermatic fluid loses viscidity and becomes watery. In some cases digestion is much impaired and the bowels become constipated. In an advanced stage the moral depression is the most serious feature; for the unhappy subject is usually ashamed to seek relief, as he would in ordinary complaints, and is apt to fall into the hands of those rapacious quacks who hire the services of a venal press to promote their nefarious business of exciting groundless fears and delusive hopes, by which victims are attracted to their toils, to be plucked without mercy.

An analysis of 175 cases by Professor S. W. Gross, M.D.,[1] shows the relative frequency of a large number of symptoms, as follows: Anxious and depressed condition of mind, 72; constant dwelling on sexual matters, 72; hypochondria, 14; mental dejection after intercourse or emission, 60; impairment of memory, 55; incapacity for prolonged mental exertion, 68; headache, 69; vertigo, 30; broken sleep, 15; insomnia, 6; drowsiness, 11; irascibility, 2; asthenopia or muscæ volitantes, 31; noises in the ears, 26; muscular weakness of the limbs and fatigue, 118; trembling of the limbs, 10; temporary reflex paraplegia, 1; pain in the back, 95; oppressed breathing, 7; pain in the chest, 3; constipation, 61; dyspepsia, 40; palpitation of the heart, 26; subjective sensation of cold, 11; and of heat, 4; loss of flesh, 9; pallor of the face, 15; feebleness of erection, with premature ejaculation, 38; irritable weakness, 29; total failure of erection, 10; elongation of the prepuce, 29; relaxation of the scrotum, 19; irritable testis, 9; varicocele, 6; hæmorrhoids, 5; coldness of genitalia, 8; sensation of heat in genitalia, 3; painful ejaculation on intercourse, 3; bloody ejaculation, 1; irritability of the bladder, 8.

As the emissions become more frequent, the erection and the orgasm are less pronounced, and the ejaculation is premature. There is pain in the head and back, with muscular fatigue and indisposition for mental effort. Then follow vertigo, loss of memory, depression of spirits, aversion to company, especially that of females, asthenopia, trembling, palpitation, shortness of breath, indigestion, and constipation. Finally there result impotence, hypochondria, insomnia, neuralgia, cold extremities, and a peculiar expression of shame. This is the usual course in neglected or ill-managed cases.

Morbid Anatomy and Pathology.—In the early stage of seminal incontinence there is preternatural irritability of the ejaculatory muscles and of the ducts of the seminal vesicles, together with excessive sensibility of this part of the urethra from undue excitation. As the case progresses the canal becomes inflamed and its walls are thickened, with narrowing of its calibre, particularly in the prostatic portion and near the meatus. Of 153 masturbators who became subjects of seminal incontinence, Professor S. W. Gross found that 127 had one or more strictures, of rather moderate narrowing in most instances, and 22 other cases not traced to masturbation all had stricture, with a single exception. Hyperæsthesia of the urethra existed in all but 11 cases. In an advanced stage the ducts of the seminal vesicles are enlarged and lose their sensibility. Inflammation of the epididymis, or of the seminal vesicles, may occur, and in the latter case is accompanied with painful purulent or bloody emissions.

Etiology.—In a large number of instances a neurotic temperament may be regarded as a predisposing cause, and this view will be confirmed by the discovery of other neuroses in the same subject, or among his near relatives. It might be more correct to say that this temperament induces the habit of masturbation. Undoubtedly ascarides, or a long and narrow prepuce, with a mass of imprisoned smegma and an irritable and herpetic glans penis, will lead to early masturbation. Habitual constipation, piles, fissures, and pruritus ani have the same effect in later years. Inquiry into the previous history will show that a considerable number have been subjects of nocturnal incontinence of urine in early childhood. Indulgence in erotic thoughts, and perusal of lascivious books, also lead directly or indirectly to seminal incontinence. The concurrence of seminal emissions with tabes dorsalis is explained by the diminished inhibitory control of the spinal cord in the functions over which it presides. Its occasional concurrence in the early stage of pulmonary phthisis, in variola, typhus fever, and chronic alcoholism, is probably to be accounted for on the same ground, but the connection is less apparent.

In the 175 cases analyzed by S. W. Gross, the exciting cause was found to be masturbation, 153 times; gonorrhœa, 7 times; masturbation and gonorrhœa, 11 times; toying with women, 1; cause obscure, 3 times. It was attributed to inherited predisposition once only. In the same list 154 were unmarried, 18 married, and 3 were widowers. Twenty-two occurred under twenty years of age; 103 between twenty and thirty years of age; 36 between thirty and forty years of age; and 14 between forty and fifty-four years of age. All the married men indulged excessively in sexual intercourse.

Diagnosis.—Whenever the emissions take place with erection and orgasm, there can be no question that they are seminal. In cases which have begun in this way the presumption is strong to the same effect. The detection of spermatozoa requires a microscopic power of four hundred diameters, but they may be absent in chronic and aggravated cases of seminal incontinence. With a history of gonorrhœa rather than of masturbation, and with emissions without erection or orgasm from the beginning, diagnosis of gleet or prostatorrhœa would be presumptive, to be confirmed by absence of spermatozoa.

Prognosis is favorable in cases which have not advanced to protracted impotence, and are not attended with profound hypochondria. A neurotic diathesis and chronic inflammation of the seminal vesicles are serious conditions. Seminal incontinence resulting from gonorrhœa or sexual excesses is more amenable to treatment than when arising from masturbation. The worst effects of the latter result from early indulgence in the habit. It is necessary in any case that the patient should be thoroughly obedient and tractable, and persevere with treatment uninterruptedly.

Treatment.—An indispensable condition to recovery is removal or discontinuance of all the etiological factors, and here is the great difficulty. Masturbation and sexual intercourse must be prohibited; erotic thoughts and whatever might suggest them must be banished; stimulating food and drinks must be eschewed; the bladder should be emptied before the hour of rest, and once or more times during the night; the bed should be rather hard, and the cover barely sufficient for comfort; the dorsal decubitus should always be avoided; both mind and body should be sufficiently occupied to prevent dwelling upon the complaint and indulging in any of its causes. A close inspection must be made of the external genitals and anus for sources of irritation. A redundant prepuce calls for circumcision. Herpes of the glans or prepuce may be relieved by the application of dry calomel or a weak solution of lunar caustic. Stricture of the urethra requires dilatation or division, and it must not be allowed to contract again. The hyperæsthesia of the canal in the early stage is best overcome by the passage of a steel sound, as large as it will admit, two or three times a week, remaining from five to twenty minutes. In case of excessive irritability its sensibility may be obtunded, prior to the introduction of the sound, by the injection of a solution of cocaine. In some cases an exquisitely sensitive, inflamed tract may be found in the prostatic portion by exploration with an acorn-pointed bougie. This having been accurately located, is best treated by a local application of lunar caustic solution, ten to thirty grains to the ounce, by a catheter syringe; or by projecting from a *porte-remède* a small quantity of cocoa butter, incorporated with about one-eighth of a grain of silver nitrate. A short frænum should be divided. External

piles may be injected with carbolic acid, and internal piles be removed by the ligature or the *écraseur*. Pruritus may be relieved by a lotion of corrosive sublimate, two or three grains to the ounce, or a five per cent. solution of carbolic acid. Constipation may be relieved by a pill containing resin. podophylli, gr. $\frac{1}{8}$; extract. bellladon., gr. $\frac{1}{4}$; extr. nucis vom., gr. $\frac{1}{4}$; pulv. aloes, gr. iij., taken at first every night, and then every other night, till the habit is overcome.

Internal medication for this malady must be adapted to the stage and the symptoms. In the stage of nocturnal pollutions the object is to diminish the excitability of the nervous tract which presides over the genitalia. The bromide of potassium and atropine are the agents of greatest value. Twenty to thirty grains of the former may be given three times a day, and one-sixtieth of a grain of the latter at bedtime. If the patient be weak and anæmic, it is preferable to give quinine and iron during the day, and sixty grains of the bromide with the atropine at night. In case of diurnal pollutions, a similar medication is appropriate. In the stage of spermatorrhœa, when the spermatic ducts are relaxed and there is atony of the ejaculatory muscles, a combination of ergot and strychnine will be found useful, say one-half drachm of the fluid extract of the former with one-twentieth grain of the latter, after meals, three times a day; or, in an anæmic condition, twenty drops of the muriated tincture of iron with five drops of the tincture of cantharides. These remedies may be supplemented by the constant galvanic current, with the positive rheophore on the perineum and the negative in the rectum, commencing with an application for two or three minutes and gradually increasing the duration, according to toleration. The strength of the current, at the beginning, should be such as the operator can pass through his own temporal region.

Abstinence from sexual indulgence and from all excitement of the organs must be enforced until the anatomical lesions are entirely healed and the functional derangement has ceased. Subsequent moderation is to be enjoined with the married, and the unmarried, if their circumstances warrant, may then be counselled to essay matrimony. *S. S. Herrick.*

[1] Disorders of the Male Sexual Organs.

SENEGA, U. S. Ph. (*Senegæ Radix*, Br. Ph.; *Radix Senegæ*, Ph. G.; *Polygale de Virginie*, Codex Med.). The root of *Polygala Senega* Linn., order *Polygalaceæ*. A delicate-looking perennial herb, with a rather thick, knotty, somewhat branched crown, from which numerous slender, wiry, generally simple, smooth, upright stems, twenty or thirty centimetres long arise, and one or two rather stout, crooked, branching woody roots descend; leaves lanceolate, two or three centimetres long, alternate, smooth. Flowers small, pinkish-white, in terminal spikes. Calyx irregular, of three small green, and two (lateral) large, petaloid sepals, the latter concave and inclosing the corolla. This consists of three partly united petals, of which the lower is concave and ornamented with a crest of papillæ. Stamens eight, diadelphous (4 × 4). Ovary transversely two-celled. Style single. Senega has a wide range in the United States from western New England and the Middle and Western States southward. It is now mostly collected in the West and South. *P. S. latifolia* is a larger form with broader leaves.

The plant takes its common name, Seneca Snakeroot, from the Seneca Indians, by whom it is reported to have been used as a remedy for snake-bites. It was introduced into modern medicine by Dr. Tennent, of Virginia, about 1734, for pleurisy and pneumonia (Flückiger), and has had times since then of very great popularity.

The root is about four inches (10 centimetres) long, with a very knotty crown, and spreading, tortuous branches, keeled when dry, fleshy and round after having been soaked in water; externally yellowish-gray, or brownish-yellow; bark thick, whitish within, inclosing an irregular, porous, yellowish wood; odor slight but unpleasant; taste sweetish, afterward acrid. The woody column of Senega root is very irregular; near the crown it is cylindrical, but lower down markedly excentric, semicylindrical, or with wide vacant gaps, or clefts, of parenchymatous tissue.

Composition.—The special interest of Senega lies in the substance originally called *Senegin*, later *polygalic acid*, and by some considered to be the same as saponin, to which it is undoubtedly related. It is amorphous, soluble in water, making a frothy solution; it is also sternutatory. It is, moreover, a glucoside, separable into *sapogenin* and sugar. The yield is about two per cent. *Oil*,

Fig. 3442.—Senega, Root and Stems. One-half natural size. (Baillon.)

resin, *gum*, and other unimportant matters are also found in it.

Action and Use.—Senega in large doses is an irritant and nauseating emetic, also a purgative; in medicinal ones it is reputed to be a stimulating expectorant. It has been extensively employed in chronic bronchitis and other diseases accompanied by cough. As an ingredient of cough preparations it has probably its most extensive use, but is much less valued than formerly; as an emmenagogue and diuretic it is obsolete.

Administration.—Dose of Senega is about one gram (1 Gm. = gr. xv.). The preparations are Abstract (*Ab-*

stractum Senegæ, U. S. Ph.), strength $\frac{2}{1}$, and the Fluid Extract (*Extractum Senegæ Fluidum*, U. S. Ph.). It is also in the Compound Syrup of Squills (*Syrupus Scillæ Compositum*, U. S. Ph.).

ALLIED PLANTS.—See RHATANY. *W. P. Bolles.*

SENILITY. In old age there normally occur certain changes in the tissues, and, as sequelæ, anatomical and physiological alterations of the senescent body. The changes are principally atrophic and degenerative.

Senile atrophy involves especially the muscles and glands, but also affects other soft parts. The cellular elements diminish in size progressively, but without apparently presenting any essential modification in their structure. Thus the muscular fibres become small, and, it is said, more uniform in size; the spleen and lymphatic glands undergo a remarkable diminution in volume and weight, which increases with the advance of age. In the digestive tract the glandular parts and villi are somewhat shrunken. Where there has been an accumulation of fat, it gradually wastes away.

Senile degeneration begins somewhat later than the atrophy. The elements become the seat of fatty or pigmentary infiltrations, or calcareous incrustations. The fatty degeneration occurs, for instance, in the striped muscle-fibres, both the voluntary and cardiac; in the smooth muscles; in the blood-vessels, especially in the cerebral arterioles, and probably also in the nerve-cells and the parenchyma of glandular organs. The pigmentary infiltrations are much rarer. Calcareous deposits occur, especially in the tendons, ligaments, and cartilages, also in the pineal gland. In the central nervous system the neuroglia tends to predominate over the nervous elements proper, and tends to become permeated by a greater or less number of amylaceous bodies; the tissue of the brain undergoes a chemical change—the fatty constituents are diminished, while the amounts of water and phosphorus are increased.

In consequence of these changes the weight and height of the body as a whole is lessened, and the size of most of its parts is lessened also; this holds true of the muscles, skeletal structures, brain, spinal cord, nerve-trunks, lungs, liver, spleen, etc.; but it does not apply to the heart or kidneys, the heart being often hypertrophied and the kidneys retaining the size of middle life. The skin becomes dry and wrinkled, the hair scanty and white, the gums toothless, the body crooked and sunken.

Physiologically there is a general impairment of the vigor, resulting from the atrophy and degeneration. There is great muscular enfeeblement; the amount of carbonic acid exhaled is diminished, as is also the vital capacity of the lungs; but, on the other hand, the respiratory rhythm is quickened. The secretions are diminished. There is less urine. The rate of the heart-beats rises.

Such, categorically given, are the changes in old age. Unfortunately, there is no thorough and satisfactory compilation of these data, which, though very numerous, are scattered through a vast literature. Until this century old age scarcely received scientific consideration; those who wrote upon it wrote like Cicero, in his *De Senectute*, from a contemplative literary standpoint. It was not until 1839 that anything very serious from the medical side was attempted. In that year Canstatt published, at Erlangen, his treatise on the diseases of old age. Since then there have been a number of manuals of similar scope, but in none of them, so far as I know, is there to be found a thorough and comprehensive review of the normal changes in old age, although such a review is urgently needed. The preceding paragraphs follow Charcot closely. (See Tuke's translation, Sydenham Society, 1881.)

Charles Sedgwick Minot.

SENNA, U. S. Ph. (*Folia Sennæ*, Ph. G.; *Sené*, Codex Med.; *Senna Alexandrina* and *S. Indica*, Br. Ph.; Alexandria and Tinnivelly (Indian) Sennas). The leaflets of several, at present mostly of two, species of *Cassia*, order *Leguminosæ* (*Cæsalpineæ*), growing wild in Nubia, Upper Egypt and Arabia, or cultivated in Southern India. In the United States, German, and French Pharmacopœias the general term covers both the principal varieties; in the British, the Alexandrian and Tinnivelly Sennas are distinguished by name; they are always entirely distinct in the market.

The genus *Cassia* is a very large one, numbering three or four hundred species, many of which produce handsome ornamental flowers; it is also the type of a tribe (*Cassiæ*) including nine or ten other genera, of which nothing need be said from a medical point of view. *Ceratonia* (St. John's Bread) is one of them. The Cassias are herbs, shrubs, or trees, with abruptly pinnate leaves, usually showy yellow flowers in axillary or terminal racemes or panicles, and, in the section to which the above Sennas belong, extremely flat pods. The following two species supply nearly all the Senna of modern commerce.

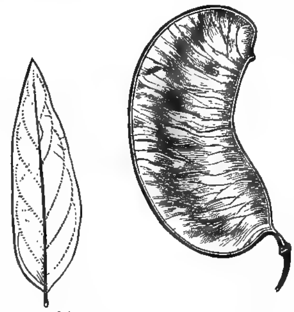

FIG. 3443.—Cassia Acutifolia, the source of Alexandria Senna, leaf and pod; about natural size. (Baillon.)

1. *C. acutifolia* Delile, is a small shrub about sixty centimetres (two feet) high, with pale, slender, round or slightly angled, branching, somewhat zigzag, smooth (at least when old) stems, alternate leaves of four or five pairs, and rather small flowers. Calyx imbricated, of five oblong, blunt sepals. Corolla subregular, of five, obovate, yellow petals, the lateral and lower ones larger than the upper. Stamens ten, the three upper abortive, the two lower lateral ones very large, the others subequal; anthers opening by terminal pores. Pistil one, a simple carpel raised upon a short stalk, and, like the longer stamens, curved upward. Pod broad, flat, coriaceous, slightly curved, rounded and oblique at the ends, containing about half a dozen seeds. This species has a wide and unknown range in Central Africa, it is abundant in Nubia, Kordofan, Sennaar, etc., and is said to be found in Timbuctoo.

2. *C. angustifolia* Vahl., is also a small shrub, a good deal like the preceding, but it has larger flowers and larger, more numerously paired leaflets. Its pod is narrower and straighter than that of *C. acutifolia*, and contains about eight seeds. It is a native of Arabia, and in the wild state supplies an inferior, carelessly collected variety of Senna (Arabian). It is also said to be found in the Somali Land. This is the species cultivated in the south of India (where it is not indigenous) as the source of Tinnivelly Senna. The leaves, under cultivation, are increased in size and improved in quality.

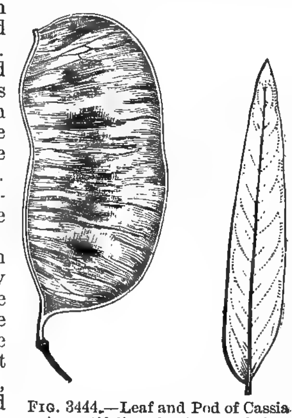

FIG. 3444.—Leaf and Pod of Cassia Angustifolia; about natural size. The leaf is Tinnivelly Senna. (Baillon.)

C. obovata Colladon, is an herbaceous or semi-shrubby perennial, of very much the same general habits as the above, but whose leaflets are broader, obovate, with blunt apex and base, the former, however, mucronate, and about two and a half centimetres long. Flowers large and handsome, much like the others, pod considerably curved. It grows over the same range as *C. acutifolia*, but also extends to West Africa and India; it has been introduced into Southern Europe, and formerly furnished the European or Italian Senna. This species formerly supplied a considerable part of the Alexandria Senna, being mixed with the leaflets of *C. acutifolia;* but at present it seldom appears

in any shape. It is of inferior quality and should be rejected.

C. brevipes of Central America, *C. Schimper* of Abyssinia, and several other species of both hemispheres, have been proposed as substitutes for Senna, but have at present no commercial existence.

Senna appears to have been introduced into European use in the ninth or tenth century; the pods were used as well as the leaves, and even preferred to them.

Collection: This, in the wild districts of Nubia and Arabia, is done in the coarsest and most primitive manner. The shrubs are cut down and exposed to the sun until the leaves are dry, when they are stripped off bringing leaf-stalks, twigs, flowers, and pods with them. They

Fig. 3445.—Cassia Obovata, the Source of an Inferior Variety of Senna. (Baillon.)

must be afterward cleaned and sorted before they are fit for use. Tinnivelly Senna is always clean.

Description.—Alexandria Senna is usually described with great care as consisting of a pretty uniform mixture of the leaflets of *C. acutifolia*, *C. obovata*, and one or two other leaves or leaflets of plants not Cassias at all (*Solenostemma Argel* Hayne, order *Asclepiadaceæ*, *Tephrosia*, *Colutea*, *Coriaria*, etc.), but this applies only to the past, as the Senna of recent years is improved in quality and appearance, and consists almost entirely of the leaflets of the desirable *C. acutifolia*, with stems and pods of the same. The following is the officinal description: "Alexandrian Senna consists of leaflets about one inch (twenty-five millimetres) long, lanceolate or lanceoval, subcoriaceous, brittle, rather pointed, unequally oblique at the base, entire, grayish-green, nearly smooth, of a peculiar odor, and a nauseous, bitter taste. It should be freed from stalks and from argel leaves (the leaves of *Solenostemma Argel* Hayne), which are frequently present; these leaves are thicker, one-veined, glaucous, and even at the base. India Senna consists of leaflets nearly two inches (five centimetres) long, acute, unequally oblique at the base, entire, dull green, slightly pubescent, of a peculiar odor and a mucilaginous, bitter taste. It should be freed from stalks, discolored leaves, and other admixtures." The leaves of Alexandria Senna are always considerably broken, those of Tinnivelly generally whole. The former commands the higher price; there appears to be no medicinal difference between them. Besides these two varieties there is Arabian, often called "Indian," Senna, because imported through Indian ports, whose leaves have the same shape, etc., described above as Indian Senna, but are smaller. It is a cheap, poor, and usually very dirty article, seldom used here. *Senna pods* form a separate article in continental shops; they have the shape, size, etc., figured above, and the same properties as the leaflets.

Composition.—*Sennacrol* and *sennapicrin* are two bitter and acrid substances, separable from senna by treatment with alcohol. The former is, the latter is not, soluble in ether. Neither of them is the valuable part of senna. This is principally found in *cathartic acid*, an uncrystallizable, dark brown, astringent-tasting substance of decidedly cathartic qualities. It is soluble in warm diluted alcohol, but is nearly insoluble in strong alcohol or water. Cathartic acid is a glucoside yielding by decomposition "*cathartogenic acid*." A coloring matter, *chrysophan*, also found in rhubarb, etc., and a sugar, *catharto-mannit*, are the remaining constituents. Cathartic acid is also found in the bark of Frangula and other *Rhamni*.

Action and Use.—This is one of the most satisfactory and generally useful of simple cathartics, usually emptying the bowels thoroughly in ten or twelve hours, with but little depression or other untoward effects, excepting a variable amount of griping; it acts principally upon the small intestine, and the amount of effect produced can generally be pretty accurately regulated, by the dose, from the mildest laxative to a brisk cathartic. It is in universal domestic use, and is the foundation of numerous proprietary laxatives. By combination with salines its activity is considerably augmented; in small doses it does not readily lose its efficiency. It appears to be partially excreted in the milk, when taken by nursing women.

Administration.—A few Senna leaves chewed every day are a favorite habitual laxative with many people, who find them to act efficiently, without griping and without producing after-sluggishness of the bowels. One or two dozen leaves usually display some effect. In large doses (six or eight grams [ʒ jss.] or more), as required for thorough action, it is apt to produce colic, unless modified by aromatics or salines. A strong alcoholic extract is inert; a watery extract, made from the residue after exhausting by alcohol, is active and much pleasanter than one made without this previous treatment. Infusion with hot water extracts the active principle (salts of cathartic acid), and makes a good form for administration, but prolonged boiling destroys it, as do also mineral acids and alkalies, by decomposing the cathartic acid. Bitters are said to increase its action.

The officinal preparations are numerous and good. The Fluid Extract (*Extractum Sennæ Fluidum*, U. S. Ph.), made with weak alcohol, represents the leaves weight for weight. It is not often given alone, but is eligible for mixture with other medicines. The Compound Infusion, Black Draught (*Infusum Sennæ Compositum*, U. S. Ph.), consists of:

Senna, 6 parts.
Manna, 12 parts.
Sulphate of Magnesium, 12 parts.
Fennel, bruised, 2 parts.
Boiling water, 100 parts.

Macerate and strain; then add water to make 100 parts. It is six per cent. senna, and twelve each of manna and Epsom salts. The Syrup (*Syrupus Sennæ*, U. S. Ph.) consists of 33 parts of senna with a little oil of coriander. The Compound Licorice Powder (*Pulvis Glycyrrhizæ Composita*) is one of the most extensively used laxatives; it is composed as follows:

Senna, 18 parts.
Licorice, 16 parts.
Fennel, 8 parts.
Washed sulphur, 8 parts.
Sugar, 50 parts.

The ingredients should be finely powdered and thoroughly mixed. One of the most elegant preparations in

the Pharmacopœia is the Confection of Senna (*Confectio Sennæ*, U. S. Ph.):

Senna, 10 parts.
Coriander, 6 parts.
Cassia fistula, 16 parts.
Tamarind, 10 parts.
Prune, 7 parts.
Fig, 12 parts.
Sugar, 50 parts.
Water, 60 parts.

It is a black extractiform mass, of pilular consistency, with a mawkish, but not disagreeable, sweet taste. Confection of senna is an appropriate remedy for chronic constipation, and is especially useful in the case of children, who will often take it as a candy. The Compound Syrup of Sarsaparilla contains twelve parts of Senna in a thousand.

ALLIED PLANTS.—Of the three hundred or more *Cassias* but few have medical importance, although many are probably cathartic. *C. marilandica* Linn., a perennial herb of the United States, is a moderately active, safe cathartic in somewhat larger doses than the Eastern Sennas; the leaves, stems, and flowers are usually collected together. *C. fistula* Linn. (see CASSIA, PURGING), a large East Indian tree, with striking cylindrical fruits half a metre long, is a mild laxative, used in the composition of Confection of Senna. The order *Leguminosæ* is one of the largest in the botanical kingdom, and includes numerous very interesting, useful, and beautiful plants, as the following partial list will show:

Baptisia tinctoria, our yellow False Indigo.
Lupinus, *Laburnums*, ornamental flowers.
Genista, Dyer's Woad.
Cytisus Scoparius Link, Broom Tops.
Trigonella Fœnum græcum Linn., Fenugreek.
Melilotus, Sweet Clovers.
Trifolium, Clovers.
Indigofera tinctoria, Indigo.
Wistaria sinensis, Wistaria.
Robinia, Locusts, etc.
Astragalus, sp. var. Tragacanth.
Glycyrrhiza glabra Linn., Licorice.
Arachis hypogea Linn., Peanuts.
Vicia, *Lens*, *Pisum*, etc., Peas, lentils, etc.
Abrus precatorius Linn.

ALLIED DRUGS.—The nearest related cathartics to Senna are probably the *Rhamni* and Rhubarb. See also Aloes, Jalap, etc. *W. P. Bolles.*

SENSATION, DISORDERS OF. The disorders of the special senses will be found discussed under the diseases of the organs to which they refer. We shall here discuss the other modes of sensation and their pathological relations, beginning with cutaneous sensibility.

All the different modalities of sensation may be affected, either singly or in various combinations, as the result of morbid processes occurring in the terminations of the sensory fibres in the integument, in their course from the periphery along the nerve-trunks, or at their central origin in the brain and spinal cord. In the majority of cases we are able to determine the site of the lesion by the sensory disturbances themselves, or by the associated symptoms.

Cutaneous sensibility includes tactile sensibility in the general sense, and common sensations. The former includes the sense of touch, the sense of location, the sense of pressure, and the sense of temperature. At the present time these different sensory qualities are commonly supposed to be inherent in different kinds of nerve terminations and fibres, but the discussion of this question must be left to the physiologist.

The common sensations include the sense of pain, pruritus, tickling, sexual feeling, and electro-cutaneous sensibility.

The sense of touch is tested by applying different objects gently to the skin, the patient's eyes being kept closed during the experiment. He is then asked to state whether he has felt anything or not, and to describe the surface of the object (sharp, blunt, rough, smooth) which is brought in contact with the skin. In ordinary examinations it is sufficient to use the head and point of a pin, the tip of one of the fingers, or the point of a lead-pencil. This should be applied gently, in order to avoid producing pain and thus confusing the sensations in the mind of the patient. As in the tests for all other forms of sensibility, the experiment must be repeated over and over again; the patient must sometimes be asked as to his sensations, although nothing has been applied to the skin; and, above all, similar tests should be made on the corresponding healthy part of the integument of the opposite side of the body, or, if this is not practicable, on some other part of the body. It is also very often advisable for the physician to repeat the various tests upon himself, in order that he may be able to compare the sensations produced in himself with the statements made by the patient. There are very few points in symptomatology with regard to which the patient, and therefore the physician, are so apt to be led astray as in the tests for disorders of sensation. This is often true, even when the patient is very intelligent; but with the ignorant we are frequently compelled to abandon all hope of arriving even at the approximate truth. The results of such examinations are almost *nil* in children—except with regard to the sense of pain—because, even though they are able to speak, they are unable to analyze their sensations.

The sense of localization is tested in two ways: first, by touching the skin with any small object and then directing the patient (with closed eyes) to indicate with the finger the part of the skin which has been touched. It is also tested by determining the smallest distance at which two sharp points can be distinguished separately.

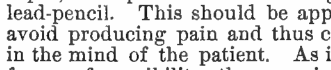

FIG. 3446.

This is done by means of an instrument known as an æsthesiometer. Sieveking's æsthesiometer (Fig. 3446) consists of a metallic rod, divided into millimetres, with two pointed arms given off at right angles to the rod. One arm is fixed to the end of the rod, the other can be moved along its whole length. Both points are applied repeatedly to the part to be tested, until we find the shortest distance (which is read off upon the scale) at which they are felt as two distinct points. The average distances at which this takes place in adults, and in a boy of twelve years, are shown in Landois' table:

	Adult. Mm.	Boy. Mm.
Tip of the tongue	1.1	1.1
Third phalanx of the finger (anterior)	2.3	1.7
Vermilion border of the lips	4.5	3.9
Second phalanx of the finger (anterior)	4.5	3.9
Third phalanx of the finger (posterior)	6.8	4.5
Tip of the nose	6.8	4.5
Head of the metacarpus (palmar)	6.8	4.5
Dorsum of the tongue White of the lips Metacarpus of the thumb	9.0	6.8
Great toe (plantar)	11.3	6.8
Second phalanx of finger (posterior)	11.3	9.0
Cheek	11.3	9.0
Eyelid	11.3	9.0
Hard palate (middle)	13.5	11.3
Malar bone (anteriorly)	15.8	11.3
Metatarsus hallucis (plantar)	15.8	9.0
First phalanx of finger (posterior)	15.8	9.0

	Adult. Mm.	Boy. Mm.
Head of metacarpus (posterior)	18.9	13.5
Inner side of lip	20.3	13.5
Malar bone (posteriorly)	22.6	15.8
Forehead (below)	22.6	18.0
Heel (posteriorly)	22.6	20.3
Occiput (below)	27.1	22.6
Dorsum of hand	31 6	22.6
Chin	33.8	22.6
Vertex	33.8	22.6
Patella	36.1	31.6
Sacrum, Gluteal region	40.6	33.8
Forearm, Leg	40.6	36.1
Dorsum of foot near the toes	40.6	36.1
Sternum	45.1	33.8
Neck (high up)	54.1	36.1
Spine (fifth dorsal vertebra, dorsal and lumbar region)	54.1	....
Neck (middle)	67.7	....
Arm, Thigh, Middle of back	67.7	31 6 to 40.6

Any marked deviation from these distances, on one side or the other, is an evidence of a morbid state. In using the æsthesiometer care must be taken that the two points are applied to the skin at the same time, and with the same degree of force (not sufficient to produce pain), and that they possess approximately the temperature of the skin. In making this test we must be especially on our guard against unintentional deception on the part of the patient, and must verify the results by repeated "control" tests.

Fig. 3447.

The sense of pressure is tested by applying, successively, different weights to the part examined, the latter being firmly supported in order to exclude the muscular sense. Eulenburg constructed a baræsthesiometer for the purpose of testing this sense. It consists (Fig. 3447) of a rod connected with a spring, and a dial-plate, upon which is registered the amount of force exerted by the rod, that is brought in contact with the skin. Eulenburg found, with the aid of this instrument, that the following increments of pressure could be appreciated on the different parts of the body:

Forehead, Lips, Dorsum of the tongue, Cheeks, Temples	$^1/_{40}$–$^1/_{30}$	Phalanges of the fingers, Forearm, Hand, Arm	$^1/_{20}$–$^1/_{10}$

Goltz devised an apparatus for the determination of the minimum amount of pressure which could be appreciated. It consists of a rubber tube, which is brought in contact with the integument, and through which waves of fluid of a known amount of force are passed.

A simple test consists in placing a coin or other weight upon the skin, and then adding others until the patient appreciates the increase. The proportion between the original weight and the added weight necessary to produce an appreciable difference, is the minimum appreciable increment.

The sense of temperature may be tested by Eulenburg's thermæsthesiometer. This consists simply of a transverse rod, to which are fastened two surface thermometers. The latter are heated to different degrees, and applied to the skin. We then note the minimum difference between the two thermometers which can be appreciated by the patient. Eulenburg found that this sense was most acute between 27° and 33° C. (80.6° and 91.4° F.). Upon the arms the minimum appreciable difference of temperature was found to be 0.2°; on the cheeks, 0.2° to 0.4°; on the temples, 0.3° to 0.4°; on the back of the hand, 0.3°; on the palm of the hand and dorsum of the foot, 0.4°; on the leg, 0.5° to 0.6° C.

A coarser method of testing the temperature sense is the application to the skin of test-tubes containing water at different degrees of heat, or placing the part alternately in warm and cold water, and noting whether the patient is able to detect the difference. When employing the latter methods we should always make the same experiment on ourselves.

Goldscheider comes to the conclusion, from his experiments, that there are special nerve-fibres for the perception of heat and of cold, and Herzen has reached the same conclusion from the observation of a case of myelitis, which will be referred to later on.

The sense of pain is tested by simply irritating the skin, by pricking it with the point of a pin, pinching it, etc. It must be remembered that there are very great normal variations in the sense of pain of different individuals. The results of irritation of the diseased part should always be compared with those of irritation of the corresponding normal part on the opposite side of the body, or, if this cannot be done, with some other healthy part of the integument. Bjoernstroem devised an "algesimeter," consisting of a pair of forceps between whose blades the skin is compressed to the point of production of pain. The amount of pressure is shown upon a scale attached to the instrument.

The electro-cutaneous sensibility has not hitherto seemed to possess any important practical bearings. The test may be made with regard to the minimum strength of current which will give rise to a perceptible sensation, and also the minimum strength which will be attended with a painful sensation. Erb employs the following method: One large moist electrode is placed on the sternum, and the other one on the part to be tested. This electrode consists of a hard-rubber tube containing about four hundred fine, insulated metal wires, its free end being made as smooth as possible. The cylinder of the faradic battery, with which the electrodes are connected, is withdrawn slowly, until the first minimum electrical sensation occurs, and the amount of withdrawal is noted; the cylinder is then withdrawn more rapidly, until a distinct sensation of pain is felt, and the amount of this withdrawal is again noted.

The rapidity of sensory conduction from the skin may also be interfered with. It is possible that the conduction may be accelerated, but the recognition of such a condition would require very delicate instruments for the measurement of time. So far as we know, no investigations have ever been made on this point. In numerous cases, however, there is an evident delay in the conduction of sensation, which can be determined by the unaided senses. If a healthy individual is pricked on the sole of the foot, *i.e.*, on the part whence the nerve-current has the longest distance to travel before reaching the cerebral centre, he will immediately manifest his perception of the irritation. When sensory conduction is delayed an appreciable interval—even at times as much as fifteen seconds—will elapse before the patient gives evidence by some sign that he has felt the prick. This delay in conduction may affect only certain forms of sensation, while that of other forms remains normal, and thus gives rise to a peculiar phenomenon, which will be considered later on.

Exner gives the following as the duration of the latent period in healthy individuals:

Stimulus.	Time between stimulation and perception, in fractions of a second.
Shock on left hand	0.12
" " forehead	0.13
" " toe of left foot	0.17

But when all is said, it will be found that refined tests are not practicable in the examination of disorders of sensation at the bedside. In the first place, an inordinately great amount of time would be required, so that a thorough examination of sensibility would often last many hours. But apart from this, the errors increase in proportion to the refinement and delicacy of the tests. The majority of individuals are unused to making a careful analysis of their sensations, and really remain ignorant of their own feelings, or are unable to convey an accurate idea of them in language. In many cases, fur-

thermore, the sensations experienced are unlike any that have been felt before, so that the patient is compelled to describe them by analogy. In those cases, on the other hand, in which there is a morbid habit of analyzing the various bodily sensations, we must be on our guard against unintentional exaggeration.

In my own examinations I have entirely discarded the use of special instruments, having come to the conclusion that even the simple æsthesiometer furnishes untrustworthy results in many cases.

Muscular sensibility will next engage our attention. This is best tested with the faradic current applied, preferably, to the motor points of the muscles. When the current acquires a certain strength the muscular contraction is accompanied by a peculiar, indefinable sensation, which is readily distinguished from electro-cutaneous sensibility. When a certain increased strength of current is reached, the patient experiences pain in the muscle. The limits of both sensations may vary from the normal. Some writers claim that muscular sensibility is dependent upon cutaneous irritation, but this is disproved by the fact that it may persist despite the most complete cutaneous anæsthesia. Moreover, recent investigations have demonstrated the existence of sensory fibres in the muscular tissue.

Our appreciation of the position of the limbs (without the aid of the sense of sight) depends not alone on the muscular sensibility, but also on that of the integument, joints, and fasciæ. This may be tested in the following manner: The physician places the limb, when the muscles are relaxed, in various positions—it is best to grasp the part by means of a handkerchief, in order to exclude the cutaneous sense of pressure—and then directs the patient to place the corresponding limb on the opposite side of the body, if the functions of the latter are normal, in a similar position. If there is paralysis or inco-ordination of the opposite limb, he is directed to describe the position of the limb which has been subjected to passive motion. This can be done with great accuracy in the normal condition.

By the *muscular sense* proper we are able to determine, with the eyes shut, the degree of contraction of the muscles during movement. We are thus able to determine the weight of objects by the amount of muscular force required to overcome it, and this sense is even more accurate than the cutaneous sense of pressure. It may be tested by suspending weights to the limb by means of a handkerchief looped over the part. For example, if the flexors of the forearm are to be tested, a handkerchief is tied into a loop, passed around the palm (the extensors being well supported on a firm base, so that they are not brought into play), and different weights are placed successively in the loop. We then note the smallest increment or decrement of weights which can be appreciated by the patient. In the normal condition an increment of $\frac{1}{40}$ can be appreciated by the muscular sense, while only $\frac{1}{30}$ can, on the average, be detected by the cutaneous sense of pressure. The action of the latter, however, can never be entirely excluded in these experiments. Another test consists in directing the patient, with the eyes closed, to perform certain movements, such as placing the finger on the tip of the nose, describing a circle with the foot, etc. When the muscular sense is impaired these movements cannot be performed with the normal degree of accuracy, but are done in a bungling fashion, or the patient shoots wide of the mark. In some cases the affection may be so marked that the patient is almost entirely unable to perform any movement when the eyes are closed, although he may be under the impression that the desired movement has been accomplished.

The real nature of the muscular sense is involved in great obscurity, although it has long been the subject of study by philosophers and physiologists, and is of far-reaching importance with regard to our notions of the mechanism of nerve action. Some writers believe that it is the result of centripetal impressions derived from the contracting muscles, others, that it results from a consciousness of the "out-going current" from the cortical centres at the moment of contraction; while Weir Mitchell suggests that it is produced by "the messages sent to the sensorium from the spinal ganglia, which every act of motor volition excites."

The various forms of sensation, which we have thus briefly considered, may present an abnormal exaggeration, diminution, or perversion. These deviations from the normal may result from an affection of the terminal ramifications of the sensory fibres in the integument, of the conducting paths in the nerve-trunks, spinal cord or brain, or of the sensory centres. We shall deal separately with each form of sensory aberration.

Cutaneous anæsthesia is the diminution or abolition of the function of the sensory nerves of the skin. The function of the various nerves may be affected in different degrees. For example, the sense of touch may be abolished, while the sense of temperature remains intact; or tactile sensibility may be abolished, while the sense of pain is greatly exaggerated, etc. When all forms of cutaneous sensibility are diminished or abolished, we speak of total anæsthesia; the term partial anæsthesia is used when certain modes of sensation are alone affected.

In many cases anæsthesia is also associated with diminution in the rapidity of conduction of the sensory impressions, and, as we shall see later on, this may also affect the different modes of sensation in different degrees.

Cutaneous anæsthesia, resulting from an affection of the terminations of the nerves, is observed in certain skin diseases, such as acute pityriasis rubra, certain forms of eczema, lichen, or psoriasis. It is also produced by congelation of the skin (by evaporation of ether or rhigolene, or prolonged exposure to cold), by hypodermic injections of narcotics (morphine, atropine, cocaine), or by the application of acids and alkalies. In these cases the anæsthesia usually affects all forms of sensation to an equal degree (total anæsthesia). Fournier observed patches of cutaneous anæsthesia scattered over the entire body in secondary syphilis, and it is probable that this condition is due to the direct action of the virus on the terminations of the nerves.

Anæsthesia may be produced by interference with conduction through the peripheral nerves. This may result from direct injury to the nerve (by gunshot or stab wounds, blows, etc.), from the pressure of tumors or aneurisms, neuritis, rheumatic influences, the application of cold to the course of the nerve, various forms of chronic poisoning (ergot, lead, arsenic), or diminished supply of arterial blood (embolism of an artery); and it also occurs in anæsthetic leprosy. It is a peculiar fact that in compression of a mixed nerve the sensory fibres are usually affected to a much less marked degree than the motor fibres; in fact, the former may appear to be entirely intact despite complete motor paralysis. In rare cases, on the other hand, the opposite condition is observed. I have noticed this particularly in compression of the ulnar nerve. The comparative immunity from anæsthesia after injury to nerves has been ascribed, by Arloing and Tripier, to the communication of the terminal sensory filaments of adjacent nerves with one another. This explanation does not apply to all cases. In view of the fact that a similar phenomenon is also observed in diseases of the spinal cord, it is probable that a lesion which, when it affects a motor fibre, will interfere entirely with conduction, will not produce the same effect upon a sensory fibre, either because the structure of the latter is more resisting, or because it reacts more readily to stimuli.

Delayed conduction of sensibility has been observed in a very few cases in connection with anæsthesia due to lesions of the peripheral nerves. Erb reported an instance of this kind in a case of injury to the brachial plexus, and Westphal mentions a similar case. Stern has also reported delayed conduction of the sense of temperature in a case of multiple neuritis.

The term *analgesia* is applied to loss of the sense of pain. This is usually coextensive with the other forms of cutaneous anæsthesia, when the condition is due to an affection of the peripheral nerves, though the sense of pain is also retained in many cases. The term *anæs-*

thesia dolorosa is applied to those cases in which the affected part is anæsthetic, but the patient suffers from severe pains in the part. This is the result of interference with conduction in the affected nerve, while at the same time the lesion causes irritation of the central portion of the nerve. The irritation is reflected in consciousness to the terminal distribution of the nerve. This symptom is especially apt to occur in compression of the spinal roots of the nerves, such as is produced at times in the paraplegia of Pott's disease, but much more frequently in cancer of the vertebræ.

Peripheral anæsthesia is also observed at times, in the later stages of severe neuralgias, in the distribution of the painful nerve.

As a general thing, anæsthesia from lesion of the peripheral nerves is complete, *i.e.*, it affects all forms of sensation in an approximately equal degree. It seems probable, however, that this would be found to be not so constant as is commonly believed, if the cases were examined more carefully with reference to this point.

Cutaneous anæsthesia may be unattended with any other symptoms, and may not be discovered until after examination by the physician, or until the patient finds that he has unwittingly injured the part by reason of the lack of sensibility. In the majority of cases, however, it is attended with paræsthesiæ (perversions of sensibility), such as numbness, formication, a feeling of furriness, etc. When the anæsthesia is the result of lesion of a mixed nerve (except in neuralgias) it is usually less marked than the coexisting paralysis of the muscles supplied by the same nerve.

In anæsthesia of the hand the patient is unable to perform delicate movements with the part unless aided by the sense of sight, and even then he is somewhat awkward in his movements.

In anæsthesia of the soles of the feet the so-called Brach-Romberg symptom may be produced. If the patient, while standing, is directed to close the eyes when the feet are brought closely together, he totters from side to side, and may even fall to the ground. Equilibrium is maintained normally by centripetal impressions from the skin, muscles, and the semicircular canals of the ears. When the former are abolished, as in anæsthesia of the soles of the feet, the other two may be unable to maintain complete equilibrium unless aided by the sense of sight.

Anæsthesia is a very frequent symptom of diseases of the spinal cord, and inasmuch as the paths of conduction of the individual fibres for the different modes of sensation here separate more widely than in the peripheral nerves, it is much more often partial than is anæsthesia due to diseases of the nerves.

In certain cases—for example, in incomplete ether or chloroform narcosis—the tactile sensation is preserved, while the sensation to pain is entirely lost. The patient, although conscious of the individual steps of an operation, is insensible to pain. It is even possible that the sense of heat may be intact, while that of cold is abolished. Herzen reports a case of myelitis of the posterior columns of the cord and of the direct cerebellar tracts, with intact anterior columns and gray matter, in which there was complete and permanent tactile anæsthesia of the lower limbs, and abolition of the sense of temperature of cold substances; while the sense of pain was normal, and likewise the sense of heat between the temperatures of 60° to 27° C. (140° to 80.6° F.). Herzen concludes that the sense of heat passes through the gray matter, the sense of cold and tactile sensation through the posterior columns. Goldscheider also comes to the conclusion, from his experiments, that there are special nerves for the sense of cold, heat, and touch.

When only certain forms of sensation are affected the sense of pain is lost much more often than that of touch, and when both are combined the affection of the former is usually much more marked than that of the latter. In much rarer cases the sense of temperature or of pressure is lost, while that of touch or of pain is retained. In the majority of cases, however, there is merely relative intactness of one or more modes of sensation.

It is particularly in diseases of the spinal cord that we meet with delayed conduction of sensibility. This, like the anæsthesia, may affect the different modes of sensation in different degrees. As a general thing, it is noticed chiefly with regard to the sense of pain or of touch, the former being the one which is usually delayed. If the patient is pricked with a pin he first makes the signal indicative of his perception of the touch, and then, at the end of a variable period (from one to four or five seconds, and even a much longer interval has been reported), he indicates the perception of pain. This condition is observed much more frequently in locomotor ataxia than in other diseases of the spinal cord. It is a singular fact that the delay in conduction is often less the more violent the painful impression is, and that it sometimes disappears temporarily during the course of the examination (Stern). In rare cases there is a similar delay in the conduction of the sensation of temperature. It has been found, however, that the transmission of the sense of temperature is slower than that of touch, even in the normal condition. Anæsthesia of muscular sensibility is also a frequent accompaniment of severe spinal diseases, and when it is associated, as it almost always is, with cutaneous anæsthesia, the patient "loses his limbs" in the dark. Schueppel reported a case of general anæsthesia (affecting almost the entire surface of the body), with loss of muscular sensibility and muscle sense, in which the patient, when in the dark, felt as if he floated free in the air.

Hysterical spinal anæsthesia may also be associated with complete abolition of muscular sensibility. Duchenne has also reported the abolition of "muscular consciousness" in hysteria. The anæsthetic limbs could only be moved when under the control of the sense of sight. In the dark, movement of the limbs became impossible.

It is often an easy matter to determine the spinal origin of anæsthesia from its distribution, but in some cases this is an extremely difficult problem. The anæsthesia may be distributed irregularly over the body in patches of various extent. This may occur in multiple lesions of the peripheral nerves (multiple neuritis), or the spinal cord (multiple sclerosis). A decision may generally be reached with the aid of the attendant symptoms, particularly by the fact that in this form of spinal anæsthesia cerebral symptoms are usually present, and indicate multiple cerebral sclerosis.

But anæsthesia of spinal origin usually assumes a paraplegic type, and is associated with paraplegia of motion. It results commonly from transverse myelitis, compression-myelitis, and sclerosis of the posterior columns; it is also frequent in hysterical paraplegia. The existence of anæsthesia with intact reflex action from the anæsthetic part is positive proof of its central origin. Spinal anæsthesia is usually associated with disturbance of the bladder, and is thus distinguished from the anæsthesia due to lesions of the cauda equina, which is also paraplegic in its distribution. Bladder disturbances are often absent in hysterical paraplegia, but this variety is usually recognized by the presence of other evidently hysterical phenomena, the absence of changes of electrical contractility, the occurrence of hysterical contractures, and the previous history of the case.

Spinal anæsthesia may appear in the shape of a girdle around the body, when the posterior roots or posterior gray columns over a slight area are affected by the lesion.

In unilateral lesions of the cord the sensory disturbances present a peculiar distribution. If the lesion is confined exactly to one lateral half of the cord, we shall find motor paralysis of the lower limb on the same side, with abolition of muscular sense and preservation or hyperæsthesia of cutaneous sensibility; the latter usually disappears after a while; in the opposite limb the motor power and muscular sense are intact. Ferrier denies, however, that muscular sense is lost on the paralyzed side and retained on the other side, so that the question must be regarded as *sub judice*. In addition, there is usually a narrow zone of anæsthesia above the hyperæsthetic region (on the side of the lesion), and above this there is sometimes a narrow girdle of hyperæsthesia. If the le-

sion is situated above the cervical enlargement, corresponding disturbances are found in the upper and lower limbs. In the majority of cases, however, all these symptoms are not present. In a case under my observation there was simply paresis of motion in one lower limb, and incomplete anæsthesia in the other.

Anæsthesia of almost the entire body has also been observed in spinal affections. This happens, for example, in a lesion of the upper part of the cervical cord, involving the ascending roots of the trigeminus nerve. I have observed a case of this kind (acute cervical myelitis) in which the diagnosis was confirmed on autopsy. In Schueppel's case, to which I have already referred, there was complete anæsthesia of almost the entire surface of the body. The autopsy showed extensive syringomyelia following myelitis, with degeneration of the posterior columns and almost complete atrophy of the posterior roots.

In transverse lesions of the lower part of the lumbar enlargement there may be anæsthesia of both limbs, with the exception of the parts supplied by the obturator and crural nerves (inner surface of the thighs), because these nerves are given off higher up.

In transverse lesions of the upper part of the lumbar enlargement the parts supplied by the obturator and crural nerves may also be anæsthetic.

In transverse lesions of the lower or upper dorsal cord the anæsthesia may extend over the lower limbs and the trunk as high up as the exit of the nerves given off from the site of disease.

In transverse lesions of the cervical enlargement there may be complete anæsthesia of the entire body below the head, and, as we have seen above, almost the entire body may be anæsthetic.

But, as in the case of anæsthesia from lesions of the peripheral nerves, that of spinal origin is very often far less marked than the motor symptoms. Indeed, there may be complete paraplegia of motion without any appreciable loss of sensation. In certain forms of spinal disease this is the rule—for example, in the compression-myelitis of Pott's disease. One case of this disease, however, has been reported in which sensation was alone affected, while the motor power was unchanged.

Anæsthesia is a frequent symptom of cerebral diseases. It is observed often in the ordinary cerebral hemiplegia due to hæmorrhage or to embolism of the middle cerebral artery. It is usually distributed over the entire paralyzed side of the body, but it is rarely as profound as the motor hemiplegia. As a general thing, all forms of cutaneous sensibility are affected alike. It usually disappears much more rapidly than the paralysis of motion. In the beginning it is frequently—much more commonly than is generally believed—associated with hemianæsthesia of the special senses (*vide* article on Cerebral Hæmorrhage). In rare cases the anæsthesia is much more marked than the disturbance of motion, and persists after the latter has disappeared. Hemianæsthesia of the special senses is an almost constant accompaniment of such cases. It results, probably, from a lesion of the posterior third of the internal capsule.

The various forms of sensation are not always affected in a uniform manner in cerebral diseases. In some cases there is abolition of the sense of pressure and temperature, while that of pain remains. A case of hemiplegia has also been reported in which there was abolition of the sense of temperature, with intact sense of pressure and pain. This has been corroborated by Rosenthal.

The relation of anæsthesia to lesions of the cortical motor centres is still the subject of dispute. There can be no doubt that in some cases of destruction of these centres the cutaneous sensibility is intact. But other cases have been reported in which a certain degree of anæsthesia was present, while in others, still, the muscular sense was lost.

The question of the relation of sensory to motor disturbances in diseases of the cortex is an extremely interesting and important one. Physiological experiments upon lower animals are almost entirely valueless in this respect, and pathological observations which are beyond criticism are extremely rare. The only thing in this connection which seems to be tolerably clear is, that muscular sense may be abolished, without paralysis of motion, in lesions of the parietal lobe. The weight of evidence also seems to me to favor the view that the centre of cutaneous sensibility is situated in the parietal lobe. It is unnecessary for us to say that many writers deny the existence of true motor centres, and claim that the so-called motor centres are really sensory, and that in cortical paralyses cutaneous sensibility and muscular sense are always affected at the same time. Anæsthesia may also appear in any organic disease of the brain (tumor, softening, abscess) which involves the sensory fibres in any part of their course, either directly or by pressure from a distance. In very rare instances hemianæsthesia may result from cerebral syphilis. Only four cases of this kind have been reported, to my knowledge—one by Fournier, three by myself. In these cases all forms of cutaneous sensation were affected, and, in addition, there was hemianæsthesia of the special senses on the same side. The sensory disturbances were associated with hemiplegia of motion in all the cases.

Hemianæsthesia of cerebral origin is not uncommon in hysteria. It is often unrecognized by the patient until an examination is made by the physician. Not alone is the integument of one-half of the body completely anæsthetic, but the sensibility of the mucous membranes and muscles, and often of the special senses on the same side of the body, is also abolished. Hysterical hemianæsthesia may or may not be associated with a corresponding hemiplegia of motion. In rarer cases hysteria is characterized by anæsthesia of the entire body. It is also not uncommon to find in this disease circumscribed patches of cutaneous anæsthesia alternating with patches of hyperæsthesia.

Hemianæsthesia has also been observed in various lesions of the pons Varolii and cerebral peduncles. The distribution is similar to that occurring in lesions of the posterior part of the internal capsule, except that sight and smell remain intact.

Hemianæsthesia, similar to that of hysteria, has also been reported in cases of chronic lead-poisoning, chronic alcoholism, and mercurial poisoning.

Anæsthesia is a not very infrequent symptom of various forms of insanity. It may involve only a small part of the integument, it may be unilateral in its distribution, or it may be present over almost the entire body. It sometimes involves the deeper structures. Rochoux reports a case in which a lunatic kept his arm in the fire until the flesh was burned off down to the bones. The anæsthesia generally affects all forms of sensation, but sometimes appears to be partial.

Circumscribed anæsthesia, especially in the distribution of the trigeminus nerve, is not rare in severe cases of melancholia. In such cases there may also be incomplete anæsthesia of the entire integument.

In acute primary stuporous dementia there may be complete anæsthesia of the entire integument, so that no impression from the outside appears to be able to reach consciousness.

Anæsthesia is also not uncommon in progressive general paresis. It is probably always present in those cases which are combined with posterior spinal sclerosis, and is also noticed in uncomplicated cases.

The anæsthesias of insanity often form a basis for the patient's illusions, and, according to some writers, may furnish a clew for treatment of the mental affection.

Oppenheim and Thomsen have applied the term "mixed (sensory-sensible) anæsthesia" to a peculiar condition which they observed in quite a number of cases of insanity and diseases of the brain. "It forms a typical symptom-complex, consisting of blunting or abolition of cutaneous sensibility in all or several qualities (bilaterally, unilaterally, or in patches), and a coincident blunting of the special senses (concentric narrowing of the field of vision of both eyes), with or without impairment of the color sense and muscular sense." The symptoms were observed in cases of dementia, chronic paranoia, and transitory conditions of terror and confusion. According to Thomsen, the symptoms are not the result of

the psychosis itself, but rather of the etiological factors of the latter. These were found, in the majority of cases, to consist of alcoholism, injury to the head, and epilepsy, either singly or in combination. The anæsthesia was sometimes temporary, sometimes it appeared to remain unchanged for years.

According to these writers "mixed anæsthesia" also occurs in epilepsy, hysteria, hystero-epilepsy, alcoholism, nervous excitability, neurasthenia, chorea, conditions of terror, railway spine and injuries to the head, multiple sclerosis, Westphal's neurosis, and organic diseases of the brain. Almost all of the patients present some psychical anomalies.

Schuetz has also reported a case of paranoia with total anæsthesia of the entire body (with the exception of the right ear, lips, and fingers of the right hand), concentric narrowing of both fields of vision, anæsthesia of the special senses on the left side, and complete loss of muscular sensibility.

Hyperæsthesia, in the strict sense of the term, is an exaggeration of sensibility. This condition is rare. It is sometimes observed under normal conditions, for example, in the blind, who endeavor to replace the sense of sight by cutaneous sensibility, and who finally become able to detect much more delicate impressions upon the skin than those who are possessed of the sense of sight. It is also seen in various occupations in which the cutaneous sensibility is being brought constantly into play. True hyperæsthesia is sometimes seen in hysteria, especially in somnambulistic conditions. It has also been observed in the first stages of acute mania. But in the majority of such cases the special senses are particularly apt to be hyperæsthetic.

True cutaneous hyperæsthesia (hyperpselaphesia of Eulenburg) is also observed occasionally as the result of peripheral changes, and may affect any of the different forms of cutaneous sensibility. The sense of temperature is sometimes exaggerated after the application of a blister, in the painful region of herpes zoster, and in rare cases of locomotor ataxia. Tactile sensibility may also be exaggerated under similar conditions.

The term hyperæsthesia is applied ordinarily to conditions which are more properly called *hyperalgia, i.e.,* the production of pain after impressions which ordinarily give rise to mere sensations of touch, pressure, etc., as, for example, when gentle stroking of the skin in the hyperæsthetic zone of herpes zoster gives rise to severe pain. Such conditions are associated, as a general thing, with true anæsthesia.

Hyperalgia may be the result of affections of the peripheral nerves, the spinal cord, and the brain. It is a frequent symptom in the first stages of various neuralgias, but usually gives way, after a while, to anæsthesia, limited to the distribution of the affected nerve. It is also a very common symptom after injuries of the nerves (gunshot wounds, contusions, etc.), and may then be associated with muscular hyperæsthesia. It is also an almost constant symptom in neuritis, and in such cases is generally associated with anæsthesia. In a case of neuritis of the brachial plexus, affecting mainly the radial nerve, and at present under my observation, there is exquisite hyperæsthesia of the integument and muscles supplied by the affected nerve, although the most careful examination fails to reveal the slightest disturbance of sensation in any other respect. Even holding the newspaper in the hand for a little while soon causes an intolerable peculiar pain in the skin and muscles. In certain of these cases muscular hyperæsthesia is observed independently of cutaneous hyperæsthesia.

The latter is also a constant attendant of causalgia, or the burning pain in the skin, first described by Weir Mitchell, after injuries to nerves, and which is usually attended with glossy skin or other trophic changes in the cutaneous appendages.

Hyperæsthesia is also observed quite often in diseases of the spinal cord. It is a very early symptom in spinal meningitis, and affects the integument and the deeper parts. At the same time, the cutaneous and tendon reflexes in the hyperæsthetic region are usually diminished, as the result of pressure on the roots of the nerves. It is sometimes observed in acute myelitis, but is by no means as frequent as anæsthesia. It generally occurs as hyperalgia.

In locomotor ataxia, likewise, hyperæsthesia is much less frequent than anæsthesia. It is often observed during the time when the patient is suffering from the fulgurating pains, and is then usually confined to circumscribed patches of skin. It generally disappears with the pains. Stern reports two cases in which the hyperæsthesia seemed to affect only the sense of touch. When the patches were gently touched with a pencil, a sensation of scratching with a needle was produced, but no feeling of pain. Hyperæsthesia to the sense of cold alone is also observed in tabes, and may be widely diffused over the body. The patients then complain of pain on being touched with cold objects, which cause no disagreeable sensation in healthy individuals.

Leyden has also called attention to a condition in tabes to which he has applied the term "relative hyperæsthesia." The patients are anæsthetic so far as regards feeble stimuli, but when the stimulus reaches a certain degree of intensity an exaggerated painful sensation is produced.

In unilateral lesions of the cord hyperæsthesia is said to be sometimes present over the entire limb on the same side as the lesion. In addition, a narrow girdle of hyperæsthesia around the trunk is sometimes observed above the narrow zone of anæsthesia.

Unilateral hyperæsthesia also occurs, in rare cases, in diseases of the pons. In some cases of pons lesions, hyperæsthesia, confined to the trigeminus nerve on the side of the lesion, has also been observed.

In cerebral hæmorrhage hemihyperæsthesia is observed rarely on the paralyzed side. It usually occurs some time after the disappearance of the hemianæsthesia, and lasts a variable length of time. It is not uncommon to find exquisite hyperæsthesia around the joints after contracture, secondary to hemiplegia, has occurred.

In tumors of the brain localized hyperæsthesia in some part of the skull (sometimes corresponding very closely to the locality of the tumor) is a quite common symptom. Hyperæsthesia of the trigeminus is observed less frequently under such circumstances.

In ordinary acute meningitis there is very often exquisite hyperæsthesia of the entire body, so that the patient shrinks at the slightest touch. This is also true of tubercular and basilar meningitis, and the hyperæsthesia is often so marked that the patient reacts to a slight stimulus with evident signs of pain, even though he is in a semi-unconscious condition.

Neurasthenia (nervous exhaustion) is often associated with localized hyperæsthesia over the spine (spinal tenderness), and sometimes with diffuse hyperæsthesia over the entire body. Hyperæsthesia limited to certain parts of the limbs is also observed in some of these cases. It usually consists of hyperalgia, but in rarer instances the sensibility to heat or cold is alone exaggerated.

Circumscribed hyperalgia is often found in migraine in the parietal region, or there may be diffuse hyperalgia of the entire side of the head. Berger also describes, in migraine, exaggerated sensibility to touch (hyperpselaphesia) and to temperature over the painful side of the head.

Hyperæsthesia is observed rarely in syphilis as a prodrome of syphilitic hemiplegia, and this may continue for some time after the paralysis has developed. It has also been noted in syphilis of the spinal cord, usually associated with paralysis.

It occurs in various ways in hysteria: there may be exaggeration of the tactile sense, or muscular sense, but more frequently of the special senses. There may even be exaggeration of individual qualities of cutaneous sensibility. For example, the perception of pulsation in different parts of the body, although the pulsation is not increased in violence, depends probably on a true hyperæsthesia of the sense of pressure in the parts.

The cutaneous sensibility may be so excessive that even the contact of a slight current of air is distressing to the

patient. Hysterical hyperæsthesia may affect the entire integument or only one side of the body. It is often confined to a circumscribed region, such as the back, the lateral or anterior surface of the chest and abdomen, the limbs, the vulva, the mammary glands, the region of the ovaries.

The term *paræsthesiæ*, or perversions of sensation, is applied to those conditions in which the sensation following a stimulus differs in kind from that normally produced under similar circumstances. In the large majority of cases these paræsthesiæ are not preceded by external stimuli, but appear to result from abnormal processes in the nerves or central nervous system. These sensations include itching, formication, numbness, and unusual feeling of heat (ardor), etc. When they are accompanied by pain, the term *paralgesiæ* is sometimes employed.

Pruritus (itching) is a peculiar sensation that cannot be defined clearly in words. It is usually symptomatic, but may also appear as an idiopathic affection. It is found in numerous skin diseases, in wounds during the formation of granulations, in jaundice, scarlatina, measles, diabetes, etc. In all such cases the symptom is generally attributed to irritation of the nerve terminations in the cutaneous papillæ, either by morbid exudations or by the presence of noxious elements in the blood. In much rarer cases pruritus is an idiopathic affection of the skin, unattended by an eruption—except such as occurs secondarily to scratching—and usually confined to circumscribed parts, though in some cases, especially in old people, it involves almost the entire integument.

Formication is the term applied to a sensation variously described as numbness, "crawling of ants," "falling asleep," etc. Unlike pruritus, it is not often produced by irritation of the terminal filaments of the nerves, but usually results from partial interference with conduction along the course of the peripheral nerves or the sensory tracts in the central organs. It may also result from the presence of poisonous elements in the blood, as, for example, in poisoning by ergot, opium, or veratrine.

One of the most frequent causes of formication is compression of the nerves. This has been experienced by everyone, in the parts supplied by the ulnar nerve, from a blow on the "funny-bone." It is often found in the more severe forms of nerve lesions attended with motor paralysis. In such cases it is usually accompanied by anæsthesia, but it may also exist independently of the latter.

Formication is also a frequent symptom in various forms of diseases of the spinal cord, especially in acute and chronic myelitis and locomotor ataxia. In myelitis it is generally experienced first in the legs and soles of the feet. Before any demonstrable changes in sensation can be detected by examination, the patient complains of a feeling of numbness in the feet, as if he were walking on velvet or a cushion of air, etc. As the disease advances this symptom generally gives place to anæsthesia. In locomotor ataxia the feeling of formication may be experienced in circumscribed parts of the body, but begins commonly in the soles of the feet. Formication in the distribution of both ulnar nerves often precedes for a long time the development of the ataxic symptoms in the upper limbs.

This symptom is also very frequent in hypochondriasis, and may appear in any part of the body. It often furnishes the basis upon which the patient erects a whole complex of symptoms. For example, if such an individual experiences formication in the back, he is apt to infer that he is suffering from some disease of the spinal cord, and "expectant attention" soon enables him to furnish a multitude of other symptoms.

In hysteria, neurasthenia, and other neuroses, formication also plays its part as a minor symptom.

The terms *ardor* and *algor* are applied to feelings of unusual heat and cold of the skin, when they arise independently of an adequate external cause. These sensations are usually, though not always, associated with a corresponding congestion or anæmia of the parts, as in the paroxysms of intermittent fever, the onset of acute infectious and febrile diseases, and in various disturbances of the vaso-motor system. They are sometimes observed independently in hysteria and neurasthenia, and are very frequent in nervous women at the menopause. A very distressing and constant sensation of heat over the entire body is also a common symptom in paralysis agitans.

Charcot first applied the term *dysæsthesia* to a peculiar condition, which he described as follows: "It is a sort of hyperæsthesia in which the slightest irritation, such as a slight pinch, or the application of a cold body, gives rise to a distressing sensation, which is always the same whatever may be the nature of the stimulus, and in which, according to the statements of the patients, a feeling of vibration predominates. These vibrations appear to ascend and descend the limb at the same time. In the majority of cases the sensations persist for some minutes, sometimes for a quarter of an hour or more, after the cessation of the cause which gave rise to them. In such cases the patient always experiences great difficulty in accurately localizing the place where the irritation had been produced. Finally, it is not rare that the stimulation of one limb, after having given rise to the phenomena indicated, is followed, at the end of some time, by an analogous sensation, which appears to be situated in a part of the opposite limb corresponding to the region primarily stimulated."

The phenomenon in question has been observed by Charcot in the compression-myelitis of Pott's disease, and in acute and chronic dorsal myelitis.

Allochiria is a peculiar perversion of sensibility, which was first described, in 1881, by Obersteiner. The term is applied to the following condition: "When we test the sensibility of a patient on the leg, for example, and find that the two points of the æsthesiometer are recognized as such at a moderate distance apart, or when a prick or pressure is fairly localized, and yet, as frequently occurs, the irritation is referred to the other side, we have the condition before us. The power of localization is retained as to details, while doubt or error exists as to the side touched, the irritation being commonly referred to the corresponding part of the other limb."

This symptom seems to have been observed in a very few cases of locomotor ataxia, compression-myelitis of Pott's disease, and hysteria.

Oppenheim has recently described a peculiar perversion of sensation, the significance of which is entirely unknown, in unilateral lesions of the brain. If the two sides of the body are subjected simultaneously to stimuli of equal intensity, the sensation is felt only on the healthy side, but is perceived on the paralyzed side when the latter is irritated alone. The stimuli are perceived on both sides if that on the paralyzed side is applied with greater intensity. This symptom was observed in only four cases of unilateral disease of the brain, although a large number of such cases were examined. It never occurs in healthy individuals.

Polyæsthesia is a rare disturbance of sensation, first described by Brown-Séquard, in which the point of a pin, when applied to the skin, is felt as two or more points.

Naunyn applies the term *after-sensation* to a peculiar disturbance which he noticed in locomotor ataxia. The pain produced by the prick of a pin rapidly disappears at first, but soon returns at the point of irritation, and then may increase in severity and persist for hours. I have also observed this symptom in cases of chronic myelitis, but the pain was not as persistent as described by Naunyn.

VISCERAL SENSATIONS.—It is very probable that the action of all the viscera, particularly those of the thorax and abdomen, is attended by a specific effect on the brain. In the normal state this does not rise to the level of consciousness, but merely affects the mood of the individual. In disordered action of the viscera, however, or of the nerves which supply them, this visceral stimulus often is converted into a conscious sensation, usually of a vague, distressing character, which may be referred either to the organ which is the seat of disordered action, or to remote parts of the body. Everyone is probably aware of the mental depression which is as-

sociated so often with constipation, and which disappears at once after a free evacuation from the bowels. The disordered action of any viscus may exercise an injurious effect in the same way.

We will now enter briefly into the consideration of the more important disturbances of visceral sensation.

Hunger is a peculiar sensation that need not be described in words; it is commonly referred to the stomach, although it is really an expression of the want of food by the general system. In certain cases there is a morbid increase of hunger, known as boulimia, which is observed chiefly in diabetes, hysteria, epilepsy, mania, general paralysis of the insane, and sometimes in cerebral syphilis. Romberg and Liveing state that this symptom sometimes occurs as a forerunner of the gouty paroxysm. In one case Eulenburg observed it, in connection with hemicrania, in a non-hysterical girl of twenty-one years of age. Willis and Liveing also mention a couple of cases in which boulimia occurred as a prodromal symptom of migraine. In rare instances it appears to be an independent neurosis. In a case under my observation it was transmitted from father to son.

In these cases the patient, even within a short time after a hearty meal, or perhaps on awaking from a sound sleep, is seized with an irresistible and sudden feeling of hunger, and devours large quantities of food. At other times the ingestion of a small amount of food serves to relieve the distressing symptoms. In severe attacks the feeling of hunger may be associated with general tremor of the body, a profuse outbreak of perspiration, and a feeling of faintness which may become almost insupportable. At the same time there may be an uneasy, gnawing sensation, with a feeling of sinking in the gastric region. Boulimia has been attributed to an anæsthesia of the gastric branches of the pneumogastric nerve, but this is by no means clearly proven. It is quite certain that the condition is of central origin in many cases. Some writers believe that it is due to an affection of the sympathetic. It belongs, in all probability, among the paræsthesiæ.

The term polyphagia indicates a condition in which satiety is not produced until an enormous amount of food has been ingested. In a number of cases of this kind, lesions of the pneumogastric have been found, and the affection is probably the result of anæsthesia of this nerve. This symptom is observed in hysteria, epilepsy, various forms of insanity, diabetes, and also in diseases of the medulla oblongata.

Thirst is an indication of the want of fluid felt by the general system, but may also arise from dryness of the mucous membrane of the palate and pharynx. Polydipsia is a morbid exaggeration of thirst. It is observed in diabetes mellitus and insipidus, and occasionally in hysteria. Cohnheim has expressed a doubt as to the occurrence of primary polydipsia, but this doubt is dispelled by the experience of Nothnagel. The latter writer reported a case in which polydipsia developed acutely half an hour after a fall on the back of the head which was attended with unconsciousness. This was followed, at the end of two to three hours, by a permanent increase in the excretion of urine. The symptom was probably the result of an injury to the medulla oblongata.

Fright is almost always associated with disturbed action of the heart, and in many cases it seems to be the result of hyperæsthesia of the sensory fibres distributed to that organ. This condition is known as præcordial fright. In uncomplicated cases the patients suffer from a feeling of impending dissolution, and, at the same time, of unspeakable anguish, attended with a distressing sense of oppression in the region of the heart. As a general thing the cardiac action is feeble, often irregular; during the attack the pulse is correspondingly feeble, the skin pale and covered with cold perspiration. In rarer cases the action of the heart is strong and forcible, the pulse full and bounding, and the face congested. The symptoms on the part of the pneumogastric are sometimes attended by phenomena which must be referred to the glosso-pharyngeal nerve, viz., a feeling of scratching in the throat, and a sense of dryness and constriction in this region. In some cases there is an intense feeling of "goneness," which is referred to the epigastric region. This may be attended or followed by profuse watery diarrhœa, or the discharge of so-called spastic urine. In severe attacks there may be confusion of ideas, and this may even pass into complete unconsciousness of the surroundings.

Præcordial fright sometimes develops in healthy individuals during dreams, especially after partaking of a heavy, indigestible meal. In the midst of a troubled, uneasy sleep there is a sudden awakening, with an agonizing sense of vague fear, a feeling of great oppression about the heart, and severe palpitation, or perhaps a few labored heart-beats. The symptoms subside in a few moments. This condition is probably a reflex symptom of irritation of the pneumogastric in the stomach.

But fright is not always of a præcordial character. It is sometimes of an indefinable general character, without any special localization. This is seen not infrequently in cases of hypochondriasis, cerebral syphilis, and at the onset of various acute infectious diseases, particularly in miliary tuberculosis. Samt states that he himself suffers from attacks of fright which are localized in the frontal region. Other localizations have also been reported.

Præcordial fright is a frequent symptom of nervous diseases. It is observed in the night terrors of childhood, where it is often the result of some reflex irritation, but is sometimes indicative of a close relationship with epilepsy. It is also seen in true epilepsy and hysteria. It may be a prodromal symptom of migraine, and, in rare cases, occurs prior to an attack of cerebral hæmorrhage. It has also been seen in acute and chronic meningitis, in rupture of an abscess, or in hæmorrhage into the ventricles of the brain. In a number of instances I have observed it in cerebral syphilis, sometimes in the absence of any other evidences of local brain disease. In angina pectoris it constitutes almost the entire malady, and may or may not be associated with organic disease of the heart or great vessels. In like manner, it is a not infrequent symptom of neuralgias of the abdominal organs. In a case of enteralgia under my observation the condition was very pronounced, and, at the same time, there was extreme dyspnœa.

Præcordial fright also appears in various forms of insanity, but plays its most important part in melancholia. In the latter affection it is often the immediate cause of deeds of violence (melancholic frenzy). Literally beside himself with terror, the patient employs violence against himself or others, in the effort to free himself from the feeling of oppression.

This condition is usually regarded as a paræsthesia or hyperæsthesia of the various sensory nerves of the heart, more rarely of the abdominal sympathetic ganglia. But this theory is by no means proven. In the first place, fright is not always præcordial in character. It is sometimes so vague as to be incapable of localization. Moreover, it plays a part sometimes in diseases which are undoubtedly cerebral in character, such as epilepsy and migraine. It seems to me to be more plausible, therefore, to regard the condition in such cases as the result of a cerebral disturbance, probably in the cortex, which is conveyed to the centres of innervation of the heart, and sometimes to other nerves (glosso-pharyngeus, etc.). In other cases it seems to result from increased irritability of the nervous supply of the heart or abdominal viscera, though even then it cannot be denied that there may also be a primary cerebral disturbance without which the peripheral hyperæsthesia would prove inefficient.

Excessive voluptuous sensations may be the result of peripheral or central causes, the latter being much more frequent than the former. This condition is observed in various diseases of the female genitals (vagina, uterus, ovaries), rarely in affections of the male genitals, in diseases of the urinary apparatus and intestines (helminthiasis). Romberg has observed it in neuralgia of the spermatic plexus. Sexual hyperæsthesia is also observed in diseases of the spinal cord, such as locomotor ataxia and

multiple sclerosis, probably as the result of irritation of the lumbar genital centre. This condition must be distinguished from priapism, which is generally unattended with increase of the sexual sensations. Among cerebral diseases it is observed in epilepsy (sometimes as a prodromal symptom, sometimes during epileptoid states), hysteria, hypochondriasis, the initial stages of melancholia, and acute mania. Sexual hyperæsthesia is also observed occasionally during convalescence from acute diseases, and very often during phthisis. It is a frequent symptom of hydrophobia. We have also noticed it very often during the menopause, sometimes even after the sexual desire had been abolished for a long time.

Sexual anæsthesia is observed more often in men than in women as an acquired condition. In women it is found often as a symptom of hysteria, perhaps associated with anæsthesia of the mucous membrane of the vulva and vagina. A similar anæsthesia of the glans penis is not infrequent in males, as the result of excessive onanism or prolonged sexual excesses of any kind, and is often associated with anæsthesia of the urethra and prostatic sinus. These are the cases in which disgusting sexual abuses are so often found, because the patient must resort to some other than the natural mode of stimulation of the genital centres in order to consummate the sexual act, *i.e.*, to secure the orgasm.

Sexual anæsthesia is also seen in locomotor ataxia, multiple sclerosis, and other cord diseases, and in numerous conditions of general exhaustion, particularly when associated with mental depression. It not infrequently forms the basis of insane delusions, especially in the female. *Leopold Putzel.*

SEPTICÆMIA AND PYÆMIA. In his admirable description of the repair of wounds, Billroth devotes a section to the "general accidental diseases which may accompany wounds and other local inflammations." He states that in the great majority of cases, in wounds of any size, fever occurs sooner or later, and of these fevers he discusses at length three forms, viz., (*a*) traumatic and inflammatory fever; (*b*) septic fever and septicæmia; (*c*) suppurative fever and pyæmia. The clinical history of these fevers may be summarized from his treatise as follows:

1. Traumatic and Inflammatory Fever.—Possibly even on the first day of the operation the patient may have been restless toward evening; he may have felt hot and thirsty, with no appetite, some headache, wakeful at night, and dull the next morning. These subjective symptoms increase until the evening of the next day. If we feel the pulse we find it more frequent than normal, the radial artery is tenser and fuller than before, the skin is hot and dry; the bodily temperature is elevated; the tongue is coated and readily becomes dry. The patient has fever. In many cases, especially where the injury has affected tissues previously healthy, the fever does not begin till the second day, increases rapidly, and, with evening remissions, remains for some days at a certain height, and then ceases gradually, rarely within twenty-four hours. Traumatic fever usually lasts a week. As long as the constitutional symptoms, especially those due to the fever, do not extend beyond this limit, and especially if the disease does not prove fatal, the terms traumatic, suppurative, or secondary fever are satisfactory. But, if other symptoms occur, and death results, these severer infections have two other names, "septicæmia" and "pyæmia."

2. Septic Fever—Septicæmia.—This kind of fever differs from the former in the greater disturbance of the wound, and the severer constitutional symptoms. The local infection is very extensive, with phlegmonous inflammation and putrefaction. The patients are apathetic and sleepy, if not entirely comatose; there may be great excitement, and occasionally maniacal delirium; the tongue is dry, often hard, and hence the speech is peculiar; the thirst is great, but patients may be too stupid to ask for water; there may be diarrhœa, but rarely vomiting; sweating may be profuse at first, but later the skin is dry and flabby; the urine is scanty, very concentrated, and occasionally albuminous; the urine and fæces are later passed in bed; bed-sores over the sacrum early occur; the *fever*, as shown by the bodily temperature, at first rises high; in acute pure septicæmia intercurrent chills *never* occur in the course of the disease, and initial chills are very rare. Later in the disease the temperature falls to the normal, or even below it; usually the patient dies in perfect collapse, with a thread-like, very frequent pulse; often the agony lasts over twenty-four hours. This is the usual course of acute pure septicæmia from recent injuries. The post-mortem conditions in fatal septicæmia vary; frequently the internal organs present no morbid appearances; if, however, there was continued profuse diarrhœa, the solitary and conglobate intestinal glands will be found swollen; the spleen is often enlarged and softened, rarely it is of normal size and firmness; the liver is usually full of blood, relaxed, and very friable, but without further change. In the heart the blood is lumpy, half-clotted, tarry, and rarely firmly coagulated. In most cases the lungs are normal, but sometimes there is diffuse single or double pleurisy of moderate extent, and also traces of pericarditis. As nothing special has been found on chemical analysis of the blood from the bodies, what we find post mortem adds little that is characteristic to the picture of the disease.

3. Suppurative Fever—Pyæmia.—The characteristic course of a case of pyæmia is as follows: Supposing the patient to be suffering from compound fracture of the leg, just above the ankle, he may feel very well and have but little fever till about the third or fourth day, when the wound becomes more inflamed, secretes relatively little pus; the surrounding skin becomes œdematous and red; the patient grows very feverish, especially toward evening; the swelling increases and slowly spreads, the whole leg becomes swollen and red, the ankle-joint very painful; on pressure over the leg a thin, badly smelling pus flows slowly from the wound; the swelling remains limited to the leg; there is no trouble of the mind, no sign of intense, acute septicæmia; the patient is exceedingly sensitive to every dressing, he is restless and discouraged; there is febris continua remittens, with high evening temperature, and frequent, full, tense pulse; the appetite is lost, and the tongue heavily coated. This would be about the twelfth day of the injury. Quantities of pus flow from different parts of the wound; somewhat above it fluctuation is distinct; this collection of pus may be evacuated through the wound by careful pressure, but the escape is greatly impeded, and an incision must be made at the above point. This being done, a moderate quantity of pus is evacuated; a few hours later the patient has a severe chill, then dry, burning heat, and, lastly, profuse sweating. The appearance of the wound improves somewhat, but this does not last long; we soon notice a new abscess near the wound, but rather behind it in the calf; there is another chill; more counter-openings are required at different spots to give exit to the pus, which forms in quantities. The left leg is the injured one; some morning the patient complains of great pain in the right knee-joint, which is somewhat swollen, and is painful on every motion. The nights are sleepless, the patient eats very little, drinks a great deal, and becomes much debilitated; he emaciates, especially in the face; the color of the skin changes to yellowish, the chills recur; the patient then begins to complain of pressure on the chest; he coughs some, but raises little sputum; on examining the chest you find a moderate pleuritic exudation on one or both sides, from which, however, the patient does not suffer much, but he complains more of the right knee, which is now much swollen, and contains a great deal of fluid; as the patient sweats a great deal, the urine becomes very concentrated, and is occasionally albuminous. Finally, bed-sores develop, but the patient does not complain much of this; he lies quietly, half-insensible, muttering to himself. This would be about the twentieth day after the injury. The wound looks dry, the patient looks miserable; the face, and especially the neck, is emaciated; the skin is very jaundiced, the eyes are dull, the trembling tongue is perfectly dry, the skin

cool, the temperature low, and only elevated at evening, the pulse small and frequent, the respirations slow, the breath of a peculiar cadaveric odor; the patient becomes entirely unconscious, and may, perhaps, remain so for twenty-four hours before death. On autopsy you find nothing pathological in the skull; heart and pericardium normal; in the right auricle and ventricle a firmly coagulated, white, fibrinous clot; both pleural cavities are filled with a cloudy, serous fluid; the surfaces of the lungs are covered with a net-like layer of jaundiced fibrine; on tearing this off, under it, in the substance of the lung, but particularly on its surface, you find quite firm nodules, as large as a bean or chestnut. These are found chiefly in the lower lobes; sections through them show that they are mostly abscesses. The parenchyma of the lungs, somewhat condensed, forms the capsule of a cavity which is filled with pus and disintegrated lung-tissue. Others of these nodules are blood-red, and, on section, the cut surface is somewhat granular, and in their midst there are occasional spots of pus of various size, making it evident that they change to abscesses. They are red infarctions terminating in abscesses. Some of these abscesses lie so near the surface that they implicate the pleura, and the pleuritis is secondary. The liver is quite vascular and friable, but is otherwise apparently normal. The spleen is somewhat enlarged, and, on section, shows a few firm, wedge-shaped nodules, with their points turned inward, and their broad outer ends along the surface; they resemble the red infarctions of the lungs, and within they also have partly broken down into pus. The intestines and urinary and genital organs show nothing abnormal. An incision into the right knee, which was painful during life, gives exit to a quantity of flocculent pus; the synovial membrane is swollen, and in part hæmorrhagic, injected; the lustre of the articular cartilage is dulled. Examination of the wound shows little more than we found on the living patient, that is, extensive suppuration of the deep and subcutaneous cellular tissue, as well as pus in the ankle-joint; the walls of all these collections of pus consist mostly of broken-down tissue; true granulation has only occurred at a few points. In the veins of the legs there are old plugs of fibrin here and there, also yellow puriform detritus, and in some places pure pus.

In the preceding sketch every surgeon who practised prior to the last decade will recognize a faithful portraiture of the general accidental diseases which formerly so uniformly accompanied wounds and other local inflammations. Any considerable operation - wound not followed by inflammation and fever, was an anomaly that excited universal surprise. A compound fracture of the leg, just above the ankle, caused by the fall of a heavy body, which was not followed by the train of symptoms above detailed, was the rare exception. At all periods of human history the healing of wounds must, from time to time, have been complicated by all of the conditions which we now recognize as septicæmia and pyæmia. In the works of the earliest medical authors, and even of the early historical writers, we discover more or less accurate accounts of the appearance of these affections among the fatal complications of wounds after great battles. But the true nature of these complications was not suspected, and hence we find a great variety of crude explanations and opinions. It is not surprising that the etiology of these wound- and suppurating fevers has excited the interest of surgeons at all periods of this history. Indeed, there is no branch of surgical literature which exhibits a larger range of study and a more thorough analysis of clinical, pathological, and experimental facts than that comprised in the terms septicæmia and pyæmia. The peculiar and mysterious train of symptoms which so often developed when the healing process pursued an unfavorable course, excited the curiosity of even the most ordinary observer, and profoundly interested the student of pathology. And the interest of all surgeons in these affections was heightened by the great fatality which attended the severer forms of fever. No complications of a wound were so serious and alarming as septicæmia and pyæmia. The apprehension of the surgeon, lest these affections be developed, was so great that he often felt compelled to decline operations unless he could choose the locality where they were to be performed, or the season of the year in which to operate. The fear of blood-poisoning following wounds has long delayed the advance of operative surgery. But, happily, the period of doubt and fear has passed away, and the art of surgery has been forever relieved of the greatest obstacle to its complete success. The terms septicæmia and pyæmia belong to the past history of surgery, and their true significance will never again be fully appreciated except by surgeons who neglect preventive measures.

The history of septicæmia and pyæmia must, therefore, comprise one of the most interesting chapters in the science and art of surgery. The practical value of this history to the modern student of surgery is not limited to the mere knowledge of the methods by which experimental physiology has solved an intricate problem of pathology, but it has a far deeper significance. That knowledge is essential to the successful practice of the preventive methods in whatever form they may be undertaken. No surgeon can properly appreciate the immense revolution which has taken place in the practice of surgery within the last decade, and apply his knowledge successfully, who does not first understand, at least in some measure, the nature and details of the investigations which led to that revolution.

This article will be devoted, therefore, to the more salient facts in the history of the investigations into the causes of septicæmia and pyæmia, with a view to illustrate their nature, and the reforms in practice which have grown out of the discovery of the conditions on which these affections depend. To the elaborate work of M. Jeannel ("L'Infection Purulente ou Pyohémie," Paris, 1880) we are chiefly indebted for the historical summary of the investigations into the nature and causes of pyæmia.

Historical Summary.—Many early writers described abscesses in parts distant from the seat of the wound. In 1559, Nicolas Massa reported a case of abscess of the lung consecutive to a wound of the head; in 1561, Ambroise Paré described cases of wounds of the head with secondary abscesses; in 1665, Marchetti attributed abscess of the liver, after wounds of the head, to the descent of the pus through the lungs and pleura; but Boerhaave (1720) first formulated the doctrine that, by the admixture of pus with the blood, this liquid is so changed as to lead to the collections of pus in the organs.

Le Dran (1731) and Heister (1739) adopted the views of Boerhaave. In 1761, Morgagni related several cases in which autopsies revealed pus in the veins, and abscesses in the viscera, after wounds of the head. He attributed their occurrence, says an author, to particles of pus which, having become mixed with the blood and disseminated, are arrested in some of the narrow passages, and, by obstructing and irritating these, offer an obstacle to the circulation of the humors, and become the cause of the production of a much larger quantity of pus than that which was primarily introduced. From this time to the middle of the eighteenth century there were many publications in which cases were reported of abscesses secondary to wounds, with speculations as to the origin of the pus in the abscesses.

Bertrandi, in 1757, presented to the Academy of Surgery, Paris, a memoir on abscesses of the liver following wounds of the head. He regarded abscess of the liver as especially liable to occur when the patient vomited, or had convulsions or epistaxis, which caused a derangement of the circulation of the blood of the head. The result of this derangement was encephalic congestion, and an active descent of the blood in the vena cava superior; the hepatic branches being in a large organ and without action, and also connected by many openings with the ascending cava, become congested, stasis follows, which results in gangrene or suppuration, more frequently the latter.

The opinion that multiple abscesses are due to sympathy was vaguely expressed by surgeons, and among

others by Pigraï, in 1612. Goursaud, in 1759, distinctly enunciated the doctrine that these abscesses were due to paralysis of the nerves of vessels, producing a stasis which resulted in inflammation. Desault adopted the theory (1794), and Larrey, in 1812, reproduced it with additional explanations. Under the term *fièvre jaune*, which he afterward abandoned, he gave very exact clinical descriptions of acute and chronic purulent infection. He regarded it as contagious. In 1817, and again, in 1829, he reported cases and attributed them to sympathetic irritation of the liver and lungs. Sir Charles Bell also adopted the opinion of Desault (1817), but admitted the possibility of latent visceral lesions. Travers, in 1818, in his statement concerning phlebitis, explains the symptoms by a lesion of the nervous system. Begin (1821), Sabatier (1822), and Boissat (1822), accord part of the action, directly or indirectly, to the nervous system. Copland (1844) and Brodie (1858) sustain the influence of the nervous system, the former attributing the action to the ganglionic system, and the latter to a lesion of the cerebro-spinal system.

In 1821, Richeraud advanced a new doctrine, in opposition to the then prevailing doctrine of Desault. He attributed abscess of the liver, following wounds of the head, to the commotion of this organ at the time of the injury. He attached great importance to the large size of the liver, its situation, and its parenchymatous tissue. He ignored the frequency of multiple abscesses of other viscera following wounds, and considered only wounds of the head and abscess of the liver.

Certain writers attributed multiple abscesses to the suppuration of pre-existing tubercles due to the traumatic fever. Though the existence of tubercles had been previously mentioned by authors, it was not until 1817 that the complete theory was broached by Sir Charles Bell. He remarks : "If there be any tendency to disease in this organ, however latent before the injury, it will be developed, and, increasing the constitutional disturbance, endanger the patient's life. It also appears that as wounds, by their sudden and more violent inflammation, produce a corresponding acute attack on the lungs, so do they often, by more gradual influence, bring on a phthisis. . . How often are we inclined to say that the patient who dies after a great operation has fallen a victim to abscess of the lungs, without duly considering how much the stimulus of the knife had to do in exciting this mischief?"

Suppression of suppuration was long considered one cause of the occurrence of multiple abscesses. This was the doctrine of metastasis, pure and simple, viz., the process of suppuration, having been suppressed in the wound, is transferred to the viscera. In 1749, Quesnay entertained the opinion that the pus formed in the vessels, and that the suppression had no effect in producing abscesses of the viscera ; the latter were not caused by the former, but *vice versa*. Boyer (1814) denied this interpretation of the phenomena. "The accidents," he remarked, "which are attributed to the suppression of suppuration appear rather to be the cause, especially in those cases in which the accidents do not precede suppression."

In 1774, John Hunter read his paper on the "Inflammation of the Internal Coats of Veins," which greatly influenced the opinions of surgical pathologists. He demonstrated the entrance of pus from the inflamed vein into the circulation, and while he attributed the fatal termination of phlebitis to the abscesses in the viscera, he did not actually announce the dependence of the abscess upon the preceding inflammation of the veins. Hodgson, in 1816, and later his translator, Breschet (1819), were the first authors who suggested the connection between phlebitis and abscesses of the viscera. The subject was further illustrated by the publication by Ribes, in 1816, of a paper containing researches on the causes of death of puerperal women, in whom he demonstrated the presence of pus in the veins. In 1820, Gendrin instituted an experiment to prove the transformation of blood into pus, a view held by Quesnay and Horne. He mixed one part of pus with eight parts of blood, and proved, with the aid of the microscope, the disappearance of the blood-globules in twenty-four hours. In 1821, James expressed a doubt as to the possibility of the penetration of pus into the vessels, but in the same year Erdmann, studying positive cases of purulent infection with abscess of the viscera, found pus in the inflamed veins, and declared that this was the cause of abscess and of death.

In 1822, Gaspard first attempted to determine the question in dispute by the experimental method, and injected pus into the veins of animals. The pus was first changed by exposure to the air. He had not in view purulent infection, but septicæmia. In 1823, Velpeau published his inaugural thesis, in which he employed the term *infection purulente* to designate the state of the blood altered by pus. Notwithstanding preceding works, the truth of the dogma of the mixture of pus and of blood was not generally received.

In 1826, Velpeau reiterated his views, in an article on "Alterations of the Blood in Diseases." He contended that the vitiation of the blood by pus was the only cause of the lesions, and rejected all primitive inflammation of the solids in the genesis of visceral abscesses. He saw in the purulent secretion of the wound the only source whence the pus was obtained to infect the blood and the general system. In 1828, Piorry advanced the opinion that the blood could be inflamed, and even suppurate, and gave to the disease which resulted from this suppuration the name of *pyohémie*. The researches of Dance (1828–29) had a very important influence on current opinions. In a series of twenty cases, followed by autopsies, he demonstrated the penetration of pus into the circulation, consecutive to phlebitis. He consequently attributed to inflammation of the veins the origin of the complications occurring to those operated upon, characterized by the presence of multiple abscesses of the viscera.

In 1834, Gunther, of Hanover, published a series of experiments of injection of filtered pus into jugular veins, for the purpose, especially, of studying the secondary accidents of phlebitis. He was successful, in twenty-two out of twenty-three operations upon the horse, in creating in the lungs inflammatory and purulent centres analogous to those of *pyohémie*. The general symptoms simulated those of purulent infection, with the difference necessarily appertaining to the constitution of these animals.

The theory, embodied in the title *embolic septicæmia*, consisted of two elements, viz., septic poisoning as the cause of the general symptoms, and vascular obstruction as the source of the abscess. This phase of the subject was largely discussed, especially by D'Arcet, Virchow, Bonnet, Hueter, and Verneuil, but the discussion did not greatly advance the general subject toward a rational conclusion. Virchow, and other writers who coincided with him, grouped these embolic affections under the term *metastatical dyscrasiæ*. Three forms were given :[1] 1, Metastasis associated with the phenomena of embolism, tending to the development of multiple centres of inflammation and their suppuration ; 2, metastasis in which there is something over and above embolism, and quite independent of its occurrence, and which may get well if secondary abscesses do not form in important viscera—septicæmia, ichorrhemia (S. Ringer) ; 3, metastasis combining the phenomena of the two former.

The doctrine of the spontaneous origin of pus in the blood was first advanced by Tessier, in 1838 (*diathèse purulente*). The belief that blood might be transformed into pus is very ancient, and the theory had not previously been applied to pyæmia. Tessier adopted the term *purulent diathesis*, by which he understood a modification of the organism, characterized by a tendency to the production of pus in the solids and coagulable liquids of the economy. This diathesis is manifested under three forms : 1, Purulent fever ; 2, purulent phlegmasia ; 3, the purulent state. The symptoms of rapid suppuration in certain parts of the body are more particularly connected with purulent fever. The formation of pus takes place equally in the liquids and in the solids, unless there is the relation of cause and effect between the two phenomena. In the course of the disease blood may be transformed into pus, and the transformation may be

Septicæmia.

general or partial; it may, alone or simultaneously, take place in the blood-vessels or lymphatics; often suppuration occurs only in the tissues and in the parenchyma of organs. From this source arise the flakes of pus found in the current of the circulation, the suppurative coagula of the heart and great vessels, the frequent phlebites, the purulent arthrites, and, finally, the suppurating foci scattered throughout the body, which have been described as metastatic abscesses. The nature of the modification of the organism which gives rise to the purulent diathesis was unknown. Moreover, traumatism is not an indispensable condition; the diathesis and purulent fever can be produced spontaneously under the influence of obstruction; they may exist even before traumatism, which may only prove to be the exciting cause.

At this period, notwithstanding Tessier's opposition, the prevailing opinion was that pyæmia is due to the mingling of pus in the blood. But the experimental method was again to furnish a new series of proofs, establishing a definite conclusion as to the effect of the artificial mixture of pus and blood. In 1842, D'Arcet reported that he had eleven or twelve times injected unaltered pus into the veins of animals; in only two cases were purulent collections, like those of pyæmia, obtained. In all of the other trials there were produced only visceral ecchymoses; the symptoms were those of purulent infection. Donné, in 1844, acknowledged that it was impossible to recognize pus-globules in blood, owing to their identity in form and volume to leucocytes. In 1846, Castelnau and Ducrest, believing that former experiments had not been conducted with sufficient exactness, undertook the injection of pus under conditions most favorable for obtaining visceral abscesses. They made seven experiments. The injection was always made upon dogs, and in the saphena vein, at the external part of the leg. The pus employed was more or less recent, and was always filtered. Five animals died, and two recovered. In one instance there was pulmonary ecchymosis, and in four cases multiple abscesses were fully formed. These abscesses were more frequent and more numerous in muscles and cellular tissue; twice they were found in the kidneys and spleen and in the articulations. The symptoms, in general, strikingly resembled those observed in wounds complicated with pyæmia, due regard being given to the particular nature of the animals operated upon. The conclusions drawn from these experiments were confirmative of the dogma of the mixture of pus and blood as the origin of purulent infection.

Following in the same path, Sédillot, in 1849 (*Brit. and Foreign Med.-Chir. Rev.*, October, 1849), undertook a series of experiments with a view of answering the following questions: "Is pyæmia the result of a diathesis, or is it caused by the introduction of pus into the blood? What is the mechanism of such introduction? Does the pus act as pus, or by means of the products it gives rise to? If it acts as pus, to which of its elements are we to attribute the poisonous properties it seems endowed with? Is it the globules, the granules, or the serosity, separated or combined, altered or unaltered in properties, that give rise to the pyæmic changes and to death? Is the cure possible; and what are the true indications of treatment?" Forty-five experiments were performed on dogs. It appears that after a single injection of a moderate quantity (four grammes) of healthy pus into the veins, the animal recovered, having sustained little inconvenience. Recovery usually took place after the injection of larger quantities (fifteen to twenty grammes), even when this was of a thickened consistency, containing many globules, the symptoms in these cases being much more severe. When the animals did die from the effects of a single injection, the metastatic abscesses were found to be only in the early stages of formation. Even after the injection of fetid pus a recovery took place, the fatal effects of this fluid evidently depending upon other causes than its fetidity. Yet in other cases a smaller quantity of fetid than of healthy pus proved fatal, and a small quantity of gangrenous pus did so speedily. It appeared also from these experiments that "as in man the course of the symptoms observed depends not upon the passage of a certain quantity of pus into the blood at one time, but upon the persistence of the source of pus, so, if we wish to imitate the effects in animals, we must produce analogous morbid conditions by a repetition of the injection of pus at short intervals."

The theory of a purulent diathesis had been proposed in opposition to that of phlebitis and purulent infections by pus supposed to be pure. The theory of a disturbance or rupture of the equilibrium of the vital forces was developed by Chauffard, in opposition to septicæmia and purulent infection by septic pus. The doctrine of Chauffard coincided with that of Tessier in this, that it rejected all mechanical causes of disease, denied to the wound and to its secretions all direct etiological influence, and sought in the individual himself the cause of pyæmia. Without denying spontaneous pyæmia, it nevertheless made the presence of a focus of suppuration, or rather of traumatism, the ordinary condition of development of the disease, and did not admit in any manner the influence of an anterior diathesis. Many authors had previously imperfectly sketched this doctrine, but Chauffard more accurately defined it in the discussion on pyæmia before the Académie de Médecine in 1871. He stated that traumatic fever indicates the expenditure of all of the vital forces of the organism in their participation in the reparation of the wound; it is neither a necessary nor a salutary fever; the organism can with advantage escape it; it is a pathological result of the perturbation, reparative, caused by traumatism; of the effort of the entire being to re-establish its integrity and organize the curative process of suppuration. The proof of the participation of the organism in the process of suppuration is the presence in the blood of leucocytes. The blood of those wounded is, therefore, in a temporary pathological state, or a state of abnormal activity which creates an unstable equilibrium that the least shock disturbs. This equilibrium is destroyed, and the abnormal pus-creating activity is deviated, by one cause or another, from its normal evolution; in the same manner as, under similar circumstances, the cancerous activity begets all cancer, the syphilitic all syphilis, etc., and also in the same manner as the pyogenic wound separates all pus. Pyæmia is constituted; centres of multiple suppuration are created under ordinary innocuous and common influences.

Virchow, in 1846, undertook to prove that purulent infection, in the literal sense of the word, does not exist. He maintained that the venous coagula of inflamed veins did not become purulent, but puriform. In 1847, passing to the examination of pyæmic blood while in circulation, and relying upon the identity of leucocytes and the white globules of pus, he attributed to an accumulation of leucocytes the appearance of blood described as pyæmia. In 1854, he demonstrated, taking in part, at least, the arguments of Cruveilhier, that the absorption of the pus-globules, entire and intact, was an impossibility, and that there is no other method of entrance of pus into the blood than by an open vessel. Gulliver, of the English army, had already stated that the puriform mass in the interior of clots does not originate in the walls of the vessel or clot, but is produced by transformation of the central layers of the clot. On microscopical examination he determined that the fluid in these clots did not contain pus.

With these facts as the basis of inquiry, viz., that the character of the contents of these clots is puriform, but not purulent, and is composed chiefly of granules, Virchow pursued the inquiry as to the final disposition of this material. It was found that these clots or thrombi finally soften, disintegrate, and the contents escape into the circulation. Virchow demonstrated the embolic character of certain products, previously thought to be inflammatory in their origin, found in the form of white, fibrine-like masses in the spleen and other organs. He was of the opinion that metastatic abscesses in the lungs were always embolic; in cases of puerperal fever, with multiple abscesses in the lungs, he alleged that thrombi or clots were always found in the pelvic vessels.

In 1850, Henry Lee performed the following experi-

ment: Perfectly pure blood, recently drawn from a vein, was mixed with pus; the result was, in his opinion, a more rapid coagulation of the blood and a firmer clot. Considering the fact of the frequent obstruction of inflamed veins by a coagulum, he concluded that the coagulation of the blood under the influence of the pus ought to be the first link in the chain of the morbid process of pyæmia. According to this theory, the presence of pus has the effect of thickening the blood, so that it is incapable of pursuing its course through the capillaries, and adheres to their walls, and transforms them into so many inflammatory centres and purulent dépôts. This doctrine obtained some credence in England, but it was intrinsically without merit.

In 1851–52 Henry Bennett noticed the resemblance between pyæmia and leucocythæmia. The resemblance was found in the identity of form and constitution existing between pus-globules and the white globules of the blood, an identity to which Donné had drawn attention in 1844.

In 1853 Dr. W. Jenner,[2] of London, attributed the multiple abscesses which follow acute specific diseases to a condition which he termed *pyogenic fever*. These abscesses were believed to be due to the diseased state of the blood. The opinions of Jenner were in accord with those previously advanced by Tessier in 1838, under the title *purulent diathesis*, which he regarded as a tendency to suppuration in the solids and coagulable fluids. Bennett[3] discussed the subject under the name *ichoræmia*.

The theory that infectious diseases are produced by micro-organisms, had long since been suggested, but in 1831 Braconnot announced the doctrine that the virulent principles are the ferments. This doctrine was based upon the fact that agents which arrest fermentation also destroy the virulent properties of the infectious liquids. In 1836 Donné discovered microscopic organisms in the pus of chancres which were not found in ordinary pus, and to which he attributed its virulence. In the following year Beauperthuis and Adet de Roseville proved the existence of micro-organisms in the pus of chancre, and in 1838 the same authors advanced the opinion that these animalcules were the cause of fermentation. In 1841 Raciborski noticed the resemblance between the development of the pustules of variola and the viscous foci and phenomena of fermentation. In the one as in the other, a minute particle of a body placed in given conditions, mingles in a mass of liquid which contains these elements, and produces a movement of decomposition, the result of which is the reproduction of a material of the nature of that which was the first cause of the movement. Comparing surgical multiple abscesses with pustules of variola and viscous foci, he felt justified in presuming that the explanation was the same for visceral abscesses. The qualities of the liquid which they contain prove in some degree their origin, and render it probable that they owe their existence to the special action of pus on the blood. But in order to produce such a remarkable modification of the mass of the blood, it is necessary that there should be a state of decomposition, as laudable pus does not produce any similar change. He, therefore, considered the action of putrid pus on the blood as absolutely comparable to fermentation, and this was, in his view, the secret of purulent infection.

In 1848 Fuchs mentioned the presence of bacteria in certain septic diseases in animals, and, in 1850, Davaine reported having discovered vibriones in a quiet state in the blood of sheep inoculated with the blood of other sheep affected with splenic fever. In the same year Pollender discovered an infinite number of rods in the blood and sanguineous extravasations of cattle dying of charbon. Many other observations were made previous to 1861, when Pasteur began his demonstrations; all were confirmatory of the existence of micro-organisms in the blood, after the injection of purulent fluids, and in certain infectious diseases.

Pasteur first demonstrated the fact that butyric fermentation has as its agent an organism, a *vibrion anaërobie* (one living without free oxygen). He next (1862) proved that in the atmospheric air there exists an innumerable multitude of organized corpuscles, which are the germs of fermentation. In 1863 he brought forward his researches upon putrefaction before the Académie des Sciences of Paris. He stated that putrefaction was determined by organized ferments of the vibrio species; these vibrionic ferments of putrefaction are all *anaërobies;* in a closed vessel putrefaction does not begin to be manifested by external signs until after a certain lapse of time, at least twenty-four hours. During this first period there is a process going on which leads to the disappearance of the oxygen gas in the putrefiable material, and its replacement by carbonic acid. If, however, the medium is neutral or alkaline, the process is effected under the influence of small infusorial *aërobies*, which live by consumption of free oxygen, notably the *monas corpusculum* and the *bacterium termo*. When the oxygen has disappeared, these animalcules perish and are precipitated to the bottom of the vase. If the liquid is free from the germs of putrid fermentation, the whole remains indefinitely in the state of rest.

Pasteur, therefore, regarded putrefaction as a fermentation ending in the reduction of putrescible matters. He distinguished two phases or periods. In the first period, under the influence of ferments due to anaërobies of the vibrio kind or genera, there occurs a transformation of azotized matters into more simple, but still complex, products. In the second period these last products are, in their turn, reduced to binary compounds of more simple form, by the action of infusorial agents of the aërobic kind (bacteria, mucosa, etc.).

The theory of germs applied to pathology was, in effect, the application to morbid processes of the doctrine of putrefaction advanced by Pasteur. At first the discussion arose upon its application to *charbon*, or splenic fever. The bacterial origin of this disease, suspected by Davaine (1850), then by Pollender (1850), and Brauel (1856–57), was demonstrated in 1863–64 by Davaine, who established the fact that when we inoculate with the blood of an animal affected with charbon and charged with bacteria, the animal inoculated is infected, and bacteria are reproduced and multiplied in the blood.

The generalization of this idea of the origin of charbon to other infectious diseases rapidly followed. In 1863 Signol had already announced the presence of bacteria in the blood of horses affected with typhus. But in regard to septicæmia and pyæmia, investigations seemed, on the contrary, to prove at first that they were not due to the presence of micro-organisms. Pasteur was the first to advance the opinion that septicæmia had a parasitic origin. In 1866 Coze and Feltz published their observations on the presence of infusoria and the state of the blood in infectious diseases.

The fact was clearly established in their minds that bacteria constitute the septic poison. In 1872 Burdon Sanderson, of London, advanced the opinion that in pyæmia there is a special poison which does not exist in septicæmia. As to the nature of the poison, this physiologist discovered that the pyæmic pus contained bacteria of a particular character, and the number seemed to be in proportion to the toxic activity of the fluid.

In the same year Klebs affirmed the identity of septicæmia and pyæmia, and attributed them to changes in the pus due to a special agent, which he designated as the *microsporon septicum*. He contended that this micro-organism has a peculiar power of penetration and destruction; it penetrates with facility the tissues and excites a process of molecular necrosis; it causes ulceration of the vessels and thus produces secondary hæmorrhages, called septic. He believed it enters the lymphatics, and that after it has reached the veins the spores accumulate around the valves, determine inflammation of the internal membrane and a consecutive thrombosis which becomes the source of emboli. Thus the *microsporon septicum* creates metastatic abscesses, either by its own peculiar local influence, or by creating thromboses.

In 1872 Davaine brought before the Academy of Medicine of Paris, a communication on septicæmia in which he contended for the progressive virulence of septicæmic blood; according to his experience the millionth, or even the trillionth, part of a drop of septicæmic blood pos-

sesses a virulence which quickly destroys a rabbit inoculated with it. He explained that the progressive virulence depends upon the reproduction and multiplication of the septic virus, which is otherwise identical with the ferment of putrefaction. The deduction which he drew from his experiments was, that septicæmia is a putrefaction effected in the blood of a living animal by the same process, and by the same agents, as putrefaction is effected in the free air, viz., by the activity of vibrios. He attributed to this cause the cadaverous odor of persons dying of septicæmia and the rapid decomposition of their bodies. The discussion which this paper elicited led to a renewal of experiments by a large number of scientific investigators, and though many of the details were disputed, there was unanimity of opinion in regard to the essential facts. The general conclusion was that in septicæmia the toxic and active agent is of an organic nature, and is a bacterium; that the disease is closely allied to putrefaction, and the process which takes place is analogous to that of putrid fermentation. The bearing of these facts upon the subject of pyæmia, and in particular upon the general accidents of an infectious and septicæmic nature occurring in this malady, is undoubted.

The symptoms produced in the animal were believed by Panum to be due to a chemical substance produced by these micro-organisms, and not to their multiplication in the blood and tissues. Bergman reports experiments in which he claims to have detected a crystalline substance which he called "sepsin." Subsequently (1873) Bergman modified his first statements, for he discovered that when putrid matters were deprived of bacteria by a process of filtration, they lost their poisonous properties, or maintained them in a very limited degree. He concluded that if sepsin is alone efficacious, it attaches itself to bacteria, and it is to sepsin that the bacteria owe their toxic properties. This confession evidently tended to confirm the original theory that the poison is inherent in bacteria.

In 1873, Samuels contributed a paper to the general subject, in which he recognized three phases in the series of septic accidents, to each of which he referred a special variety of infusoria. The effect of these organisms was as follows: 1, *phlogogenous*, or to excite an inflammation; 2, *septogenous*, or to give rise to the putrid or infectious phenomena observed upon the living organism; 3, *pyrogenous*, or to cause fever and suppuration. From his experiments he believed that the following division of micro-organisms might be made: 1, The bacterium termo was phlogogenous; 2, spores, collected in the form of a rosary, and vibriones, were septogenous; 3, bacteria (unnamed) larger and more brilliant than bacterium termo, were more especially pyrogenous.

Koch[6] concluded from his experiments that the pathogenic bacteria consist of different species. To prove that he did not stand alone in this view he quotes Cohn as stating that, in spite of the fact that many dispute the necessity of separating bacteria into genera and species, he separates bacteria of different form and fermenting power from each other. Eidam, also, came to the conclusion that different forms of bacteria require different forms of nutriment, and that they behave differently toward physical and chemical influences. Koch was able so to isolate and cultivate two different species in mice, as to determine their special infective power.

Is septicæmia the result of the action of ptomaïnes or of microbes? was the question which Jeannel and Laulanié attempted to answer. Ptomaïnes can pass through the layer of granulations lining a wound, since they are in a state of solution, while microbes cannot enter the circulation unless a solution of continuity exists. Now, as septicæmia is only observed when a break in the continuity of the living membranes of a wound exists, the authors attribute to the effects of ptomaïnes a subsidiary part, while the principal function is performed by microbes.

Petrone[9] experimented on the blood and serum from all the tissues of patients dying from virulent septicæmia. One portion of the blood and serum was injected unaltered under the skin of rabbits. Another portion was boiled and thoroughly filtered before injection, and a certain quantity of the same fluid boiled was introduced into clean disinfected tubes containing a little beef-broth, and then closed, hermetically sealed, and placed in a warm situation. All of the animals presented the same symptoms, and all died; the necropsy showed the same lesions in all, and the same micro-organisms in the blood, serous, and intestinal fluids. The blood of all of these animals caused death when injected into other rabbits. The blood in the tubes did not become turbid. The conclusions are that in septicæmia the bacteria are not a primary, but rather a secondary, fact, and that the virus of septicæmia is probably represented by a chemical poison; in other words, the bacteria acquire their virulent property through a chemical ferment contained in the septic fluid. This conclusion, the author believes, suggests the pre-existence in the animal organism of ordinary schizomycetes, innocuous, but which in the presence of septic poisons become transformed into pathogenic bacteria, and the fact, experimentally demonstrable, that the bacteria only are able to develop in the animal organism the poison in question. Of these two consequences he holds that the first is the most acceptable and most logical (*London Medical Record*).

Results of Investigations.—The preceding sketch briefly outlines the course of investigations into the etiology of the complications of wounds, but it gives a very meagre view of the vast amount of labor which has been expended upon this subject, especially during the present century. These studies have been undertaken and vigorously prosecuted by the most eminent physiologists, pathologists, and scientists of every period. In the early history of these investigations speculation took the place of experimentation, and the most absurd theories were advocated. As pathological inquiries advanced in importance and accuracy more rational theories prevailed. When, finally, experimentation was adopted as the basis of forming an opinion, a new impulse was given to these investigations, and far more accurate views began to prevail. At length came the revelation of the power of micro-organisms to establish morbid processes in the animal system, and their presence in the pus in septicæmia and in the abscesses of pyæmia seemed to determine at once the true nature of these affections. But it is apparent, from the more recent literature of this subject, that, while there is a consensus of opinion as to the potential force of micro-organisms in initiating the morbid processes, there is still a wide divergence of opinion as to the details of their operation. The tendency evidently now is toward a belief in the multiplication of the pathogenous bacteria, and their division into species, each having its special morbific power. In regard to the nature and action of bacteria, it is held (Ziegler, "Path. Anat.") that the factors which determine the invasion and the course of development of bacteria within the human body are two. On the one hand, the bacteria must be endowed with certain vital properties of a special kind; on the other hand, there must be a predisposition on the part of the system. Slight chemical changes in the constitution of a tissue often enough determine whether a given bacterium can develop in the tissue or not. In many cases, bacterial invasion depends on the formation of a local necrosis or wound, in which the fungus can settle and develop; in other cases some grave disturbance of the circulation may lead to a failure of resistance on the part of the tissue. Many bacteria can only come to development within the human body on rare occasions, as their usual habitat is without it; others only meet with fit conditions for their existence and growth within the body, and do not multiply without. These micro-organisms (Cheyne) grow on various soils, though some are more particular than others; the substances essential for their nourishment are water, phosphates, salts of potash, carbonaceous and nitrogenous organic substances; most forms require free oxygen, or grow much more rapidly in it, but there are some which will not live unless oxygen is almost or entirely absent. As the result of their vital action these bodies produce extensive alterations in the materials in which they grow; they break up the complex organic com-

pounds, and reduce them to simpler forms; in this way the effects are slight and transient; if the wound is larger, as when it is left to heal by granulation, the absorbed material gives rise to fever, which is called traumatic; and again, the wound may be so large and the absorption of the poison so rapid as to cause fatal symptoms. This is called septic intoxication.

It is maintained (Lister, Cheyne) that while the products of the growth of certain bacteria give rise to general effects—traumatic fever and septic intoxication—they also act locally on the wound and cause inflammation and suppuration. Though inflammation and suppuration in a wound may be due to other causes, yet the chief causes are the growth of micro-organisms in the discharges from the wounds, or in the tissues. They grow in the walls of the wounds, and give rise to irritating products which keep up the inflammation and suppuration; they often cause extension of the inflammatory process, or burrowing of the pus, and sometimes, spreading into the neighboring tissues, they give rise to the formation of abscesses. When the pus of an acute

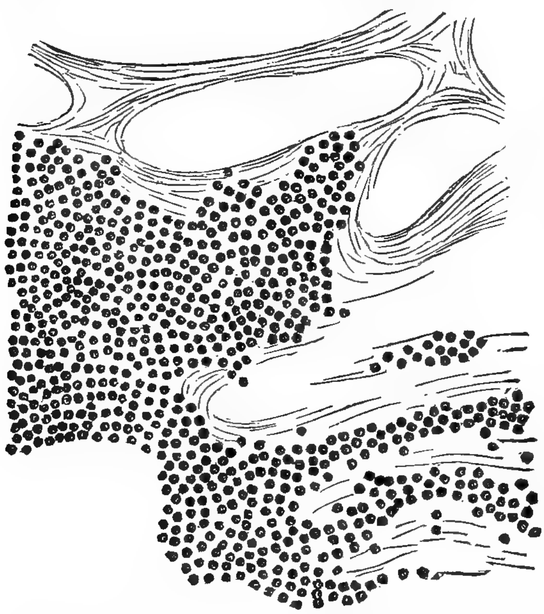

FIG. 3448.—Grouped Micrococci Invading Abscess Wall. (Ogston.)

abscess is examined micrococci are always found in it, sometimes in large numbers.

An illustrative example of the growth of micro-organisms in the tissues is seen in erysipelas. If portions of the spreading margin of the redness and of the healthy skin in the immediate vicinity be excised and cut into sections, it will be found that in the healthy skin, immediately beyond the red margin, the lymphatic vessels contain large numbers of a minute micrococcus frequently arranged in chains. At the red margin itself there are inflammatory appearances as well; the lymph-vessels contain not only micrococci, but also numerous leucocytes, and there is a small-celled infiltration around them and in the skin; the micrococci also extend into the lymph-spaces. Inflammation and suppuration may be caused (Ziegler), not merely by growth of micro-organisms in the discharges of the wound, but also by growth of micro-organisms in the tissues (Fig. 3448). This effect is only caused by certain micro-organisms, for, on the one hand, many micro-organisms will not grow in the living blood or tissues, but yet, growing in the discharges, can produce irritating materials, and cause suppuration; while, on the other hand, many micro-organisms grow in the living tissues without causing suppuration. The micro-organisms which grow in the living tissues and cause suppuration belong, so far as is known, almost entirely to the group of micrococci; they cause fermentation and decomposition of organic substances. In some instances, well-known chemical substances are formed, and the agency of the micro-organisms is extensively employed in the manufacture of various articles of food and drink; in other cases, however, the substances which they produce are extremely poisonous, and when injected into animals cause symptoms of poisoning resembling the effects of various alkaloids.

Some micro-organisms can grow in the animal body, giving rise to a variety of diseases; some are fatal to most animals, and others are only pathogenic in certain species of animals. The diseases caused by the growth of these bodies in the blood and tissues are grouped together under the term "infective diseases," of which there are two kinds, viz., those in which the infection occurs from a wound or open surface—the traumatic infective diseases,—and those in which no wound is necessary, and where the pathogenic organisms are supposed to be able to enter the body through the unbroken surface.

Some micro-organisms produce such alterations in organic fluids that the injection of these fluids into animals is followed soon after the injection by symptoms of poisoning, and if in sufficient quantities, by fatal results. If the quantity of poison is slight there is a moderate elevation of temperature, which soon subsides; if the quantity is greater the fever is higher and more prolonged; but if there is a fatal dose the temperature soon sinks below the normal, sometimes accompanied by vomiting and diarrhœa. The clinical expression of these facts is as follows: Where a wound is small and but a very limited amount of infection enters the system, the traumatic fever is absent or light; if a large amount is absorbed the fever is more or less severe, according to the amount; a sufficient amount may be absorbed to prove fatal at once.

It may be stated as a conclusion that two theories have chiefly prevailed as to the introduction of bacteria into the animal system, and their action.

The first theory explains their action as primarily in the wound, where they set up chemical changes which result in the formation of a poison originally called "sepsin" by Bergman. This poison, absorbed into the circulation, induces fever or septic intoxication. Under favorable circumstances coagulation of the blood occurs, and thus gives rise to thromboses. From these clots arise emboli which clog the small vessels of organs, and result in abscesses.

The second theory attributes to the direct action of the micro-organisms, first on the wound, and second on the blood and tissues, the symptoms of septicæmia and pyæmia.

The latter theory is more generally accepted. According to this doctrine,[6] non-pathogenous bacteria exist in the healthy organism in large numbers, and subsist upon substances accessible to them; the result of their action is the occurrence of chemical changes in these substances. If the organism is in a normal condition these changes are not harmful, or are quickly eliminated from the system. But pathogenous bacteria have the power of settling in living tissue; all that is necessary is that a bacterium should reach a spot that affords the conditions requisite for its development; it then multiplies and forms colonies or swarms; these may, according to the species of the fungus and the nature of its soil, remain in aggregations forming heaps or masses, or may spread through the tissues. The bacteria may force their way into the substance of the constituent elements, and especially into the tissue-cells, which are sometimes found to be crammed with bacteria. The cells attacked by the fungi often appear quite uninjured, or they may be altered; the epithelial cells swell up and liquefy or degenerate into flaky, homogeneous lumps, or turbid, denucleated masses; often they break down into granular detritus; the nucleus is broken up, or swells and disappears; the fibrous elements of the connective tissue degenerate like the epithelial cells; the ground-substance undergoes a change at the same time, becomes turbid, loses its structure, and ultimately dissolves. The inflammatory process set up by

bacterial action may be of very different intensity and extent in different cases; it may be slight and transient, or it may be severe and terminate in suppuration and necrosis; occasionally a more or less perfect granulation-tissue is formed as a result of the inflammation. Again, this inflammation often results in a great aggregation of living cells in the affected tissue, and these may so act as to repel the continued advance of the fungi, which soon perish, and the result is healing and cicatrization. The fixed tissue-cells of the region may also act so as to check the development of the bacteria; if this happen the bacterial invasion continues to advance; they first enter the surrounding tissues, passing along the natural lines of division, then they break into the lymphatics, and often into the blood-vessels also. If they can live in lymph or blood they go on multiplying; if not, they perish; many bacteria, like the micrococcus of erysipelas, flourish best in the lymphatics; others, like the anthrax bacillus, are more at home in the blood.

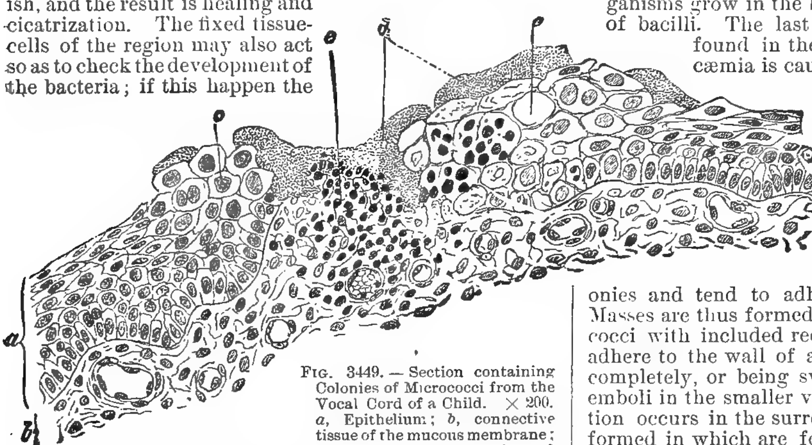

FIG. 3449. — Section containing Colonies of Micrococci from the Vocal Cord of a Child. × 200. *a*, Epithelium; *b*, connective tissue of the mucous membrane; *c*, swollen, degenerated, and denucleated epithelial cells; *d*, layer of micrococci; *e*, inflammatory small-celled infiltration of the degenerated epithelium and of the fibrous structures. (Ziegler.)

They reach the blood either through the lymphatics or directly; in the latter case the walls of the veins in the invaded region are penetrated by the micro-organisms, or they pass into the veins from the capillaries; once in the current they are carried on by it to remote parts; many perish in the blood, others again increase and multiply. Of the last some, as anthrax bacillus, thrive best in blood that is in motion; others, as tubercle bacillus and pyæmic micrococcus, prefer blood that is at rest, and only grow when they come to a standstill in some venule or capillary. The tissue changes are the slightest in the case of bacteria which circulate and multiply in the blood (Fig. 3450). Bacteria which settle in the smaller vessels give rise to various forms of degeneration (Fig. 3451), necroses, inflammations, and hæmorrhages.

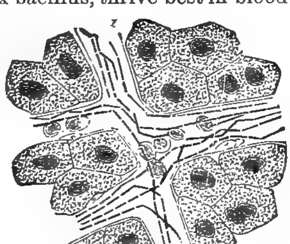

FIG. 3450.—Micro-organisms in the Circulating Fluid. (Ziegler.)

The Nature of Septicæmia and Pyæmia.—The application of these facts to the explanation of the symptoms of these affections has been variously made by writers. This difference of opinion is due to the inherent difficulty of accurately determining the nature of the symptoms and pathological conditions which exist, their order of sequence, and the ultimate relation of micro-organisms to these obscure phenomena. The tendency now evidently is to regard both septicæmia and pyæmia as diseases having many forms. Cheyne remarks: "Septicæmia is a complicated affection, and probably arises under several circumstances; continued absorption of the poisonous material from wounds will keep up a feverish state with all the symptoms of septicæmia, and if long continued may terminate fatally; in other cases the micrococci grow in the tissues of the wound, and pour their products or ptomaïnes, as they are called, into the blood; here micrococci may be found in the blood, but the essential seat of disease is the tissues. In a third form micrococci grow in the blood, and multiplying there, give rise to the symptoms. In a fourth form organisms grow in the blood, but they belong to the class of bacilli. The last two cases correspond to what is found in the lower animals. In them septicæmia is caused by more than one form of organism growing in the blood, and giving rise to symptoms and post-mortem appearances which can only be classed together as septicæmia."

Pyæmia in rabbits (Koch, Cheyne) has been shown to be due to the growth of micrococci in the blood. These cocci are very minute; they grow in colonies and tend to adhere to the red blood-corpuscles. Masses are thus formed composed of colonies of micrococci with included red corpuscles. These masses may adhere to the wall of a blood-vessel, grow and block it completely, or being swept on in the circulation, form emboli in the smaller vessels. In either case inflammation occurs in the surrounding tissue, and an abscess is formed in which are found numerous micrococci. The inoculation of another animal with the pus from these abscesses, or of the blood containing the micrococci, is followed by the reproduction of the disease.

Koch employs the term "traumatic infective diseases,"[7] and states that he applies it to "a group of affections formerly known as traumatic fever, purulent infection, putrid infection, septicæmia, pyæmia, but which were included at a subsequent period (when the view became generally accepted that these diseases were essentially of the same nature) under the title 'pyæmic or septicæmic processes.'" The similarity of the two affections is noticeable in the fact that, though pyæmia was alone thought to be characterized by metastatic abscess, yet a more careful study showed isolated, microscopic, metastatic deposits in cases which had all of the characteristic symptoms of septicæmia. Birch-Hirschfeld defines septicæmia to be a disease due to alterations of the blood, as the result of the absorption of the products of putrefaction; while pyæmia is due to a general infection derived from the surface of a wound or from a centre of primary suppurative inflammation, caused, probably, by micro-organisms and not by putrid infection.

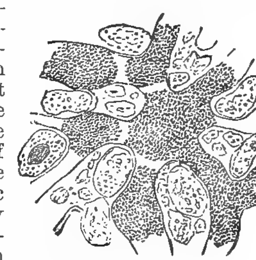

FIG. 3451.—Micro-organisms in Stagnant Blood. (Ziegler.)

Billroth's definitions are, in general, more useful for clinical studies. He remarks ("Surgical Pathology"): "By septicæmia we understand a constitutional, generally acute disease, which is due to the absorption of various putrid substances into the blood, and it is thought that these act as ferments in the blood, and spoil it so that it cannot fulfil its physiological functions." "Pyæmia holds the same relation to simple inflammatory and suppurative fever that septicæmia does to simple primary traumatic fever; it is symptomatologically characterized by intermittent attacks of fever, and in its pathological anatomy by the frequency of metastatic abscesses and metastatic diffuse inflammation."

The Committee of the Pathological Society of London, in their report on the nature and causes of those infectious diseases known as pyæmia, septicæmia, and purulent infection, accept the conclusion that there are two distinct forms of septicæmia. One form occurs when putrid blood is injected subcutaneously, no organisms ap-

pear, and the disease cannot be transmitted by inoculation; this is septic intoxication. In the other form the poison has been injected, and organisms appear abundantly in the blood, and are very virulent. The committee make ten groups of pyæmia, viz.: 1, Pyæmia secondary to an open wound, but without evidence of embolism; 2, venous thrombosis as a secondary affection; 3, venous thrombosis and softening of thrombus without embolism; 4, venous thrombosis and softening of thrombus with secondary abscesses in other viscera, but not in the lungs; 5, venous thrombosis with softening and abscesses in the lungs and other viscera; 6, venous thrombosis, softening of thrombus, and embolic abscesses in the lungs; 7, pyæmia secondary to infective periostitis; 8, pyæmia secondary to infective endocarditis; 9, infective myositis; 10, spontaneous septicæmia and pyæmia.

Symptoms.—The symptoms in well-defined cases of septicæmia and pyæmia following wounds, are accurately given in the extracts from Billroth's work. The chief distinction there made between these two forms of wound complication is based upon the pathological conditions long since established, viz., the existence (pyæmia) or non-existence (septicæmia) of multiple abscesses. This distinction is undoubtedly still the most convenient and most accurate in practice, as the symptoms vary in no small degree according to the presence or absence of this element in each case. For practical clinical purposes the relations of these wound complications have been clearly set forth by Billroth in the illustrative cases quoted at the commencement of this article. To those cases, therefore, we refer as embodying the order of symptoms of those "general accidental diseases which may accompany wounds and other local inflammations."

Diagnosis.—The diagnosis of septicæmia and pyæmia, when these affections develop in regular order after wounds or injuries, is not difficult. They may, however, occur under circumstances which render the diagnosis very difficult, and this is especially true when there has been no antecedent wound. The symptoms are often so masked as to lead the observer quite astray. The diseases which are most liable to be taken for both of these affections are enteric fever, typhus, inflammation of the kidneys and bladder, acute rheumatism, etc.

Wagner ("On Occult Septicæmia," *London Medical Record*, February 15, 1882) regards septicæmia as much more frequent than is generally believed. He is of the opinion that, in consequence of ignorance of its symptomatology, many cases are overlooked. He formulates its symptoms thus: 1. The general condition is serious; there is a febrile state, suddenly apparent, rarely preceded by a regular rigor, but attended with much shivering, and very often with severe rheumatoid pains of the bones and joints. 2. The patient experiences so much discomfort that he is obliged to take to his bed at once, or, at the latest, after some days. 3. There is violent fever of the remittent or intermittent type, but always irregular; the exacerbations usually assume the aspect of a severe rigor. 4. The pulse is very frequent, usually dicrotic. 5. There is frequency of respiration, which cannot be explained by the mere elevation of the temperature, and which, in the majority of cases, is connected with serious affections of the lungs or pleura. 6. There is hypertrophy of the spleen, with scarcely any appreciable increase in the size of the liver. 7. There is more or less marked abdominal meteorism, often accompanied by intestinal borborygmi, occasionally by frequent fluid stools. 8. There is moderate albuminuria, rarely tube-casts or blood-corpuscles in the urine. 9. There is a pustular or papular cutaneous exanthem, with a hæmorrhagic basis. 10. Icterus is rarely intense. 11. Subjective and objective symptoms are met with in the large articulations and the long bones, especially rheumatoid pains, occasionally attended with swelling or redness of the joints. 12. Serious cerebral symptoms occur, such as delirium, convulsions, and coma. 13. The progress of the affection is rapid. 14. Medicinal treatment by quinine, the salicylates, etc., is unsuccessful.

The affections with which septico-pyæmia may be confounded are more especially typhoid fever, of which the progress is very much less rapid and less tumultuous, and which is never accompanied by icterus or by an exanthem similar to that described, nor by joint lesions; miliary tubercle, which it is almost impossible to diagnose; and epidemic cerebro-spinal meningitis, which presents, perhaps, still greater difficulties, since the rapidity of the progress and the presence of an exanthem can no longer be considered as means of diagnosis. The question is still further obscured by the fact that the wound does not always exist, and that in place of it there may be internal suppuration, necessarily overlooked because it does not give rise to any characteristic symptoms. In a certain number of cases it has been impossible to find any starting-point, notwithstanding the certainty that pyæmia existed.

Wunderlich, in 1857, described some cases as primary pyæmia; Schutzenberger also spoke of cases of this kind, and recommended careful examination of the scalp in cases of acute fever. Cases of pyæmia without any discoverable lesions have been reported (Cavafy, Whipham, Dickinson, *London Lancet*, June 26, 1886). In three cases autopsies were made and multiple abscesses were found, but no lesions were discovered through which the poison could have entered the system.

Treatment.—The discovery of the etiological relations of micro-organisms to suppuration opened a new and most important field of inquiry. The question now arose, can these germs be destroyed without complicating the wound, and, if so, what is the most useful agent? In determining this question we must acknowledge the great services to practical and scientific surgery of Sir Joseph Lister. We would not detract from the merits of a long line of earnest students who so faithfully labored in this field of experimental pathology, many of whose works were so often apparently unproductive. Even their errors often led to new and more successful efforts, and hence added, though indirectly, to the total sum of knowledge necessary to the final, complete elucidation of this most obscure subject. But in these later times no one has so intelligently and so perseveringly striven to apply the knowledge gained as to the correct etiology of septicæmia and pyæmia, and as to their prevention.

The methods of preventing these diseases are fully discussed in the article on Antiseptics, and need not be noticed here. When they do occur the treatment should be directed, first, to the entire removal of the source of putrid material, and second, to sustaining the patient's strength. It is now possible, by evacuating and cleansing abscesses, by the removal of carious bone, and by the disinfection of sources of putrid emanations, to remove at once the cause of both septicæmia and pyæmia.

SEVEN SPRINGS. *Location*, Washington County, Va. *Post-office*, Glade Spring, Washington County, Va.

Access.—By the Norfolk & Western Railroad to Glade Spring, thence two miles to the springs; or to Saltville, thence five miles to the springs.

Therapeutic Properties.—Their medicinal properties are tonic, alterative, diuretic, antiperiodic.

These springs, seven in number, are situated in Washington County, in the southern part of Virginia, amid the Blue Ridge Mountains, famed for their beautiful mountain scenery. The waters of the springs are evaporated, leaving the solid ingredients, which are bottled and sold throughout the country as "the Seven Springs Iron and Alum Mass."

Analysis (by J. W. Mallet, M.D., Chemist).—The mass appears as a stiff dough, or soft solid, of light gray color, and marked acid reaction to test-paper. The contents of several bottles having been thoroughly mixed, the follow-

ing composition was found for the mixture in one hundred parts:

Aluminium sulphate	15.215
Ferric sulphate (persul. iron)	4.628
Ferrous sulphate (protosul. iron)	0.412
Nickel sulphate	0.162
Cobalt sulphate	0.014
Manganese sulphate	0.257
Copper sulphate	0.008
Zinc sulphate	0.301
Magnesium sulphate	16.006
Strontium sulphate	trace
Calcium sulphate	17.538
Potassium sulphate	0.060
Sodium sulphate	0.226
Lithium sulphate	0.019
Ammonium sulphate	0.022
Sodium chloride	0.326
Calcium fluoride	trace
Calcium phosphate	trace
Silica	1.504
Organic matter	0.123
Water	42.938
	99.759

G. B. F.

SEWAGE, DISPOSAL OF. Under this heading will be considered not only the disposal of the contents of sewers, but also the other methods of disposing of the refuse products of households and communities.

In using the term "disposal" we may avoid confusion if we distinguish between immediate disposal, on the premises, of refuse matters as they are day by day produced, and the ultimate disposal by which they are rendered innocuous by utilization or removal, or both.

I shall describe, first, the methods employed for immediate disposal; secondly, those for ultimate disposal; and, lastly, shall compare the merits of the various systems and their relative adaptability to the needs and circumstances of cities, villages, and isolated houses.

I. The Modes of Immediate Disposal at present in use may be classified as follows:

1. The privy-pit and privy-vault.
2. Dry methods.
3. The water-carriage system, or wet method, as it is sometimes called.
4. Pneumatic systems.

1. Privy-pit and Privy-vault.—It is hardly necessary to describe the privy-pit system, if indeed we should apply the term "system" to such a crude and barbaric device as an excavation in the earth for the reception and storing of filth. I shall endeavor to do a certain measure of justice to its demerits and their results in their appropriate place, in the last division of this article.

In the privy-vault a slight improvement is made on the pit by placing in the excavation a water-tight cask, tank, or receptacle, made of cement, masonry, or other material. By these means it is intended to prevent soaking of the filth into the soil, but the receptacle often becomes leaky.

In places where these pits and vaults are allowed to exist removal is effected in various ways, the most primitive being by carts, sometimes with a boarded cover, sometimes with a layer of ashes or earth spread over the night-soil. In other places removal is made by means of some form of "Odorless Excavator." These machines act on the principle of the exhaust-pump: the contents of the privy or cesspool are drawn into a tank upon wheels; or they may be transferred to detached barrels, thus obviating the necessity of keeping the pump idle while the night-soil is being conveyed away, and also affording greater facility of transportation. The apparatus for the latter is more complicated, of course, than that of the "tank" method; from a description of this barrel-system (Fig. 3452) the principle of the other may readily be understood. The small hand-pump seen in the foreground is for alternately exhausting and compressing (as may be required) the air in the pump-receiver *B*. The little furnaces *H* and *L* are for deodorizing the air displaced from *B* and *O*, respectively. These latter are strong oak casks. The suction hose, *C*, is lined with a spiral, flat, galvanized iron or brass coil to keep it from collapsing, should anything obstruct its lower end during the process of exhausting the air from *B*. The following extract from Ames' description of the "Eagle Odorless Excavating Apparatus," will explain its other parts and mode of action:

"Lift the gate *a*, on pump-receiver *B*; see that the lower gate *b* is shut tight. Work the brakes, when the air will be exhausted from the receiver via the throat-valve opening and air-hose, *f v*. The contents of the vault will at once rise through the suction-hose, *C*, into the receiver, till the material lifts the cork float-valve and stops the pump, the receiver being full. Instantly shut the upper gate, *a*. The foul air exhausted from *B* has passed through the pump and short air-hose, *k*, under the fire to the deodorizer *H*, and is consumed.

"To transfer the material to the barrels or tank on the wagon, uncouple the end of air-hose, *G*, from the suction-spud of the pump. Remove the free end of air-hose, *k*, from the throat of the deodorizer, and couple the ends of *k* and *G* together.

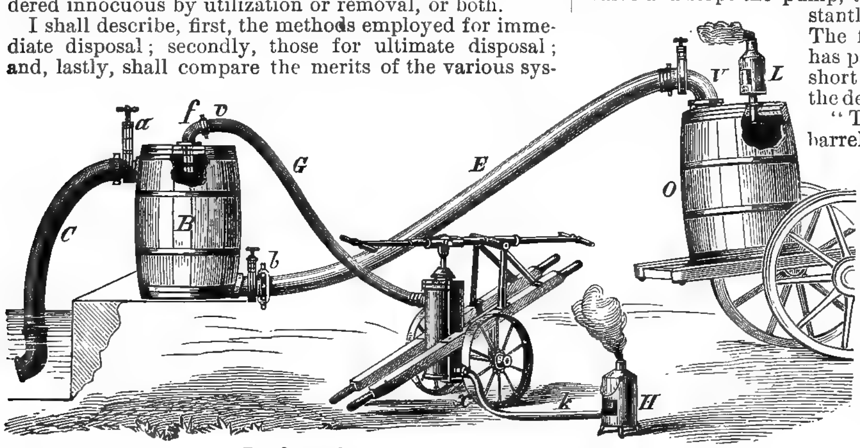

Fig. 3452.—Odorless Excavator Barrel System

"Have goose-neck valve *V*, on the wagon-barrel, lifted. Lift lower gate, *b*, on receiver, and work the brakes, when the compressed air, driven in at the top of the receiver, will rapidly force the contents through the leading hose into the wagon-barrel. When the wagon-barrel is full, its float-valve will be lifted, and the roar of the wagon-deodorizer, *L* (which has consumed the foul air forced from the barrel), will cease. The goose-neck valve, *V*, and deodorizer, *L*, may now be coupled with the next wagon-barrel, and the process resumed as described. If a long line of leading hose is used, it will be necessary to reserve one wagon-barrel for its contents, or it may be returned on itself, and the contents discharged into the vault."

A method which is in operation in some places is to fill a strong metal cylinder with steam; this condenses on the way to the scene of operation, creating a vacuum; one end of a hose is attached to the cylinder, the other being lowered into the vault; a valve in the coupling of the cylinder and hose is now opened and the contents of the vault are drawn into the cylinder.

In another method a vacuum is produced by the revolution of the wheels of the wagon on its way to the vault which is to be emptied. This method is in use in Chicago.

It is nearly always necessary to complete the emptying by means of the shovel, owing to the presence of sticks, tin-cans, or other rigid bodies. It would be desirable, also, to cleanse the besmeared surface of the vault with a solution of corrosive sublimate or other deodorant.

2. Dry Methods.—These may be divided into (*a*) the dry-earth and dry-ash systems; (*b*) the various midden systems; (*c*) the pail systems; (*d*) dessication.

(*a*) *In dry-earth and dry-ash systems*, dry earth or dry ashes are mingled with the fæces in sufficient quantity to absorb all moisture from them, to render them inodorous and to prevent decomposition. The earth should be well dried in the sun, or by artificial heat, and then stored in a dry place. It should contain no lumps, and it is better that it should be sifted or screened so as to form a very fine powder. The earth best adapted is a clay loam; sand and gravel are of no use for the purpose. All fluids, except the urine passed during defecation, must be excluded. A small quantity of earth should be placed in the receptacle to begin with, and earth should be added after each defecation. If a large quantity of fæces is allowed to accumulate before the earth is thrown in, the mass is more liable to noxious decomposition in its interior. Besides, the odor from the uncovered fæces is in the meantime very offensive, especially as the contents of the closet are generally above ground, an excavation being unnecessary and indeed objectionable, unless the expense of a water-tight vault is incurred for the purpose of excluding surface and subsoil water and moisture. Hence it becomes almost a necessity to the success of the system in a mixed community, and especially where there are children, that some automatic method of applying the deodorizer be employed. A good closet of this kind is one on the principle of the Heap patent, such as is shown in elevation in Fig. 3453, and in section in Fig. 3454, by which the working of the closet may be understood. The lid is shown half open; just beneath it is seen the hopper (H), made of galvanized iron and hung upon the pivot X; attached to the upper posterior part of the hopper is a weight (I) which keeps it in the position indicated by the continuous lines when the closet is not in use. The seat (S) is hinged to the riser in front, and to its posterior edge is attached the small wheel or roller (W); when the seat is pressed upon, this wheel, acting upon the inclined plane of the hopper, forces it back to the position indicated by the dotted lines. When the pressure is removed the hopper flies forward, striking the buffer (R), and in this way a quantity of earth is thrown and scattered in the receptacle (P). The weight (I) assists in throwing the hopper forward. A "urine separator" may be attached for the purpose of keeping the contents of the pail as dry as possible. This attachment is not to be recommended: even though a disinfectant be placed in the urinal the latter may become offensive, and the separate vessel is unnecessary if a sufficient quantity of earth is used.

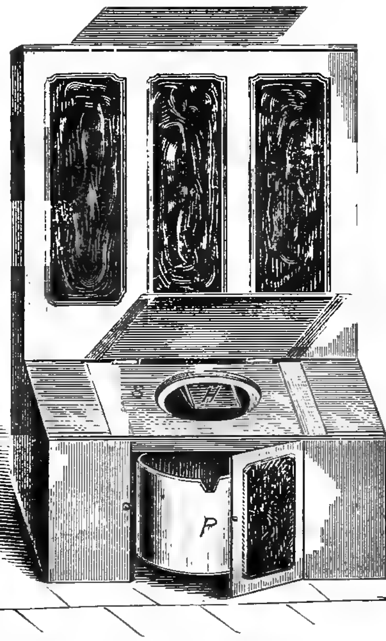

Fig. 3453.—Heap's Dry-earth Closet. Elevation.

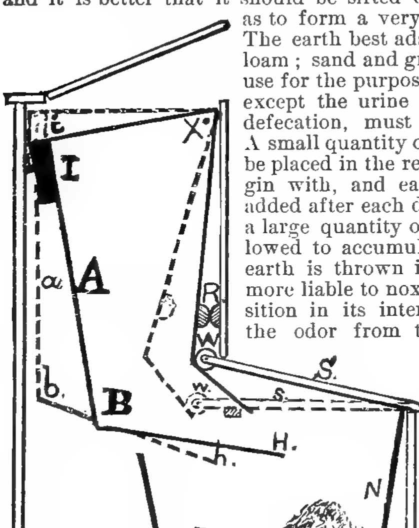

Fig. 3454.—Heap's Dry-earth Closet. Sectional view.

In the case of adults regularly employing a dry-earth closet, a simple contrivance will answer, such as that represented in Fig. 3455, which shows the excrement tub, B, beneath the seat, and the other tub, A, holding dry earth or ashes, which are applied by means of a scoop. The hinged door, C, permits the removal of the pails. It might for some reasons be preferable to do without this door, and to remove the pail through a hinged seat.

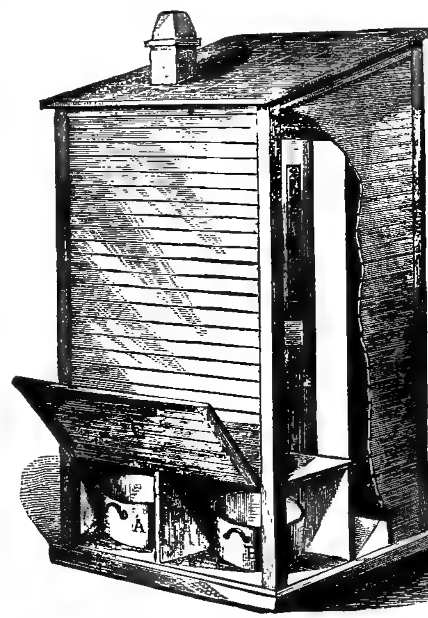

Fig. 3455.—Simple Form of Dry-earth or Dry-ash Privy.

Before leaving this subject, reference must be made to the closets invented by the Rev. Henry Moule, M.A., of Fordington, Dorset, England, to whom is due the credit of introducing the system of dry-earth closets, and who has experimented largely with them. The mixture of earth and excrement undergoes a species of dry fermentation, and should be kept dry till this takes place, a period of some six weeks being required; otherwise the contents of the closet must be removed to some place where they can be utilized without offence. If kept till the process of fermentation has taken place, the product may be used again and again with the same result. The amount of earth required is variously estimated, the average being about a litre, or one and a half imperial pint per head *per diem*. Most authorities consider that finely

sifted coal ashes answer almost as well as earth ; some think that they do not prevent the occurrence of offensive fermentation. In my own somewhat limited observation I have found them answer very well. Charcoal, made from burning street-sweepings and sea-weed, is said to be very useful, and to answer the purpose in smaller quantity than earth.

In some places so-called dry-earth closets have brought the system into disrepute by faults in the management: the earth not being dry and fine, its deodorizing and anti-putrefactive properties have been lost ; or the hopper becomes clogged ; or the receptacles are down below the ground-level and are not kept dry ; or slop-water is thrown in ; or there is neglect on the part of the corporation in providing dry earth and in seeing to the removal and storing of the product.

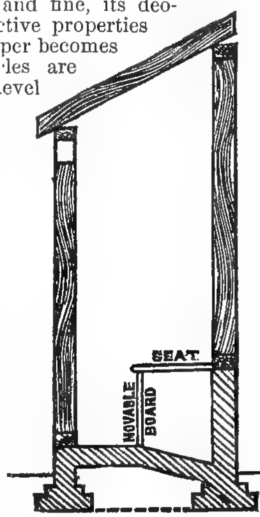

Fig. 3456.—Hull Ash-closet.

The invention of improved cinder-sifters has done much to render more easy the use of the dry-ash closet system, and it has also lessened the amount and improved the quality of the resultant products of the next system to which we have to refer.

(*b*) *The Midden System.*—Included under this system are several kinds of closets or vaults, which have taken different names, generally from the places in which they have been used. They differ somewhat in details, but have the following features in common : ashes, garbage, excrement, dust, waste-paper, and all household refuse, except slop-water, are thrown into a water-tight receptacle, from which the contents are removed at short intervals by scavengers. Fig. 3456 represents a section of the Hull ash-closet. The floor, back, and ends of the receptacle are of brick or masonry laid in cement. The refuse is thrown in through the hole in the seat. In front is a movable board, through which the contents may be removed by the scavenger's shovel and broom. A useful modification would be to hinge the seat at the left-hand end. I have recently been informed that this is often the case in Manchester. That city presents some of the transitional stages from the Midden to the "pail system." Fig. 3457 represents a mode by which the ashes are thrown into a movable receptacle as they are sifted, the cinders being kept for fuel.

Fig. 3457.—Manchester Cinder-sifter and Excrement-tub.

(*c*) *The Pail System.*—In this system pails or small tubs are placed beneath the seat ; and, as a rule, nothing but excrement is placed in the pails. Frequent removal takes place —in Rochdale once a week.

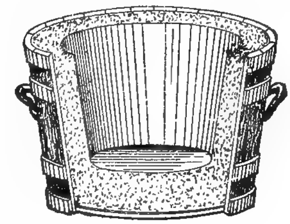

Fig. 3458.—Goux System : Pail lined with Absorbent.

A wagon, made airtight by rubber joints, takes away the full pails, fresh ones being left in their stead. The pails are provided with tight double lids. In some places they are strong, iron-bound wooden pails, or half-casks ; in others they are made of galvanized iron.

This system is principally in use in cities far removed from agricultural districts, and where the contents must be made into *poudrette* or artificial manure, and must, therefore, present a strong fertilizing power in small bulk.

In the Goux system, however, a slight departure is made, the pail (Fig. 3458) being lined with a slightly absorbent material, which, according to the trade circular of the Goux Company, may be composed of "stable litter, leaves, spent tan or hops, sawdust, shavings, shoddy, flax-dressings, or the thousand-and-one convenient substances to be found in every place." With the above a little charcoal, soot, gypsum, or other deodorant may be mixed. A little of this filling is placed in the bottom of the pail, the mould (Fig. 3459) is set upon it, and the interspace packed. It is stated that a boy can fill a hundred pails in an hour. When the pail is removed any filling projecting above the rest of the contents is broken down to cover the excrement.

Fig. 3459. — Goux System : Mould used in Lining-pail.

The Nottingham system differs still more widely, and resembles the Midden system, inasmuch as the ashes and other refuse are allowed to be thrown into the tubs. The reason assigned is that Nottingham is in an agricultural district, and bulky manure can be utilized. When the health officer has been notified of the existence of infectious disease in a house, a red tub is sent containing a germicide.

In all the above dry methods the closets require provision for ventilation.

(*d*) *Desiccation.*—I use this term to designate a method lately introduced, by which a continuous stream of air is made to pass over the fæcal contents of a trough or long vault beneath a series of closets. The method may be readily understood by a reference to the accompanying cut (Fig. 3460) of part of a section of a building ventilated by the process of the Smead-Dowd Company of Toronto. The foul air drawn off from the building is made to pass through the closet vault on its way to the foul-air chimney. The fæces are so dried that they may be handled without any danger of soiling the fingers. The system is in operation in several places in the States of Pennsylvania, Ohio, Iowa, Wisconsin, New York, and in the Province of Ontario, and it gives great satisfaction. The small heater seen at the base of the foul air chimney is for use on muggy, heavy days in summer, the furnace not being in operation. Ventilation of the closets is efficiently secured, the air being drawn through the seats.

It should be noted that in all the dry methods separate provision must be made for disposing of the bedroom, kitchen, and laundry slops.

3. The Water-carriage System.—This has already been considered, so far as it relates to the interior of houses, under the headings Habitations, General Principles of House Plumbing, and will be further treated of in the article Sewerage, the ultimate disposal only of the contents of sewers being taken up in this article.

4. Pneumatic Systems.—Under this heading are to be included (*a*) the Liernur system and (*b*) the Berlier system. The Shone system is sometimes called a pneumatic system, but it is really a mode of pumping, in connection with the water-carriage system, and will be referred to in the article Sewerage.

(*a*) *The Liernur system* is the invention of Captain Liernur, a Belgian engineer. A large steam air-pump exhausts the air in a set of central reservoirs, and in the air-tight iron mains which connect these central reservoirs with smaller ones under the sidewalk crossings in the streets (Fig. 3462). These latter are visited daily. By means of a key a valve is opened in the pipe leading from the street reservoir to the central reservoir, and the air in the former being thus partially exhausted, the valve is closed, and another valve, in the pipe leading (by its branches) to the houses, is opened. This operation having been repeated several times, the sewage matter contained in the drains and in the traps at the bottoms of the soil-pipes is drawn into the street reservoir, and thence to one of the central reservoirs. From these latter it is raised, also by a vacuum process, into tanks "hermetically sealed." From these it may be drawn into air-tight barrels and taken to the country for direct application to the land, or converted into *poudrette* or artificial manure. The main pipe connects with the street reservoir by two branches, one at the top of the reservoir, by which the air is exhausted, the other reaching nearly to the bottom, by which the sewage is drawn out. Some of the closets are supplied with a mechanism by which a small quantity of water is supplied at each using; but most of them have no water-supply, the hoppers being so constructed that no droppings are supposed to touch their sides in falling to the trap; these closet-traps are never emptied, the main soil-pipe being open at its upper extremity. It will be evident that it would be impossible to draw the contents of the pipes out by suction, unless the whole bore of the pipe were filled at certain points. This is done at intervals by making an upward grade, through which the sewage is drawn, and then it runs down to the next rise. The effect is similar to that of suction on a siphon-trap, or series of siphon-traps.

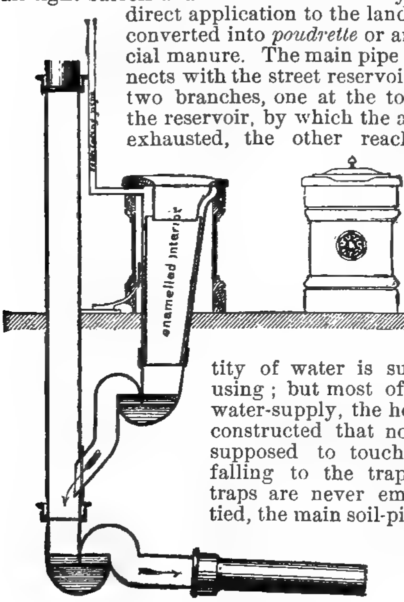

Fig. 3461.—Liernur Pneumatic System: Closet, Soil-pipe, and Commencement of Drain.

(*b*) *The Berlier system* receives its name from its originator, M. J. B. Berlier, and is employed in Paris.

In it there are no street reservoirs, their place being

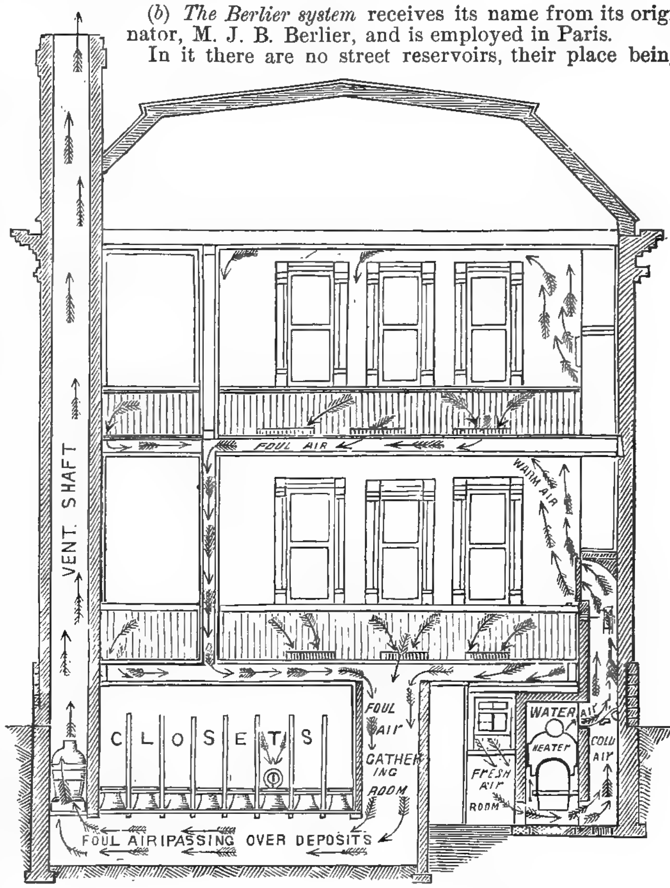

Fig. 3460.—Smead-Dowd System of Closets.

taken by a tank and evacuator in each building. The emptying of the latter is automatic. The soil-pipe empties its contents through the top of the tank (Fig. 3463), which contains a strainer for intercepting cloths and other large articles which might obstruct the pipes. The presence of these may be detected by means of an axle, on which are fixed arms, or "beaters," and which can be revolved from the outside. These beaters also serve to break up masses of fæcal matter lodged on the strainer. Obstructions may be removed through a door in the tank. From the tank the sewage passes into the evacuator. The bottom of the latter is conical, and communicates with the pneumatic tube, the opening between the two being closed by a rubber ball when the evacuator is empty. This ball is attached to a large, pear-shaped float, which rises when the fluid in the evacuator reaches a certain height. When the float and ball rise, the fluid rushes from the evacuator into the pneumatic tube. The float works up and down on a vertical rod, and so, as the fluid rushes out, the ball again falls into its place. There is now no further obstruction till the sewage reaches the central reservoir, or vat, in which the pneu-

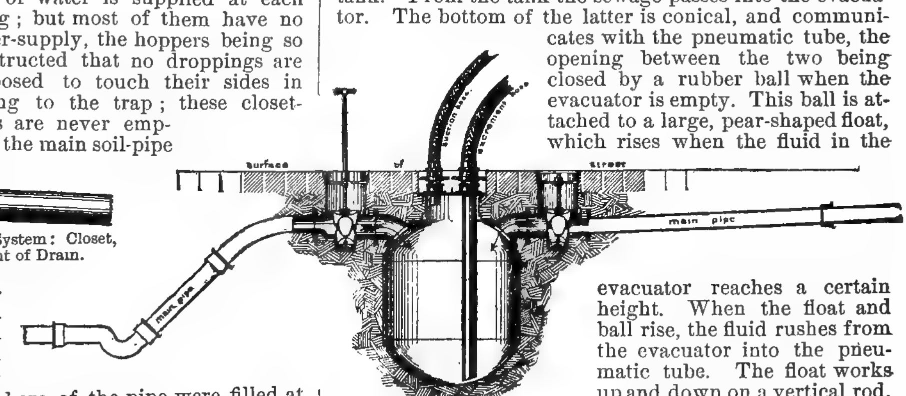

Fig. 3462.—Liernur Pneumatic System: Street Reservoir and Pipes leading to and from it.

matic system terminates. The pneumatic pipes from the houses and in the contiguous streets are ten centimetres (four inches), and the main pipe is fifteen centimetres (six inches) in diameter. From the vat the sewage is forced, by a rotary pump, into the river for the present; but eventually it is intended to utilize it in some adjoining country district. It will have been seen that the pneumatic action in this system is constant, and the emptying of the house-receivers automatic, the only dependence upon corporation servants being at the central pumping-station.

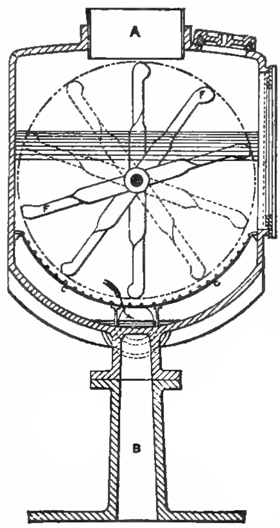

FIG. 3463.—Berlier Pneumatic System: "Receiver." A. Entrance of soil-pipe; B, stand; C. strainer; F, arms revolving on axle (E); the arrow shows pipe for passage of sewage to the "evacuator."

It may here be noted that these pneumatic methods, like the dry systems, do not provide for the disposal of domestic, kitchen, and bedroom slops, the object being to obtain the excrement in concentrated form for utilization. Further reference to their disadvantages and to any reasons which may be advanced for their existence, will be made when we come to compare the relative merits of the various systems, after considering the modes of ultimate disposal.

II. ULTIMATE DISPOSAL.—At the outset it may be stated that, as a rule, no system of sewage disposal will yield a pecuniary profit, although in a few exceptional cases such a result is claimed—as, for example, at Pullman, Ill., and in some places on the continent of Europe. The plains of Gennevilliers, on the outskirts of Paris, have, by the employment of sewage, been transformed from sandy wastes into beautiful gardens, and the value of property has been greatly enhanced. But, as a rule, the highest result that is looked for is to gain as much as will reduce to a minimum the cost of ridding a community of its waste products, which, if not properly disposed of, would produce an increase of sickness and mortality.

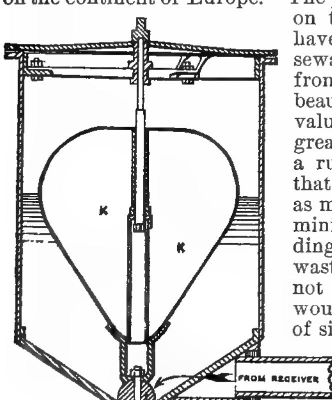

FIG. 3464.—Berlier System: "Evacuator." K is a pear-shaped float, which on rising carries the ball I, and allows the sewage to rush through the discharge-pipe J, into the pneumatic tube below; the arrow indicates the other end of the pipe shown by an arrow in Fig. 3463.

In the case of manufactories it sometimes happens that neglected waste products may be converted from offensive nuisances into substances of commercial value.

In order to simplify and condense our consideration of ultimate disposal, we may classify refuse products as follows:

1. Concentrated excreta, or night-soil, which has not undergone any artificial change, and which has resulted from the adoption of the privy-pit, privy-vault, pail, or pneumatic systems.
2. Garbage.
3. Dry-earth and dry-ash products.
4. Liquid sewage.

1. THE MODES OF DISPOSING OF NIGHT-SOIL are (*a*) direct application to land; (*b*) manufacturing into artificial manure; (*c*) cremation; (*d*) carbonization.

(*a*) *Night-soil is sometimes applied directly to the land.* This cannot be done without producing an offensive nuisance to persons residing in the neighborhood, and it is difficult to find an uninhabited place near enough to the community from which the night-soil is removed. "Sanitary agents"—this is one of the recent euphemisms—will frequently annoy a rural neighborhood till the nuisance and the deterioration of health are no longer tolerable, and the arm of the law is invoked with sufficient pertinacity to put a stop to their proceedings.

On the outskirts of large cities where there are extensive market-gardens, cesspools are sometimes built, the night-soil is mixed with fluid and applied to the soil in which are growing plants. Sufficient care is not always exercised in the mode of application, and, in case the plants are ready for market, this may give rise to unpleasant and baneful results.

(*b*) *The manufacture of dry artificial manure.* This may be effected by drying the excreta and resolving them into a powder, as, for example, in Amsterdam, where the Liernur system is employed, and *poudrette* is manufactured by the aid of superheated steam and special machinery. Or the excrement may be mixed with other substances before drying, as in Rochdale, where the pails are emptied into trenches containing ashes, the drying being hastened by the addition of sulphuric acid; or in Birmingham, where one of General H. Y. D. Scott's processes is employed, namely, adding to the contents of the pails magnesia, distilling off ammonia, collecting it in sulphuric acid—forming a sulphate of ammonia—and then adding phosphoric acid. The solid residue is dried for manure. Heat from the burning of other refuse is employed in this process.

In Glasgow admixture of ashes and street sweepings takes place; the process will be described presently. Poudrette made from excreta alone cannot be stored with full confidence that it will remain innocuous. Fevers have been known to result from its storage and transportation, and these have sometimes presented typhoid characteristics.

(*c*) *Cremation* is another mode of disposing of night-soil. It is in operation in many places on this continent as well as in Europe, and among those where I have been informed by health authorities that it has given satisfaction, I may mention Montreal, Ont., and Des Moines, Ia. A description of these cremators or destructors will be more appropriately given presently, when we speak of the associated destruction of garbage.

The dried excreta resulting from the use of the Smead-Dowd system may be readily burned on the spot. Iron caps are provided for the closet-seats, with a shallow rim coming down past the wooden seat. The whole thus becomes an iron vault, and a small fire being kindled at one end, the contents of the vault are quickly burned out. Or they may be raked out and thrown into the heating furnace. They may, of course, be carted away without offence and used on land.

(*d*) *Carbonization* is the term employed to designate a process with which the names of Mr. Hickey, of Bengal, Mr. Stanford, and, later, Mr. Fryer, of Manchester and Nottingham, have been connected. Fryer's patent method has been used in Manchester. The dry refuse being taken to the works along with the pails, the contents of the dust- and garbage-carts are sorted in a manner similar to that employed in the more recent works at Glasgow presently to be described. The coarser portions are burned in the destructors, while all suitable material is, by the heat from the destructors, reduced to charcoal in revolving cylinders, called carbonizers; and in a third set of chambers, called concretors, the excreta, mixed with a little sulphuric acid, are resolved into artificial manure, a small quantity of carbon from the carbonizers being sometimes added.

2. GARBAGE.—As a typical example, conveying much useful information regarding some of the recent modes of disposal of refuse, I propose to describe the system adopted at the works lately set in operation at Crawford

Street, Glasgow. I may premise by saying that in Glasgow they are by degrees abolishing the pit and vault of former days, that the number of water-closets is increasing, and that in addition the pail system is in use. The works at Crawford Street present some improvements on similar works established a few years ago in the same city.

I quote from the remarks of Lord Provost McOnie at the opening of the works: "All the carts on entering are weighed. Any material, such as stable manure, which requires no manipulation, is carted straight into the middle floor, where closed hatches are provided for simply shooting it into the railway wagons. All the general city refuse, which is composed of (1) contents of ash-pits and bins, (2) excreta, and (3) street sweepings, is taken to the top floor, where special provision is made for each variety. The contents of ash-pits and bins are shot into revolving screens of new design. Each screen (making fourteen revolutions per minute) has a double action, and, although in one piece, is practically a screen within a screen. By the first action upon the inner mesh, sloping from west to east, all the rougher rubbish which will not pass through a one and one-third inch opening is separated and delivered on a travelling carrier at the east end of the screen; and by the second action upon the outer mesh, sloping in the opposite direction, the material which has passed through the inner mesh travels back over the one-half inch outer mesh. The material—chiefly cinder—which passes over this one-half inch mesh is delivered at the opposite end of the screen from the rubbish, and is thereafter passed down a shoot to the front of the boilers, where it is used as fuel and serves to raise steam for the works. The fine ash and smaller manurial particles fall through both meshes of the screen, and thence down a shoot into the mixing machines, which stand upon an elevated platform, on the floor immediately below. Into these mixers there passes at the same time a mechanically regulated quantity of excreta. The carts and vans in which this material is collected also ascend to the top floor, where the contents are passed through gratings into closed cast-iron tanks, which rest on the second floor, and from which, by a simple mechanical arrangement, the desired supply is allowed to escape into the mixers along with the fine ash, which absorbs and deodorizes it. In order to fix the ammonia and further deodorize the compound, provision is made for adding sulphuric acid, or other disinfectant or deodorant, to the excreta in the tanks." The other material which is shot into the mixer is the more concentrated detritus from the paved streets of the city (the sweepings and scrapings of the macadamized streets being sent off to a heather swamp which is being reclaimed). It is also taken to the top floor, passed, if wet, through drainage tanks, and then added, in certain proportion, to the compound already described in "the mixing machines, whose revolving blades thoroughly mix the whole into a deodorized compound, which is delivered into the railway wagons direct, and the farmers are supplied with a prepared manure in good condition for spreading on the land. The rough rubbish, it has been observed, is delivered by the inner screen on a travelling carrier. This is an endless web of iron plates on pitched chains, which is made to travel thirty feet per minute. Women are stationed in front of it to pick off anything which can be sold or utilized. One picks off, first of all, what is manurial, such as dirty straw, pulsy matter, vegetable refuse, etc., and this garbage she drops down a shoot by her side to the wagon direct, where it gets mixed with the compound as it comes from the mixer. The other materials picked off for use are old iron, old boots, meat tins, rags, paper, etc. The remainder is shot from the carrier into a specially constructed cremating furnace, where it is reduced to cinders, which are, of course, innocuous, and, like common furnace ashes, go to make roads or fill up ground. [In some places they are ground up for mortar and sold.] The various articles of garbage above referred to are mostly sold to persons who can make use of them. Old iron goes for precipitating copper; ammonia is extracted from old boots; solder is taken from meat tins, and so on." There are four sets of rails running inside the building, with a trav-

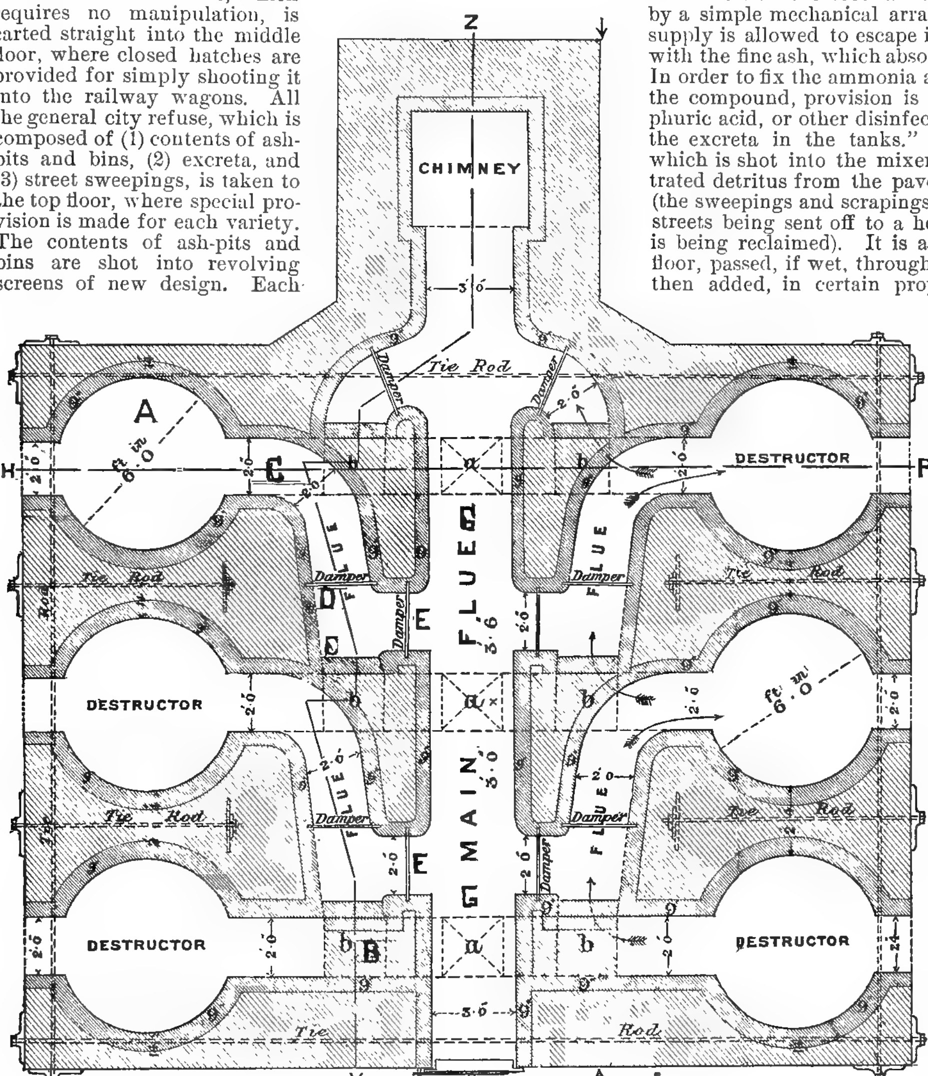

Fig. 3465.—Beehive Destructor: Plan through Line S T of Fig. 3466.

erser for shifting wagons from one to the other; all traversing and hauling are done by steam-power. A large exhaust-fan carries off foul air and sends it through the furnace-fires. Lavatories, baths, and eating-rooms are provided for the work-people. One great feature of this establishment is that nothing capable of decomposition is left on the premises for twenty-four hours.

Of refuse crematories, or destructors (as they are mostly called to distinguish them from *incineraria*), there are already many varieties. In the most successful it is claimed that little or no fuel is used, except to start the fires, but that, on the other hand, the heat from the burning refuse is used in destroying night-soil, furnishing motor power, ventilating sewers, etc. One that has been long and extensively used is the Bee-hive Destructor of Mr. J. E. Stafford, A.M.I.C.E., of Burnley, Lancashire, England, for which there are agents in America. There may be used either a single cell-destructor, or one of many cells, the latter being the most effective, the heated gases from one cell being carried over to the next—contributing heat and giving up to destruction the noxious vapors. A destructor with six cells is shown in Fig. 3465, the plan being taken just below the grates, on the line *S T* of Fig. 3466. Fig. 3466 shows a vertical section through two opposite cells on the line *H P* of Fig. 3465. Fig. 3467 is a vertical section through the zigzag line *Y Z* of Fig. 3465, and shows the flues leading from the upper surface of one fire to the lower surface of the next, and from the last fire to the chimney.

Fires being lighted on the grate-bars *K*, carts are driven to the shoot *J* (Fig. 3466), down which the garbage is dumped; sliding down the refuse chamber *B*, where it becomes somewhat dried, it reaches the combustion-chamber *A*. When the fires are first started, or when from any other cause there is a poor draught through the flues *C, C* (Figs. 3465 and 3467), the dampers *D, D, D* (Figs. 3467 and 3465) may be shut, and *E, E, E* opened (Fig. 3465), and the smoke will pass through the flues *b, b, b,* directly to the main flue *G*, and so to the chimney. When the fires are good and the flues *C, C* clear, the position of the dampers is reversed, and the vapors pass through the flues *C, C* and through the successive fires on their way to the main flue *G*. As in all crematories, the parts exposed to fire are lined with fire-brick.

The Engle Cremator "has been recently invented at Des Moines, Ia.; it contains two fireplaces, one at each end, and is so arranged that the gases of either can be passed through the other fire by a shifting of dampers. The bottom of the furnace is made of heavy iron plates, so set that they form a chamber beneath, through which the fire may pass on its way to the flue. Just above these plates

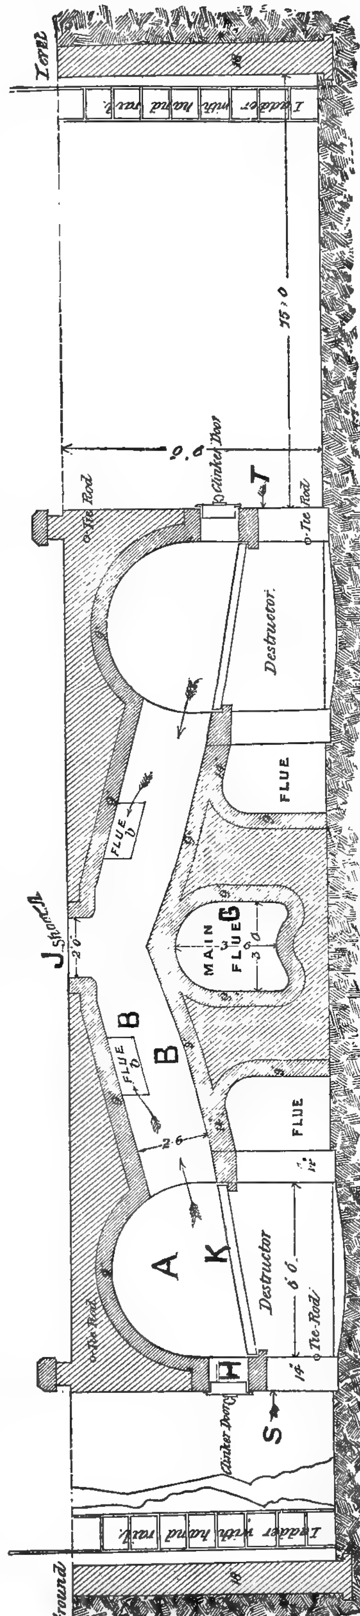

FIG. 3466.—Bee-hive Destructor: Section through Line *H P* of Fig. 3465.

there is a grating upon which the material lodges after it is dumped or thrown in at the top. The fires are so arranged that one will pass over the top of the material to be consumed, driving the gas forward and downward through the other fire, there inflaming all of the gases from the material, and using the heat to maintain the fires of the furnace, and at the same time rendering the escaping material [gas] from the flues inodorous and nearly transparent."

At Montreal, Q., garbage and night-soil are cremated in a furnace (Fig. 3468) of very simple construction, and the result is said to be very satisfactory. The furnace was planned by the City Contractor, Mr. William Mann. The grate is a little over sixteen feet long and nine wide, extending by a gentle upward incline from the fireplace at one end, where the fire is started, to the flue at the other end. The combustion-chamber is quadrilateral, a little over sixteen feet long, nine broad, and ten high. On each side of it are nine doors; three at its upper portion open out upon a stage on to which carts are driven, the refuse being put into the furnace through these doors; the next lower doors open just above the line of the grate, and are used for stirring the fire; the three lowest are at the bottom of the furnace, and are used for removing the ashes. Under the grate is a receptacle for water (not shown in the sectional cut, Fig. 3468). This may be varied in different furnaces, the object being to prevent over-heating and destruction of the grate. This latter consists of iron bars, their ends being laid on the brick, the inter-spaces between them being two inches. The flue is about twenty two inches long and eighteen wide—inside measurement. The chimney is ninety feet high. Among other furnaces may be mentioned the Rider Furnace, of Pittsburg, Pa., which has been but a very short time in operation, and of which, therefore, nothing very satisfactory can be said.

While there is no doubt as to the success of garbage-cremation, the various forms of furnace may be said to be still on trial, as the reader may have inferred from the above descriptions. It seems as though the best results would be obtained by cremating on a large scale, and maintaining a constant high temperature; by so arranging the furnaces that surface-heat may be utilized in drying material on its way to the fire; and by consuming the heated gases on their way to the chimney.

Individual householders can materially aid in the disposal of garbage. Vegetable matters, if carefully kept from grease and animal contamination, may be given to a horse or cow, if one is kept. In some cities and towns garbage is, to a great extent, burned by the householders. It may be prepared for burning in a receptacle fashioned something like a steamer used for cooking.

3. OF DRY-EARTH AND DRY-ASH METHODS nothing need be added to what was said in the section treating of immediate disposal.

4. LIQUID SEWAGE.—The modes of ultimate disposal are: (*a*) Emptying into tanks or cesspools; (*b*) discharging into some body of water; (*c*) irrigation; (*d*) filtration; (*e*) precipitation and deodorization.

(*a*) *Cesspools* are excavations in the earth into which sewage is allowed to flow. They are sometimes water-tight, and sometimes the sewage is allowed to percolate through the bottom. Their walls and roofs may be of wood, brick, masonry, or cement. Sometimes the walls are allowed to be pervious as well as the bottom. They are generally provided with an overflow, unless the soaking away of the sewage is fully insured. Old wells are occasionally turned into receptacles for sewage. In those rare cases where cesspools are allowable, they should be ventilated by a tall outlet, and shorter inlet, shaft.

(*b*) *Discharge into some body of water.*—This is the mode which has been generally adopted and continued in each individual case, until it has caused a nuisance such that means have been taken to prevent it. So general had the nuisance become in England, owing to the density of population, that in 1876 the Rivers Pollution Prevention Act was passed, providing that no rivers or streams should be polluted through the admission of crude sewage. For years, both before and since that time, the question of sewage-disposal has engaged the attention of numerous parliamentary committees and commissions, and of many of the foremost scientific men. Some places, as, for example, cities situated on rivers like the Lower Mississippi and St. Lawrence, are so favorably situated that they are relieved from this difficulty; but in very many places on this continent it has become a very urgent and serious one, owing to the pollution of the atmosphere and of the sources of water-supplies; and it has given rise to commissions of inquiry, the reports of some of which form valuable contributions to the literature of the subject. Among them may be mentioned the reports of Dr. Charles F. Folsom, Mr. J. P. Kirkwood, C.E., and others, in the Annual Report for 1876 of the Massachusetts State Board of Health, and the later report (1884) of Mr. Samuel Gray, City Engineer of Providence, R. I.

In discharging into the ocean much difficulty has arisen from the action of tides, coupled with the fact that oxidation takes place far less readily than in fresh water (see Sewerage).

(*c*) *Irrigation.*—This consists in discharging the sewage upon or into the soil in such a way that it shall be acted on by growing vegetation. The soil acts as a filter, straining out particles; then, by the separating action of the earth-particles, a large surface of the fluid is exposed to the action of the air, and the organic is reduced to inorganic matter. The experiments of Müntz, Pasteur, and others, go to prove that this process is aided by micro-organisms in the soil. Vegetation also assists by utilizing the inorganic substances.

Hence, it will be apparent that there must be alternations of sewage and air in the soil, and that the soil must be in such a condition as to allow the sewage to run through and out of it, and that the vegetation must not be overdosed. There are great differences, moreover, in the capacity of various kinds of plants for utilizing sewage: In England osiers, Hungarian grass, Italian rye-grass, cabbages, mangolds, and other coarse-grained and succulent vegetables are especially recommended. But the market must also be considered. During a recent visit to Pullman the writer was informed by the courteous farm-superintendent, Mr. E. T. Martin, that he grew Italian rye-grass, but could not get cattle-feeders to take it away, although he offered finally to give it to them. The stalks grew very thick, rank, and watery. The principal crops at Pullman are cabbages, celery, and onions; turnips do well, but the market is unreliable. Potatoes fail utterly. Other vegetables can be raised, but those mentioned are found to suit best. It is a common mistake to suppose that rain is not needed on sewage-farms; it is necessary for the destruction of insect-pests. The Pullman farm has yielded a fair profit on the investment, apart altogether from sanitary advantages, except in those years

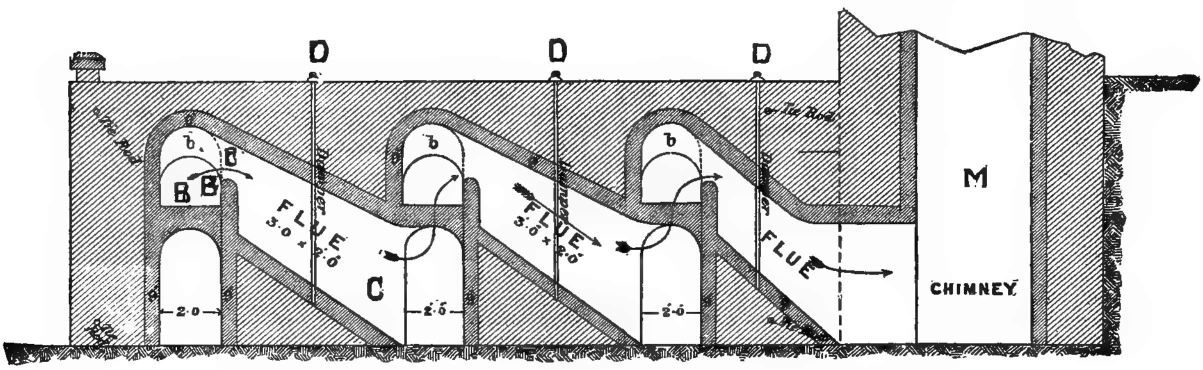

FIG. 3467.—Bee-hive Destructor: Section through the Zig-zag Line *Y Z* of Fig. 3465.

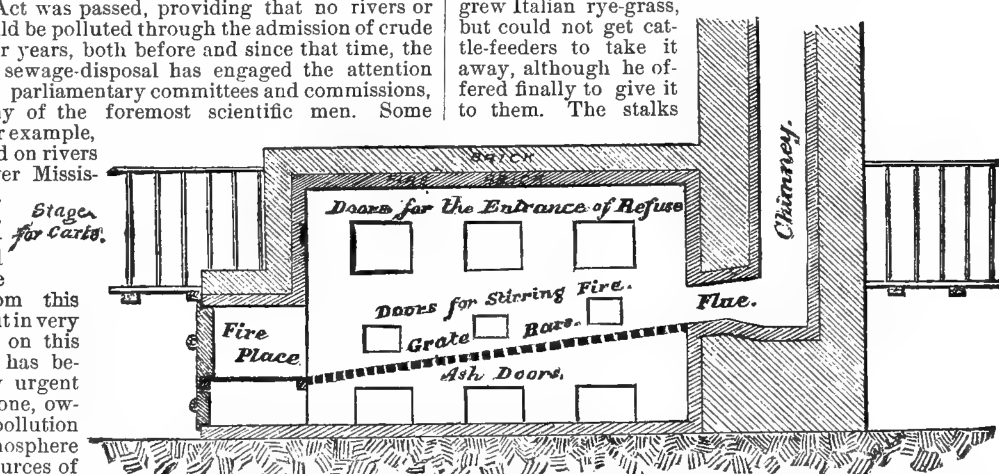

FIG. 3468.—Cut showing principle of Montreal Garbage Destructor.

when frost or other unfortunate accidents have had a destructive influence.

Sandy loams, and loams with a substratum of gravel or chalk, are well adapted for irrigation. In the case of stiffer soils, subsoil drainage is necessary. Experience has shown that it is not well to use pipes of a smaller diameter than four inches for this purpose. They should be laid at a depth of from four to six feet, but the distance between the lines of drain varies very much in practice; in some places we read of their being forty inches apart, in others as much as eighteen feet. These subsoil pipes should, of course, be porous and open-jointed.

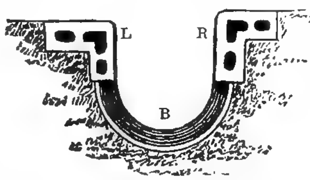

FIG. 3469.—Tile-carrier, with separate Side-pieces.

Solid substances are screened out before the sewage is applied to the land. In some places the sewage is conducted or pumped to the highest part of the farm, and thence distributed by sluices and "carriers" in the several methods presently to be described; in others it is carried in underground pipes and pumped from hydrants placed at intervals—one hydrant to every two and one-third acres is the apportionment at Pullman. It is applied to the land in various ways: it may be poured out upon it in a stream, the direction of which may be changed by hose, boxes, or half-pipes, which latter may be turned with the foot; to this the term "broad irrigation" is applied. Grass land often receives a "surface treatment" of this kind, a section thus treated being fenced off for a few days before cattle are allowed on it. A rain following the application of the sewage improves the land very much for pasture purposes. A modified form of broad irrigation is what is termed the "contour" or "catch-water" method, which consists of a series of shallow channels, or carriers, terraced one above the other, with gently sloping land between; the water flows into and overflows the highest carrier, then down the slope into the next, and so on. The carriers follow as far as possible the contour of the ground, and the distance is regulated by the slope and nature of the soil—an average of two hundred feet is recommended.

The "carriers" may be formed in the earth itself, which is generally firm enough, or they may be edged with turf, or tiles may be used, as shown in Fig. 3469. The capping of these tiles may be used as a footpath—a great advantage. It may be noticed, too, that the side R is higher than L, which allows the sewage to overflow. In carriers valves are sometimes placed, similar to the flap-valve in the Palmer trap (see Sewerage), but regulated as to the amount of opening by a handle. These must, of course, be contained in a closed-pipe carrier. The side-pieces (L, R, Fig. 3469) are made separate from the bottom tile B, and additional side-pieces may be let in, thus making the carrier deeper, if required as a conducting main. These main carriers or sluices are sometimes constructed in the earth and edged as above described, or they may be of tile or cement.

Fig. 3470 represents a farm on the "flat-bed" system. The surface must be graded so as to have a slight inclination—say one foot in fifty, to one in one hundred and fifty, according to the nature of the soil, the crop, and the amount of irrigation required. The sewage is conducted along the main sluice A, E, and can be stopped at any desired point by the main dam F; it is led into the laterals by the gates G, G, G, and it may be stopped at any required distance by the lesser dams D, D. The sewage is thus made to flow over a portion of the land for a few hours at a time, at intervals of as many days as may be found necessary. A method is in operation (and is being gradually extended) at Pullman by which a more uniform result is obtained. The beds are arranged in sets of six, three on each side of a broad, low, turf

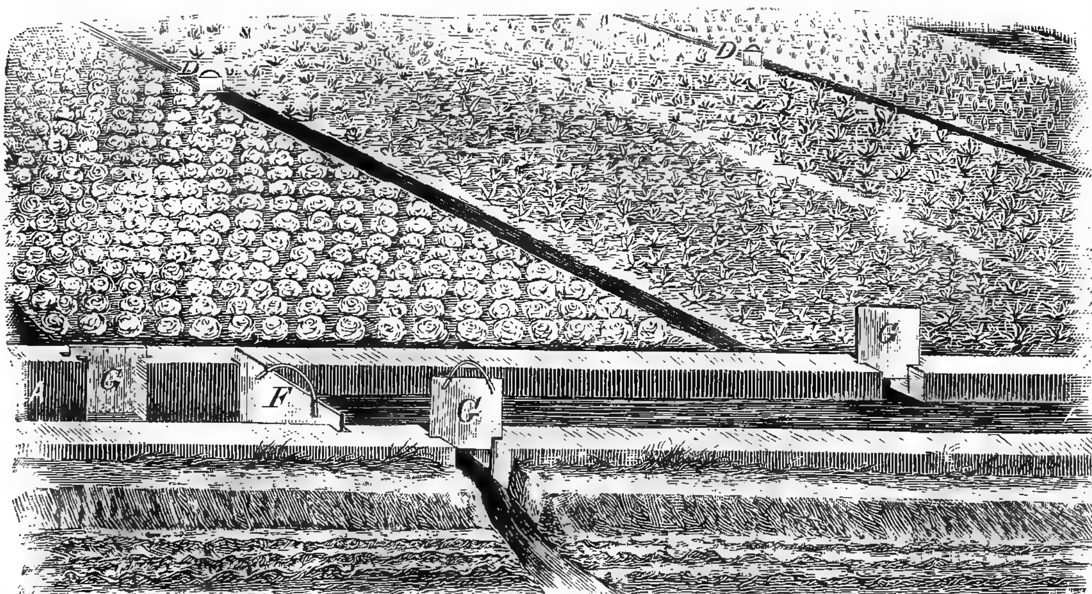

FIG. 3470.—A Sewage-Farm, Irrigated on the Flat-bed System. (From Dr. Folsom's Report.)

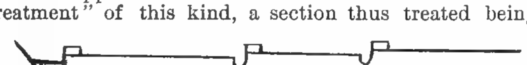

FIG. 3471.—Section of Land Irrigated on the Flat-bed * System, the sewage in this case being confined by a strip of turf on the lower edge of each bed, and supplied by a carrier at the upper edge.

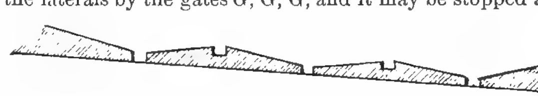

FIG. 3472.—"Pane-and-gutter" or "Ridge-and-furrow" System of Sewage Irrigation.

* I am aware that the term "flat-bed" system has received a different application at the hands of some; but it is used as given in the text by Mr. Wm. Eassie, C.E., F.L.S., F.G.S., as also are the terms "pane and gutter" and "sewage-cropping," respectively applied to the next two modes. See Our Homes, Cassell & Co., London, 1883.

wall, which runs lengthwise down the slope; the remaining sides of each bed are also surrounded by a little turf wall, and in this rink-like form the sewage can be more evenly spread; a hydrant stands at the head of the broad dividing wall, and, by means of a sluice-box, supplies sewage to the beds on either side; at the lower end of each of the first and second beds, close by this median

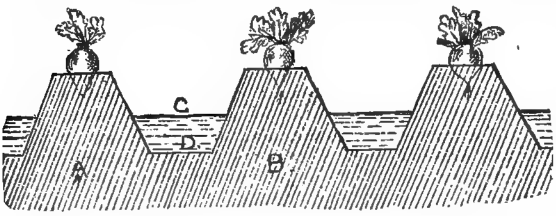

FIG. 3473.—"Sewage-cropping," by allowing the sewage (C) to flow in the gutter (D) and percolate into the beds on either side.

wall, is a small sluice-gate, so that the sewage can be let into the lower beds only, or into any of them at will.

In Fig. 3471 is shown a section of a series of beds on a somewhat similar principle.

The "pane and gutter" or "ridge and furrow" method is represented in Fig. 3472.

The land should be deeply cultivated and well pulverized, and arranged in ridges and furrows so as to form long beds, as shown in Fig. 3472. These should be from forty to ninety feet wide, according as the land is light and loamy, or of a less porous nature. The slope should be from one in twenty to one in forty, according to the nature of the soil. The sewage is then conducted in a carrier or shallow trench along the ridge, and allowed to overflow and soak through the sloping bed; if grading and distancing be carefully done, there will be little overflow left to be carried off in the gutters by the time they are reached.

In some places porous or perforated and open-jointed tiles are placed on the ridges instead of the carriers.

Another mode of applying the sewage is to allow it to flow into gutters or channels in the earth, and soak through the sides of these channels into beds on either side, from

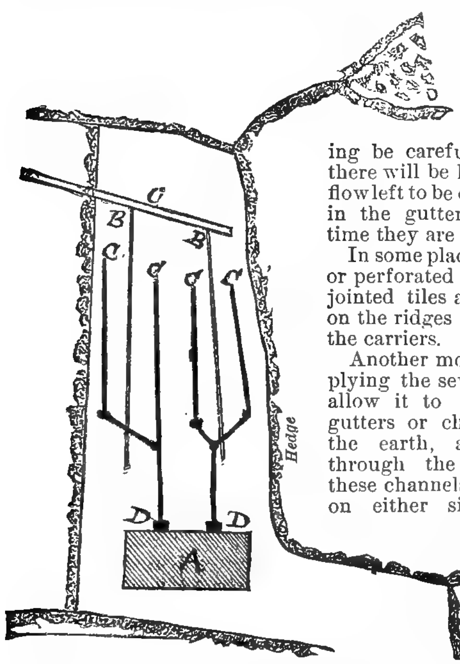

FIG. 3474.—A Diagram showing the mode of disposing of the Sewage of the Double Cottage A, by Subsoil Irrigation.

which it is taken up by the roots of vegetation. It will be evident that the sides of these channels will require to be scraped or loosened more frequently than in the other methods, so as to allow more ready percolation. Fig. 3473 gives an example of this method of irrigation, to which the term "sewage-cropping" is applied by Mr. Eassie. In this case the distance A B from centre to centre of the beds is about two feet, but they are often much wider; the depth of sewage-space in the gutter, C to D, is about nine inches; the length of the distance to be traversed in the gutter by an outflow of sewage will, as before, depend upon the character of the land, and may be about one hundred feet in light soils, and more in less porous soils.

Subsoil Irrigation.—There are at times circumstances, such as close proximity to dwellings, which render it undesirable to have sewage exposed on the surface, and in these cases it may be applied about a foot below the surface. This must not be confounded with subsoil drainage referred to above. Unless the subsoil is very porous, we still have to employ subsoil effluent drains below the subsoil irrigation-drains. This is shown in connection with the disposal of the sewage of two cottages in Fig. 3474. It is not prudent to have the sewage discharge into the soil near the dwellings, and the black lines nearest the tanks D D represent water-tight glazed tiles which conduct the sewage into porous tiles with open joints, represented by the branch lines C C C C; the effluent drains are represented by the light lines B B, converging into O, the main effluent. Subirrigation-drains have to be raised, as they are liable to become clogged. It is well to do this every season, or bends only may be raised, as they are most liable to clog. In taking up the drains another advantage may be gained, as their lines may then be laid in fresh portions of the soil.

In places where the flow is small, as in private houses, the sewage, if left to discharge as formed, would not reach the end of the system of pipes, but would expend itself near the point of delivery. To overcome this difficulty a tank is employed, the sewage being discharged periodically. The tank may be made to discharge by some automatic arrangement, as seen in Field's Flush-tank (Fig. 3475). This is a cylindrical iron tank, *A*. In the case of its receiving sewage from a disconnected pipe (see Sewerage) it should have a trapped inlet, *B*, which also serves as a movable cover. *C* is a ventilating opening; *D* is the siphon; *F*, termed the "discharging trough," consists of a small chamber, which may be turned around so that it may connect properly with the pipes *G*, through which the sewage discharges. It has a movable cover for getting at the mouth of the siphon. This trough forms a temporary check to the flow, so that the siphon can be brought into action. Another advantage of this periodic discharge is the period of rest which is given to the soil, the necessity for which has been alluded to.

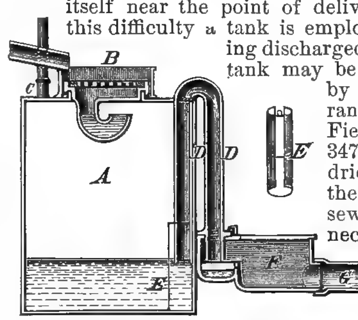

FIG. 3475.—Field's Automatic Flush-tank.

In irrigation on the large scale this intermittent action must be regulated by the attendants according to the crop. Sometimes it is desirable to allow three or four days to elapse between the successive irrigations. It is always desirable to have a fallow or idle field on to which sewage may be turned, when the crops would be injured by it, or when they are being taken off.

In irrigating on the large scale the distance traversed is generally sufficient to break up fæcal matter, and the action of pumps has a similar effect, so that all may be turned on to the land. There are many other matters in sewers, however, which must be screened out. Where their value as manure is not a consideration, the excreta are sometimes intercepted, and treated by some of the methods recommended for night-soil. In household irrigation—by gravity—they are generally intercepted. The solids are sometimes precipitated by some of the methods presently to be described, and the supernatant fluid alone is used in irrigation. This is not to be recommended from an economic point of view.

I have before stated that in the dry and pneumatic methods the disposal of the slop-water has to be provided for. This may be done by means of irrigation.

Town sewage can be far more profitably treated if the separate system of sewerage (see Sewerage) has been adopted, thereby rendering the sewage less in quantity and more concentrated.

The amount of land required for irrigation will, of course, vary with the nature of the soil and character of the sewage, but one acre to one hundred people is given as a fair proportion.

It was at one time considered doubtful whether sewage could be disposed of by irrigation in winter in very cold climates. This difficulty has been solved by the experience of Dantzig, of the City of Pullman, before alluded to, and of the State Asylum for the Insane at Augusta, Me., where the sewage flows out in winter. Its warmth keeps it from freezing, and it flows over the ground; if this is covered with snow it works its way underneath. It is found that the soil purifies it even without the action of growing plants.

(*d*) *Filtration.*—Intermittent downward filtration resembles very much the mode of irrigation with subsoil drainage. The drains are placed at a greater depth if the nature of the soil and outfall permit, and larger quantities of sewage are poured upon the land, and with greater frequency; as less regard is had to the paying result in cropping, a less quantity of land is required. The land is divided into several filter-beds—four at Merthyr Tydvil—the sewage being successively poured for a certain number of hours upon each; in this way time for aëration is given. At Merthyr Tydvil irrigation upon another tract has been added.

Upward filtration has been tried, as at Ealing, but has not proved satisfactory. Of carbon-filtration the same may be said, the carbon being at present too expensive.

(*e*) *Precipitation and Deodorization.*—After the agitation against sewage-pollution began, a vast number of processes were proposed, ranging from simple subsidence in tanks to the use of chemicals, appalling in their number and variety. It most cases these chemicals are mixed with the sewage in settling tanks, the clarified liquid being decanted off and the precipitated sludge being dried, or put on land at once. Some of the processes contemplate the addition of the chemicals in the sewers. Among the most recent of these is the permanganate of soda process of the Widnes Alkali Co., of Widnes, Lancashire, which may be understood by the accompanying cut (Fig. 3476), and description.

The following well-arranged, brief list of some of the more important chemical methods that have been tried I extract from Gray's Report, before alluded to:

"1. Processes that employ salts of alumina as the chief precipitating agent:

"The Coventry process. Crude sulphate of alumina, salts of iron, and lime."

"The Native Guano, or A, B, C, process. Alum, blood, clay, and animal charcoal." [In addition to these the original specification stated that magnesia, magnesia limestone, manganate of potash, chloride of sodium, and burnt clay might be added, and that vegetable might be substituted for animal charcoal.]

"The phosphate sewage process patented by Mr. David Forbes and Dr. Astley P. Price. Phosphate of alumina and lime."

"Bird's process. Sulphuric acid and clay."

"Stothert's process. Lime, sulphate of alumina, sulphate of zinc, and charcoal."

"2. Processes which employ lime as the chief precipitating agent:

"Hille's process. Lime, tar, salts of magnesium, etc."

"Marsden and Collins' process. Lime, carbon (a waste product of prussiate of potash manufacture), house ashes, soda, and perchloride of iron."

"Holden's process. Sulphate of iron, lime, coal-dust, and clay."

"Fulda's process. Lime and sulphate of soda."

"Blythe's process. Superphosphate of lime, with magnesia and lime."

"Whitthread's process. Dicalcic and monocalcic phosphate and milk of lime."

"Campbell's process. Soluble phosphate of lime."

"Hanson's process. Lime, black ash, and red hematite treated with sulphuric acid."

"Goodall's process. Lime, animal carbon, ashes, and sesqui-persulphate of iron."

"The Lime process. Milk of lime."

"General Scott's process. Milk of lime; the sludge being burnt, forming Portland cement."

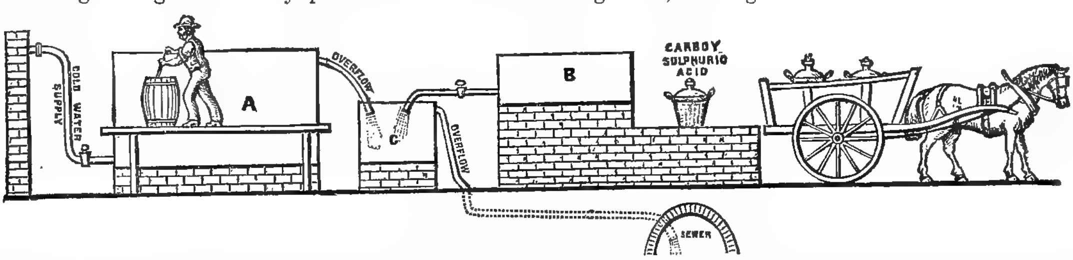

FIG. 3476.—Process of the Widnes Alkali Co., for Deodorizing the Contents of Sewers, by forming and mixing with them (as made) Permanganate of Soda. A is an iron tank about six feet by six feet by four feet, with cold-water supply-pipe and overflow-pipe. Manganate of soda is introduced into this tank, the cold-water inlet-tap opened, and the solution flows out of the overflow-pipe into the mixing vessel C, a small, lead-lined cistern about two feet by two feet by two feet. Here it meets with sulphuric acid from the lead-lined cistern B (about four feet by four feet by two feet in dimensions), the flow of which acid is regulated in such quantity as to turn to a bright pink color the manganate of soda solution from tank A. The manganate of soda solution is thus turned into a permanganate of soda solution in the tank C, and runs through the overflow-pipe at the top of C into the drain or sewer where it is required. The process is a continuous one, the manganate being fed slowly into A, while the inlet water-pipe regulates the rate of overflow to the required quantity.

"3. Processes in which salts of iron are used as precipitants:

"Chloride of iron and lime."

"Sulphate of iron and lime."

"4. Miscellaneous processes."

These processes are very numerous, but have led to no practical results. In England, from 1856 to 1876, there were four hundred and seventeen patents issued, all more or less connected with sewage and manures.

Of the many methods that have been tried for the chemical treatment of sewage, there are but three that stand prominent at the present time. These processes are those of "The Rivers' Purification Association, Limited [which controls and employs principally that which is], better known as the Coventry process.

"The Native Guano Company, Limited—better known as the A, B, C, process; and

"The lime process."

The precipitated "sludge" itself becomes a nuisance during the drying process; in order to get rid of the water (which generally amounts to about ninety per cent.), heated floors, blasts of air, and other artificial methods are resorted to. But one which seems more likely to prove satisfactory is the filter-press of Messrs. S. H. Johnson & Co., of Stratford, England (Fig. 3477).

"It consists of a number of narrow cells held in a suitable frame, the interior faces being provided with appropriate drainage surfaces communicating with an outlet, and covered by a filtering medium, generally cloth or paper. The interiors of the cells so built up are in communication directly with each other, or with a common channel for the introduction of the matter operated upon,

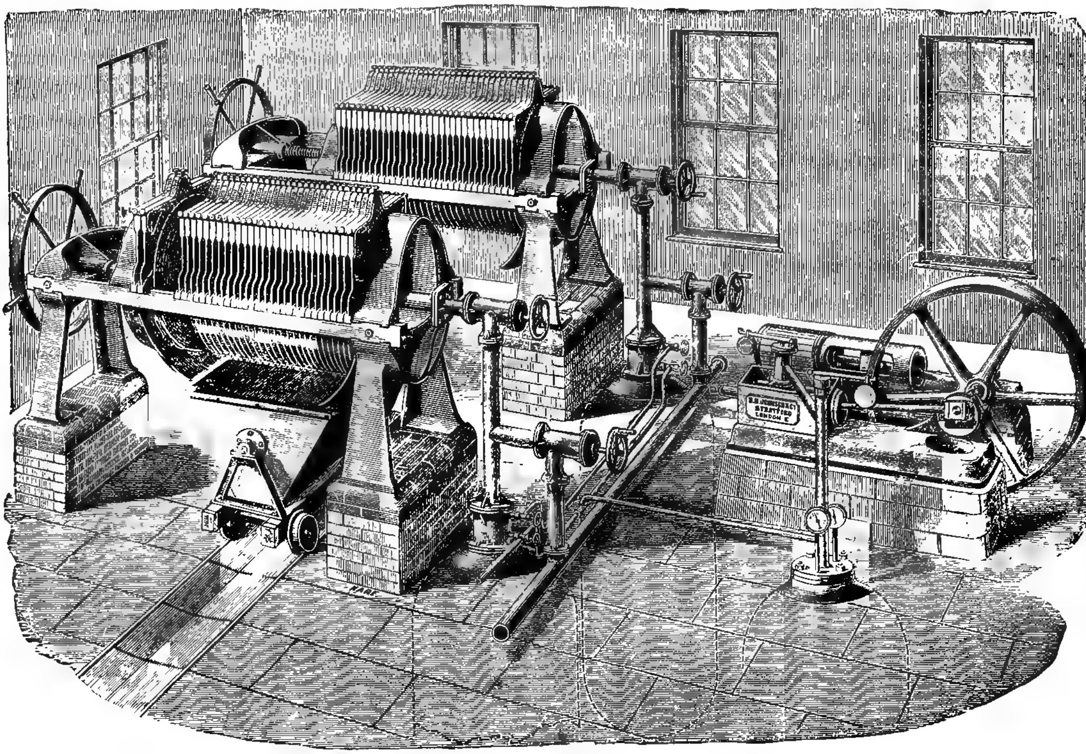

FIG. 3477.—Johnson's Filter-presses for drying Sludge.

and as nothing introduced into the cells can find an exit without passing through the cloth the solid matter fills up their interior, the liquid leaving by the drainage surfaces." The sludge is forced into them by the action of compressed air. The sludge-cakes are removed upon opening the press; they contain about fifty per cent. of solids and fifty per cent. of water, eight hundred parts per thousand of water having been forced out, leaving still one hundred of water and one hundred of solids.

The cost of the treatment of sewage by precipitation varies in English towns from seventeen cents to sixty cents per head of population per annum. But, as labor, chemicals, and apparatus are more costly in this country, we might have to double these amounts in order to obtain practical results here.

III. A COMPARISON OF THE ABOVE METHODS, AND THEIR ADAPTABILITY TO CITIES, VILLAGES, ETC.—We will now compare the merits of the various methods described, and their relative adaptability to the needs and circumstances of cities, villages, and isolated houses.

The Privy-pit and Privy-vault Systems.—It is hardly necessary in a work of this kind to describe at length the evils of the privy-pit: the poisoning of wells, the pollution of soil and air, the effects of the exposure of the nude person over a large pit full of cold and mephitic gases, the conveyance of germs of disease into the air and water, the general deterioration of health from taking into the body such air and water even when specific germs are not present—all these evils the medical reader should be able to comprehend and amplify for himself. I may, however, state a few facts illustrative of the extent of pollution from this cause. I was asked to examine, a few days ago, a site on which is to be erected an addition to one of our largest public schools. On one edge of the site a row of privies had existed; on the contiguous edge, about fifty feet distant, is an old well; the cellar excavation, about forty-three by twenty-eight feet, had been dug to the required depth of about seven feet. The structure of the soil is sand overlying a stratum of blue clay, with pockets of sand dipping into the latter. It was found that this entire area was a mass of stinking filth. How far beyond and around this filth extends I cannot say. The school has been supplied for some time with city water from Lake Ontario. A method of treating such a sewage-polluted site would be to remove all the soil down to the clay, to scrape the latter and flood it with a solution of bichloride of mercury, 1 in 500, and to lay a good concrete floor, the space between the clay and the concrete being previously filled with a mixture of clean clay loam and chloride of lime, or quick-lime; as an additional precaution air-spaces of porous tile, or brick arches, might be formed under the concrete floor, connecting with a hollow wall air-space outside the foundation at two sides of the building, one of these latter being connected with a furnace flue, the other communicating with the outside air. A contemporary issue of a newspaper in one of our country towns relates the following incident: "A short time since in making an excavation for a building, the workmen struck a vein of polluted earth, the stench from which was almost unbearable. Being curious to see and know the cause, I had the men follow the vein and found that it had its origin in a pit, and its outlet in a well, the distance to which was about one hundred and forty feet. In its passage the liquid matter from the pit had defiled the earth for several feet in all directions." Similar soil pollution exists around and amid dwellings in city, town, and country, everywhere, and we are occasionally aroused by unmaskings of what is continually, but secretly, going on around us. A calculation from actual facts will help to show the intensity of this evil: In some of the thickly inhabited portions of cities, even on this continent, we will find as many as five hundred people on a space of seventy by two hundred yards. Taking the basis, as given by physiologists, of two and a half to three ounces of fæces and forty ounces of urine per diem, for each individual, there is deposited in, and spread through, the subsoil of this area every year from fourteen to eighteen tons of fæces, and more than forty-five thousand gallons of urine, besides slop water, all which is left to slowly decompose for years without removal. It seems strange that such con-

Sewage.

ditions should have been so long tolerated, but the people at large are slow to act on the *dicta* of a few sanitarians until the facts and consequences have been made plain to them; they are slow to move out of old grooves, especially when private rights and convenience stand in the way. Moreover, proper disposal of sewage in communities requires combined action, and it is often difficult to get municipal corporations to act on scientific principles, especially when it is thought that a little false economy will better serve political interests. Medical men must persevere in their efforts to awaken the public to a realization of the extent and nature of the evil. Boards of health generally must follow the example of those boards which are bringing about a rectification of this evil.

In many places the work was begun by ordering the cleansing, filling, and replacing, by some proper substitute, of every pit or vault reported to the board of health and found to be a nuisance. In others the board has introduced and carried out, throughout an entire district, some proper system under its own oversight.

The privy-vault is somewhat less objectionable than the mere pit, inasmuch as it is at first water-tight; but there is great danger of soakage or of pollution of soil and water eventually occurring, and in the meantime the vaults pollute the air.

The Midden system is not to be commended. It is a very doubtful improvement over the old want of system.

Deposits of garbage in cities, towns, and villages are responsible for much sickness. Garbage—decomposable animal and vegetable matter, generally mixed with ashes and other rubbish—is dumped into hollow places, and after a time excavations are made in these. Sometimes the cellars and foundations of houses are constructed in this "made soil," and the ascensional current draws up the gases of decomposition from the soil. Occasionally the owner and builder are not aware of the nature of the site.

The diminution of mortality by the introduction of improved means of sewage disposal is shown in the following tables, and from it may be inferred a great decrease in the amount of sickness, and a consequent gain in material wealth:

City.	Period.	Sanitary condition.	Death-rate per 100,000 from typhoid fever.	Period.	Changes in sanitary condition.	Death-rate per 100,000 from typhoid fever.
Frankfort-on-the-Main	1854–59	No sewerage.	87	1875–80	Sewerage completed.	24
Dantzic	1865–69	No sewerage; no proper water-supply.	108	1871–75	Water-supply introduced.	90
				1878–80	Sewerage added.	18
Munich	1854–59	Absolutely no regulations for keeping the soil clean.	242	1860–65	Reforms begun by cementing the sides and bottoms of cesspits.	168
				1866–73	Partial sewerage.	133
				1876–80	Sewerage improved.	87
				1881–84	Sewerage still further improved.	17

Place.	Average mortality per 1,000 before construction of works.	Average mortality per 1,000 since completion of works.	Saving of life.	Reduction of typhoid fever.	Reduction in rate of phthisis.
			Per cent.	Per cent.	Per cent.
Banbury	23.4	20.5	12½	48	41
Cardiff	33.2	22.6	32	40	17
Croydon	23.7	18.6	22	63	17
Dover	22.6	20.9	7	36	20
Ely	23.9	20.5	14	56	47
Leicester	26.4	25.2	4½	48	32
Macclesfield	29.8	23.7	20	48	31
Merthyr	33.2	26.2	18	60	11
Newport	31.8	21.6	32	36	32

Salisbury	27.5	21.9	20	76	49
Warwick	22.7	21.0	7½	52	19

A large number of statistics illustrating this subject may also be found in a paper by Mr. Erwin F. Smith, published in the "Annual Report of the State Board of Health of Michigan" for 1885.

Water-carriage is undoubtedly the most preferable method in places where the sewage can be properly got rid of without further outlay, or where it can be utilized with little or no loss. It is quite possible that the time may not be very far distant when there may be some better and more intelligent understanding between the agriculturist and the sanitary authority, when there may be some such combination as will put an end to some of the difficulties and loss at present attendant upon sewage disposal and utilization. But accepting the fact that there is generally at the present day a small loss, this is counterbalanced over and over again by the gain to the community in the saving of life, time, and the expenses resulting from sickness and death. But as this saving is brought about in varying degrees by all sanitary improvements, we may briefly consider what are the special reasons for preferring the water-carriage system:

First, in all systems there must be some means of disposing of chamber, house, and kitchen slops; and, strange as it may at first sight appear, it has been found in large communities that the exclusion of excreta makes but a slight difference in the character of the sewage. From De Chaumont's edition of Parkes' "Hygiene" ("Wood's Library" for November, 1883, pp. 32, 52), the following remarks are quoted: "This difficulty is felt in the case of the foul water flowing from houses and factories without admixture of excreta almost as much as in sewer-water with excreta. The exclusion of excreta . . would indeed hardly lessen the difficulty—" . . "the solid excreta of only six per cent. of the inhabitants [of Birmingham] pass into the sewers, while the solid excreta of the remainder pass into middens. The problem of disposal is as serious for Birmingham as if all the excreta passed in." The conclusion of the Second Rivers Pollution Commission accords with this.

Secondly, after a proper building of the entire system, there is more perfect automatic action and less dependence upon individuals.

Thirdly, the conveniences are much greater, and the encouragement given to the liberal use of water conduces to health.

Fourthly, in a well-constructed system of sewerage all refuse, except garbage, leaves the community within a few hours of the time it becomes refuse; and garbage may, by individual household management, be destroyed in the same time.

Many persons have objected that the water-carriage

system makes avenues for the entrance of sewer-gases into houses. This objection holds not against the system as it should be, but against the faulty and defective contrivances that are too often allowed. How these defects may be obviated is shown in the articles on Habitations: General Principles of House Plumbing, and on Sewerage. To enforce correct principles in spite of the wilful neglect of avaricious and unscrupulous builders and tradesmen, we must come to a strict system of inspection of plans and buildings.

The groundlessness of the above objection to the introduction of systems of sewerage will be evident from the statistics already given and referred to.

Then, again, fears have been expressed regarding the salubrity of localities in the neighborhood of sewage farms, and regarding the wholesomeness of the products of the latter. On these subjects M. A. Durand-Claye quotes from a letter addressed by Dr. Frankland to M. Mille, inspecteur général des Ponts et Chaussées. "In reply to your letter of the 12th inst. [May, 1881], I will say that I have followed with the most lively interest the recent researches of your illustrious compatriot, M. Pasteur, and I consider them of the highest importance. . . .

"These considerations, however, have not modified my opinion as to the harmlessness of sewage irrigation; for its harmlessness has been proved by ample experience. . . . It has been recently proved by experiments in my laboratory, that although bacteria live and multiply in sulphuric acid, in cyanogen, and other deadly poisons, they are at once destroyed by that inoffensive material, metallic iron.

"That there may be in nature powerful agents for the destruction of the germs of disease cannot be doubted. . . . Experience seems to show that some of them are active in the process of sewage irrigation; for it has been demonstrated many times in this country that sewage, *even when infected by cholera and typhoid fever*, has never, when used in irrigation, transmitted disease, either to those living on the irrigation fields, or to those who consume the crops raised upon them."

Microscopic examination of Paris sewage, and of the effluent from the irrigation fields, shows the number of microbes per cubic centimetre to be twenty thousand, and twelve, respectively; and chemical analysis also shows a remarkable purification to have taken place.

Dry Systems.—The difficulties connected with the constant oversight required by the dry-earth, and dry-ash, and pail systems in a mixed community, will have been apparent, and the offensiveness caused by several days' storage, without deodorant, in the latter system, is an additional objection. In both, too, there is a continuous outlay.

There are, however, circumstances in which these systems may be advisable; as, for example, to serve a temporary purpose till the more permanent system of water-carriage and its suitable disposal can be introduced. In the case of railroad carriages, too, either the dry-earth or dry-ash method, or pail with disinfectant solution, should be employed; the present disgusting and unpleasant mode is well adapted for spreading typhoid fever and cholera, should the latter pass the maritime barriers. A resolution which aims at bringing about the substitution just indicated has been adopted by the American Public Health Association, at its recent meeting at Memphis, Tenn. (November, 1887), and should receive general support. In places where neither a suitable outfall nor land suitable for irrigation is obtainable, one of the dry systems for excreta, and precipitation for slop-water, may be employed.

Pneumatic System.—It was to meet the needs of places of this character that the Liernur system was introduced, but it is apparently an uncleanly and somewhat offensive method (see Sewerage), and has not met with much favor.

Disposal of Surface Water.—A question of a general nature presents itself for consideration: Shall we allow the surface water to enter the sewers? If we do so, instead of adopting the separate system of sewerage (see Sewerage), we so dilute the sewage and increase its quantity that we render its utilization (except under circumstances rarely met with) much more difficult and costly, besides increasing the cost of the sewers, and rendering them, as a rule, more likely to become foul in dry weather. If we do not allow the surface water to enter, what are we going to do with the horse-droppings and other surface filth? The question must be differently answered according to varying circumstances.

We are now in a position to apply the foregoing facts and principles to the various conditions of cities, villages, and isolated houses. In so doing individual opinion may differ somewhat, according to the objects which may seem to different persons to be of greatest importance, and according to the point of view from which they look at them.

In cities the water-carriage system is likely to prevail for the reasons already stated. Where an outfall into a body of water may be permitted without any of the evils of water pollution, and if the surface slopes toward the water-front, then the surface and rain water may be allowed to flow along surface channels in gutters (unless the volume is too great), and the separate system may be employed for sewage. If there is no suitable outfall, then the first washings (being more concentrated) may be intercepted by the sewers (see Sewerage), and the larger volume be excluded. If there be a sufficient quantity of suitable land near the city, irrigation or filtration may be resorted to. If distance or other reasons forbid this, then precipitation may be employed. In either case, while it is not well to stint people in the amount of water they use, it is well to prevent waste and leakage. In cities with large sewers, built for both storm water and sewage, especially when there is little fall, it is well to encourage the use of plenty of water, in dry seasons more particularly. If surface water is excluded from the sewers, road pavements should be built and frequently swept, and other roadways should be scraped clean. In employing irrigation, if there be a large quantity of light, suitable land near the city, and a good fall, we need be less sparing of the quantity of water entering the sewers than if the reverse conditions prevailed. While it is true that very light, sandy soil is well adapted for irrigation and filtration purposes, sand a few inches above the water, as on a lake shore, is of no use, however dry it may look. A few inches down the sewage stagnates in the water, and runs laterally instead of running off. Cesspools should never be allowed in cities, nor should vaults or pits. Where these two latter do exist the choice of ultimate disposal is between cremation along with the garbage, and the deodorizing and making of artificial manure. They should never be allowed to connect with the sewers, unless with vaults we include latrines with water-supply (see Sewerage). In cities which are very flat, and with broken surface, the use of Shone's ejectors should be borne in mind.

In villages with scattered houses, and in the isolated parts of cities, the dry-earth or dry-ash system may be used. But in compact villages the water-carriage system may well be employed. A central tank may be built and some form of pump used if there is not sufficient fall. Whatever mode is employed, it should at once be systematized, and corporation sanitary officials should have the oversight of it. The surface water may be left to look after itself—the filth per capita being smaller and the quantity of surface and subsoil water greater than in cities.

In isolated houses the householder can readily decide between the water-carriage and dry-earth or dry-ash systems, as to the mode best adopted to his surroundings, and the occupation of himself and his servants. If he has plenty of water and a suitable water-service, water-carriage with a small glazed sewer will be the best method. If he has not an outfall which will not be a nuisance to himself or his neighbors, he may employ irrigation or subirrigation on the cottage plan, described before. The tank must be protected from frost, and separated from the soil-pipe by a disconnecting trap (see Sewerage), or by a trap and vent-pipe. Cesspools should not be employed unless they are so situated that they cannot possi-

bly contaminate wells or the soil in the vicinity of houses. During the course of an investigation into the causes of typhoid fever in a large public building, I caused to be unearthed a cesspool, the existence of which was not known to the officers of the institution, who supposed the drain for the soil-pipe opened into the main drain. Sewage had been for a long time filtering into the basement.

For isolated buildings it appears as though the Smead-Dowd apparatus would serve the double purpose of carrying off foul air and disposing of the excreta.

In all cases the householder can greatly aid the sanitary authorities in the disposal of garbage, but in country places he ought to find no difficulty in utilizing it. It should be borne in mind that ashes make, with the wet earth, excellent hard walks.

In conclusion, I wish to express my indebtedness to the gentlemen to whom reference has been made in this article, for the assistance obtained from their writings.

Wm. Oldright.

Appended are some suggestions and a form of tender and specification which may be of some service in small communities where the dry-earth system has to be introduced. They are taken from a pamphlet issued by the Provincial Board of Health of Ontario for use in the Municipalities.

The following suggestions are made to Municipalities contemplating the establishment of the dry-earth system:

In the outlying portions of a town or village where garden space is ample, the householder may safely be allowed to procure the earth necessary and to dispose of the used earth as manure in the garden and fields. The sole duty of the Municipality will be to see that the old privy-pits are done away with, and proper dry-earth closets substituted, and to occasionally inspect the premises.

In the central and more thickly populated portions it will be necessary to make special provision for the supply and removal of earth. This may be done by contract or day labor—if by contract the contractor may be allowed to sell the resulting manure for his own benefit.

Perhaps the simplest and fairest method of meeting the expenses connected with this system would be for each householder to pay the Municipality for the earth delivered at so much per cart load, and for the earth removed in the same way; all the carts used in the work to be of exactly the same size, and to have their contents in cubic feet branded on the sides.

It might happen that, even in the crowded districts, many householders might find it preferable to use ashes instead of earth; in such cases, if payment were made in the manner above suggested the householder would pay simply for the removal of the product, *i.e.*, for the work required to be done, and for nothing more.

The Municipality may also make each person bear the expenses of the preliminary work done on his own premises, such as the cleaning and refilling of privy-pits, the building or repairing of privy-houses, providing earth-closets, etc.

As it would be difficult to include the repairs of existing privy-houses in a contract, such work had better be done by day labor, either by the Municipality or by the householder or owner.

In order to supply the earth, the Municipality might set aside, or purchase, a certain quantity of land, or else the contractor might be allowed to obtain earth at his own expense.

The earth removed should be deposited in such places as may be approved of by the local health officer, until such time as it is sold for manure.

A good shed should be built at the place where the earth is procured, under which a sufficient store should be kept in reserve, so as to tide over periods of stormy and wet weather, when the earth would otherwise be unfit for use.

It would not be necessary that the earth should be supplied and removed at stated periods. It will be found sufficient in general for each householder to notify the contractor or the local health officer of his needs as they occur, in order that they may be immediately attended to. This should be subject, however, to the discretionary power of the local health officers, for the whole system of earth-closets in the Municipality will, of course, be under the jurisdiction of the local health board.

With careful management the supply necessary may be reckoned at the rate of one cubic foot of earth per individual, per month, if used only once; but as the earth may be used several times without becoming offensive, the quantity required may be reduced considerably. However, where earth is plentiful this plan is not recommended.

It may be of assistance to individuals, and to municipal authorities, to have approximate information of the prices of automatic closets complete, and of closet fixtures. The prices asked are somewhat as follows:

Closet, for house use, neatly finished, all complete, and which can be placed in a vacant room or shed, ready for use, according to material and finish, about	$14 00 to $16 00
Commode closet, neatly finished, which can be easily moved from one room to another in case of sickness, about ...	12 00 to 14 00
Closet to be placed over a vault, plainly finished, with hopper	10 00
Fixtures for vault closets, with seat, about	5 50 to 8 00
Extra pail for the commode closet, for greater convenience	0 75

For quantities, for schools and public buildings, some reduction could be obtained from the above prices.

The following are proposed forms of specification and tender for the works connected with the system of dry-earth removal:

FORM OF SPECIFICATION

MUNICIPALITY OF ——.

Date..................

Dry-earth System of Removal.

The work to be done consists of the following items:

1. All privy-pits within the Municipality to be thoroughly cleansed and filled with clean earth, the number of the same being approximately ——.
2. The contents of the privy-pits to be removed to ——, where they are to be thoroughly mixed with a sufficient proportion of fresh earth (or ashes) to render the mass an inoffensive manure.
3. Earth-closets of some approved pattern, either patented designs or consisting simply of excrement- and dry-earth tubs placed under hinged seats, to be substituted for the former privy-pits.
(Clauses 4 to 12, inclusive, apply to thickly settled districts.)
4. Earth to be supplied for use in the closets, and the used earth or ashes, as the case may be, to be removed to a suitable place.
5. The earth supplied to be loamy in its nature. Earth difficult to screen or bring to a powdery condition will not be allowed to be used.
6. The earth to be obtained at ——.
7. The earth or ashes after use in the closets to be deposited at ——.
8. The quantity of earth to be supplied may be reckoned at one cubic foot per individual, per month, but this quantity may be lessened by the earth being used more than once, and also by the use of ashes.
9. The earth to be delivered and removed in carts containing —— cubic feet, having their capacity branded on the sides.
10. Sheds to be built on the premises of each householder, for the proper storing and screening of the earth, where none suitable for the purpose exist.
11. A suitable shed to be built at the place where the earth is procured, wherein a sufficient quantity is to be maintained to prevent scarcity in the supply, arising from the long continuance of weather during which excavation cannot be carried on.
12. The district to be supplied with earth contains about —— inhabitants, and is bounded as follows: ——
13. The prices for cleaning and filling privy-pits, providing earth-closets, building privy-houses and sheds, supplying and removing earth, ashes, etc., must include all the labor, tools, sheds, materials, land,* horses and carts, and all other appliances and expenses necessary for the proper carrying out the work.
14. The contractor will not be permitted to take advantage of any error or omission in the foregoing specification, as full instructions will always be given should any error or omission be discovered.
15. The work will be carried on under the inspection of, and subject to the approval of, the local health officer.
16. Payments will be made monthly, on the certificate of the local health officer, for all work included in this specification. In the case of the delivery of earth and removal of soil, the bills of the contractor, certified by the householder, may be accepted by the local health officer.

FORM OF TENDER.

MUNICIPALITY OF ——.

System of Dry-earth Removal.

	$ c.
Cleansing and refilling privy-pits, including proper disposal of contents, per pit	——
Earth-closets, patented designs, per closet	——
" " dry-earth tub, excrement-tub, and scoop, per set	——
Privy-houses, each	——
Sheds for storing and screening earth, etc., each	——
Supplying earth for use in closets, per cubic yard	——
" " " per load	——
Removing earth or ashes from closets, per cubic yard	——
" " " per load	——

The undersigned hereby propose and undertake to perform all the work, and furnish all the material, plant, etc., required for the proper performance of the same, in accordance with the specifications and advertisements dated ——, copies of which are hereunto attached, and are prepared to enter into a contract with the Municipality of ——, for the due performance of the same, at and for the rates and prices set forth in the foregoing schedule.

SEWERAGE. Under the heading Habitations: General Principles of Plumbing, the commencement of the water-carriage system, within the house, has already been considered; and in the article Sewage, Disposal of, the ultimate treatment of the contents of sewers has been dealt with, as well as the modes of disposing of refuse matter by other systems. In this article it is proposed to give such a consideration of the "water-carriage system" from the house to the outfall as may be of profit and interest to the medical reader, thus filling up the gap between the two articles above referred to. And while we are obliged, in order to attain this object, to glance over the field of the sanitary engineer, *minutiæ* of engineering will not be attempted.

PRELIMINARY CONSIDERATIONS.—In connection with the sewerage of any particular place, there are certain preliminary considerations which must be taken up.

* Where the Municipality has *not* set aside or purchased land for the purpose.

One of these has been partially discussed in the article on the Disposal of Sewage; I refer to the question of deciding between the combined and the separate methods of sewerage; nothing but excreta, laundry, and kitchen slops, and certain kinds of waste from manufactories and stables, being allowed to enter the sewers in the separate system, and in some cases enough of the rain-water from the roofs for flushing purposes; while in the combined system all the storm and surface water is also admitted.

The position and character of the outfall will have an important bearing upon the whole character of a sewerage system. If the outfall be such that we have to treat the sewage by irrigation or precipitation, this will be one element in determining some method by which only the concentrated portions will pass to the outfall, the superfluous storm-water being diverted into other channels.

The amount and character of the rainfall—whether equable or varying—will have to be considered, with a similar object in view. Heavy rains tax the capacity of the sewers far more than frequent gentle showers, even though the total annual rainfall may be more in the latter than in the former case.

The geological and physical nature of the soil will have a manifold influence; a sandy or loamy soil, especially if the slope be not great, will leave much less water to go into the sewers or down the gutters than a more impenetrable and steeply sloping one. The configuration of the soil may cause engineering difficulties, which again may enter into the determination of the system to be adopted; and the existence of rock or sand may present difficulties in construction or in permanence.

The area and population—present and prospective—will also have to be considered. With scattered population the difficulties are increased, especially those of the combined system. On the other hand, sufficient care is not always exercised in regulating the size of sewers to meet the probable growth of the sewerage system of a town or city.

The bearings of water-supply, of the *habits of the people*, and of the *sanitary appliances already in existence*, will be apparent. An abundant supply of water, with careless waste, may unduly tax the sewers, and unduly dilute the sewage; or a scanty supply may promote the liability to deposit.

THE FOLLOWING PRINCIPLES must be kept in view in connection with systems of sewerage:

All matters entering the sewers should be removed, and removed completely, to a suitable outfall (no lodgements, no leakage).

They should pass entirely from the sewerage system before there is time for decomposition to take place. The limit is often placed at twenty-four hours; but when we come to speak of velocity it will be seen that in the largest ordinary system not half that time will be consumed if the sewers are so constructed as to be self-cleansing.

There should be free ventilation through the entire system.

Means should be provided to direct the necessary escape of the gaseous contents to points where they cannot come in contact with human beings, and to prevent escape at points where they may come so in contact.

These principles, and violations of them, will be explained more fully as we now proceed to take up the various points in the construction of sewers.

CONSTRUCTION OF SEWERS.—The *materials* of which sewers are constructed.

Tiles answer well up to a diameter of eighteen inches or two feet. They should be of salt-glazed, vitrified earthenware; lead-glazed pipes chip, and allow soakage and leakage. Their strength may be tested by placing heavy weights upon them, or dropping weights on to them in a trench; they may be placed under a weighted lever, arranged like the arm which carries the weight of a safety-valve; or they may be laid horizontally with a block under each end and the weight applied in the centre. The best test, however, would seem to be by hydraulic pressure from the inside; sometimes pipes having fire-cracks and looking to be poor will stand this most natural test better than others whose appearance is not so bad. They should be true-fitting, for any defects in contour, such as shown in Fig. 3478, will affect the formation of joints and give rise to leakage.

FIG. 3478.—Pipe Defective in the Contour of its Socket End and making a Leaky Joint.

Fig. 3479 represents the form of tile most commonly used, having a socket at one end into which the other (spigot) end of the next pipe above is placed to make the joint.

Fig. 3480 shows a different form of pipe, without any socket—the joint being made by placing the ends of two pipes in contiguity inside the ring, Fig. 3481.

Fig. 3482 is a representation of Doulton's opercular pipe, which is of service in enabling a person to search for and remove any obstruction, as in faulty places where there is little fall, or where for some other reason stoppage may be feared. Jenning's access pipes (Fig. 3483) are plain at both ends, and are laid in chairs (C) similar to the metals of a railway, the pipes being kept six, nine, or twelve inches apart, according to the diameter. They provide for the same object as the last-named pipe, and they have the advantage that, on lifting the upper part of the saddle, a pipe may be lifted out and a junction inserted to allow of the connection of another line of sewer at any subsequent time. The saddles may also be so placed as to allow of the passage of subsoil water beneath the pipes. They present one serious defect, however; the invert, or bottom, does not present an even, smooth surface, and cannot be made to do so, although an attempt be made to fill in with cement; it might be improved by a raised piece in the centres of the chairs or saddles. Other forms of tiles are used, but those above described are the best suited for practical purposes.

FIG. 3479.—Socket Pipe.

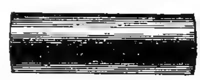

FIG. 3480.—Ring Pipe.

FIG. 3481.—Ring.

Iron pipes must be used when a larger size of pipe is required, or when any unusual strain or pressure has to be borne, as where there is a long or heavy lift in pumping, or where some stream or chasm has to be crossed. They should be tested and examined, in the manner above described, for brittleness and defects in their walls and contour. They are sometimes enamelled inside when used for house connections; but for such purpose, where there is no heavy pressure or strain, the glazed tiles are preferable.

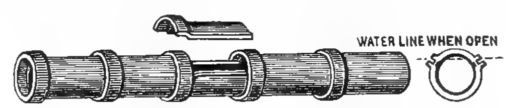

FIG. 3482.—Doulton's Opercular Pipe.

Brick must be the chief material for large sewers. The bricks should be very hard and impenetrable, especially for the invert, to withstand the grinding friction of the passing contents. Their strength may be tested by a weighted lever, as above described in the case of tiles. Their porosity is a very important point, and may be tested by weighing them when kiln-dried, and again after soaking in water. Great care should be exercised in seeing that they are built with good (water-proof) ce-

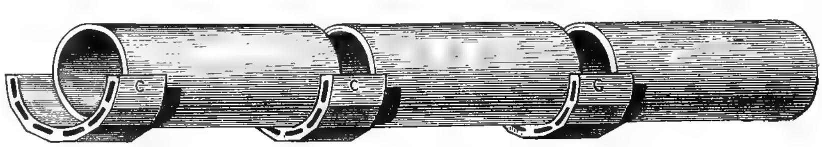

FIG. 3483.—Jenning's Access Pipe.

Sewerage.

ment, that the joints between the bricks are smooth and even, and that the sewer is not covered in too soon, before the joints have had time to set and harden.

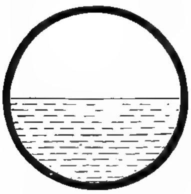

FIG. 3484.—Circular-shaped Sewer.

Concrete and artificial stone have been used, but not very extensively, nor with much success.

Wood. The too common practice of using wooden box-drains must be condemned, unless as a temporary makeshift. Sometimes a form of barrel-drain, bound with metallic hoops, is used. This protest against box-drains might seem to be superfluous; but it is not more than five years since it was found that, in a city afflicted with an epidemic of typhoid fever, one of the main sewers was a box-drain, with no bottom (except the earth), the sides being held together by pieces of scantling laid on the earth. With this were connected the drains of cesspools and houses, some of the latter of wood and untrapped.

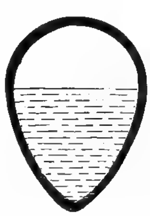

FIG. 3485.—Ovate-shaped Sewer.

The *shape* of sewers is a very important consideration, and must vary according as the flow is expected to be equable or variable; if equable, the circular form (Fig. 3484) is to be preferred, because it gives the greatest capacity with the least expense of wall. Hence it is almost exclusively used in the separate system of sewerage. If the flow is variable, the ovate shape gives the advantage of the deep narrow stream; and when the quantity of sewage is small, deposit is less apt to take place. Hence the use of this shape in the combined system. In old times sewers had to be cleaned out by scavengers, with the same regularity as chimneys were swept. The bottoms were broad, flat, and uneven; the slow, sluggish streams allowed deposits to be formed, which quickly increased by their own impeding action. The same plan is commonly followed with box-drains (Fig. 3486). In cases where they are employed (and it should only be temporarily), they should be set angle down, so as to give the fluid its greatest possible depth and force, and prevent deposit.

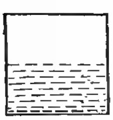

FIG. 3486.—Box-drain laid flat, with Deposit accumulating.

Joints have been incidentally described above as regards their modes of formation, when a description was given of sewer-pipes. They should be true fitting, so as to prevent gaps out of which the cement or clay may fall or be forced. Care should also be taken to prevent the apposed ends from losing their concentricity when laid: if the joints be fitted with puddling-clay or other soft material, this will give way under the downward pressure of the small end of the pipe, until this latter rests directly on the receiving collar of the next pipe, leaving no space between them on the under wall, but a large gap on the upper (Fig. 3488). This will be especially the case if no spaces have been cut to receive the shoulders. To prevent it the joints should be stuffed with oakum, and then with puddling-clay or cement, or, if the pipes be of iron, with lead, and should be thoroughly calked. This method of making joints will also prevent the filling of cement or lead from running into the inside and forming a nucleus for deposit. It will also help to prevent the intrusion of rootlets of trees, which are apt to insinuate themselves and cause accumulation and choking. Some persons try to kill rootlets by mixing bichloride of mercury in the filling. This is a poor expedient at best.

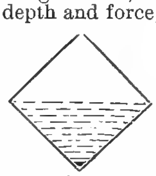

FIG. 3487.—Box-drain placed angle down, so as to avoid Deposit.

FIG. 3488.—Defective Joint; no packing having been used, the spigot end has displaced the cement and left an opening above.

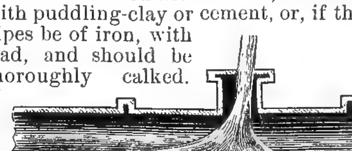

FIG. 3489.—Improper Junction.

Junctions of sewers, whether they are in a vertical or horizontal plane, should not be at right angles (Fig. 3489), as the interruption of the stream and the eddies thus formed will cause deposit which, when once commenced, will rapidly increase. The tributary stream should be made to enter in a course somewhat parallel to that in the main sewer (Fig. 3490).

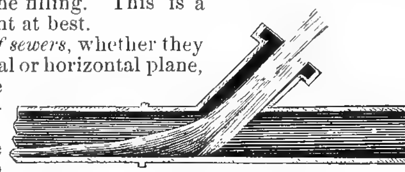

FIG. 3490.—Proper Junction.

For junctions, **Y**-pipes (Figs. 3490 and 3493) and **V**-pipes (Fig. 3492) are manufactured. The use of the **T**-pipe (Fig. 3491) should be for inspection holes and ventilating openings. The **V**-pipe is used where the main drain is made of two branches uniting, and flows in a direction between the lines of the branches; two branches should never run into a third drain with their mouths opposite to each other; one should enter a little lower than the other.

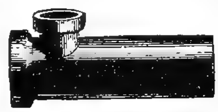

FIG. 3491.—T-pipe, for Use in Ventilating and for Inspection Openings.

Where a small sewer-pipe has to be received into the socket of a larger one, an "increasing-pipe" (Fig. 3494) is used to prevent a bad joint, which would be made if the gap were filled with cement and pieces of brick or stone. Fig. 3495 shows the reverse, or "diminishing-pipe."

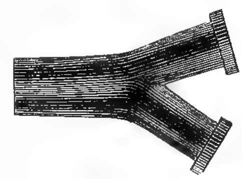

FIG. 3492.—V-pipe, for Junction where the Main Drain runs in a Direction different from that of either Branch.

The *direction* of a sewer should be as straight as possible, so as to retain the velocity. If it requires to be changed, gradual curves should be made. It sometimes happens that an impediment or junction may require a slight deflection. An "offset" (Fig. 3496), or "bends," "quarter-bends," or "elbows" (Fig. 3497), may then be of service.

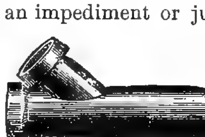

FIG. 3493.—Y-pipe.

The *foundation* or *bed* of a sewer should be firm and solid, so as not to permit of any breaking or disjointing. If pipes are used, small excavations should be made to receive the shoulders, so that these shall not have to bear the whole weight of pipe, contents, and superincumbent earth, with no support to the rest of the pipe, which is then liable to break or crack. Provision should be made for carrying away subsoil water, which is liable to make for the new earth formed in digging the bed of the drain. If the drain lie *in* a porous stratum and *over* an impenetrable one, the chances of the water running along its course will be especially great. Some tiles are made with a subsoil space, porous or perforated, so as to carry off this water. Fig. 3498 represents a sewer made of artificial stone in this way, in which the sewer, *A*, and subsoil space, *B*, are all in one piece; *C*, *C*, *C*, are small orifices through which the subsoil water makes its way into the subsoil space. Invert blocks with subsoil space are also made separately for the bottoms of brick sewers, which are then built upon them.

FIG. 3494.—Increasing-pipe.

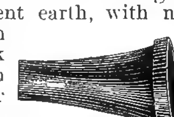

FIG. 3495.—Diminishing-pipe.

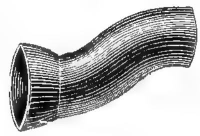

FIG. 3496.—An Offset.

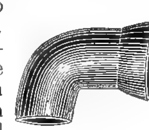

FIG. 3497.—Bend, or Elbow.

Want of attention to the foundation of sewers, especially where tiles are used, is one of the most common causes of deposit and of sewage pollution of the soil; then decompositon occurs, and foul gases are evolved. The writer has seen rows of houses rendered untenantable from the occurrence of diphtheria and other zymotic diseases from this cause. In one instance, where a sewer had been laid in sand, it had to be taken up in less than a year; the sewer had assumed a zigzag outline, and the tiles were choked with sand and sewage.

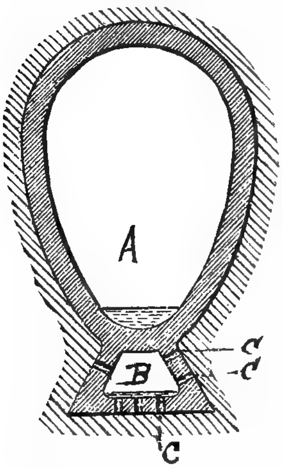

FIG. 3498.—Sewer-pipe of Artificial Stone, with Subsoil Space.

The *velocity of the stream* in sewers is dependent, not only upon the slope or fall, but also upon the shape, size, smoothness, and evenness of surface and the volume and equableness of flow. The ordinary velocity required will also depend upon the nature of the matters to be carried and the facilities for flushing. Some of these interdependent points have already been considered.

The *size of the sewer* requires careful consideration on the part of the engineer. If the sewers are too small there will be flooding of the connections with the lower portion of the insufficient sewer or system of sewers; if too large there is needless expense, and, what is of greater importance, there may be deposit from sluggish flow, and there will be a larger space for sewage exhalations to form in. I know of an institution with about five hundred inmates, situated about one hundred yards from the edge of one of our great lakes, which has two five-foot brick sewers to carry off its sewage! They were built in the good old times, and by convict labor. Fortunately, they had a short and rapid fall. The invert of one of them subsequently made a good foundation for a one-foot tile sewer which was recommended to be put in.

It has been found by experience that it is not well to have sewers for a mixed population smaller than nine inches, as they are very liable to obstruction. In Memphis, I am informed by Colonel Merriwether, City Engineer, that it is a common thing to find them obstructed by the carpenter's rule with its six-inch joints.

Mr. Baldwin Latham, in his work on "Sanitary Engineering," gives formulæ and tables for computing the velocity in sewers of various slope, size, and volume. He also states the results of a number of experiments for determining the carrying power of sewer-streams. From these it would appear that, for efficient house-drains, a velocity of three feet per second is necessary; and that this would require, in a nine-inch drain, a fall of 1 in 206; in a six-inch, 1 in 137; and in a four-inch, 1 in 92; and it is presupposed that the drains would run half full. The quantities of sewage discharged under these circumstances will be 39.76, 17.66, and 7.85 cubic feet, respectively. When running full they are capable of discharging double these amounts, but the velocity and scouring force will not receive any further increase. The point to be borne in mind is, that if the sewers cannot obtain sufficient fluid to half fill them, the slope must be greater. In the case of street-sewers it will be evident, on consideration, that it is in the upper ends that the least volume of sewage will be found, and hence the most natural position for flushing apparatus—the head of the sewer—is that where it is most needed; the size, too, may here be less, and this will add to the facility for flushing.

For *flushing*, various devices are in use. One very extensively employed is Field's automatic flush-tank, represented and described in the article on Sewage, Disposal of (see Fig. 3475). Somewhat similar is Van Vranken's flush-tank (Fig. 3499). The lower end of the longer or descending limb of the siphon is constantly immersed in water contained in a small tilting-tank, hung in a chamber below the bottom of the main tank. The drain is connected with this chamber. When the water rises in the main tank as high as the arch of the siphon and trickles over into the tilting-tank, the centre of gravity in the latter is changed, and it tilts over to the position shown by the dotted lines; the level of the water in it is suddenly lowered about an inch, and this starts the siphon action by which the main-tank is rapidly emptied. With both these tanks the intention is to allow them to fill slowly by a small trickle of water; by experience this can be so adjusted as to fill them once or twice in the twenty-four hours. In some places suspended matter in the water interferes with this intention. The tanks hold from one to two hundred gallons each. It is found that only about two per cent. of the total water-supply is required for flushing.

In valve-tanks (such as Pierson's tank) the valve is displaced from the outlet by a float attachment. In collapsing-tanks the sides collapse by the sudden filling and sinking of a floating vessel.

Large tilting-tanks and flushing-gates are also employed. They may be operated by automatic mechanism.

Flushing-gates are sometimes placed in the courses of sewers at long distances from their heads, the sewage itself being the flushing medium. It should be borne in mind that such an arrangement is liable to cause deposit above the gate, and that the scouring action is exerted below, and not to any appreciable extent above, the point where it is situated. Hence this method is not to be recommended.

In some sewers, where only a very slight fall can be obtained, flushing all along the line of the sewer has to be resorted to. In Chicago, for example, a "pill" (to be explained presently) is placed just above the man-hole opening, and the contents of a flushing-cart are poured down the latter into the sewer.

Cleansing of sewers by other methods has sometimes to be resorted to, notwithstanding the fact that the aim of sanitary engineers is to so construct them that they shall be self-cleansing. To facilitate the task of keeping

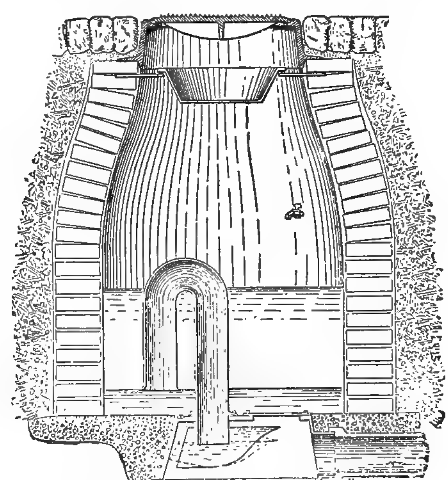

FIG. 3499.—Van Vranken's Flush-tank.

sewers clean, man-holes, inspection openings, lamp-holes, and cleansing openings are constructed.

Fig. 3500, copied from Dr. Ford's article in Buck's "Hygiene," shows a form of man-hole with ventilating grating and dirt-box adopted by Mr. Denton. It is provided with steps for descending to the sewer-pipe with which it is connected.

Another form of man-hole and ventilator (Fig. 3501) will be described when we come to speak of the ventila-

tion of sewers. The object of these man-holes is for workmen to descend, inspect the sewers, and cleanse them. This is done by means of various kinds of scrapers, rakes, hoes, drills, screws, balls, brushes, hooks, etc., which may be mounted on jointed rods such as those used by chimney-sweeps. Even with the sewers of the separate system, specially designed to avoid deposit, and flushed daily, it is found necessary, in Memphis and elsewhere, to use periodically the "pill" and brush. The "pill" is a hollow water-tight globe of thin metal, made three inches smaller in diameter than the sewer. The end of a rope is attached to a staple on one side of the pill, which is lowered down a man-hole or inspection-opening into the sewer and allowed to float (still held by the rope) down to the next opening. The pill may be held, or drawn back a little, at any point, and the volume of fluid, being obliged to pass through the three-inch crescent beneath it, will scour away any movable deposit. As soon as the pill reaches the next opening, a brush may be attached to the other end of the rope at the opening above, and drawn through the portion of sewer which has just been traversed by the pill.

Observation- or inspection-openings have been sufficiently explained in the above description. They are, of course, smaller than man-holes.

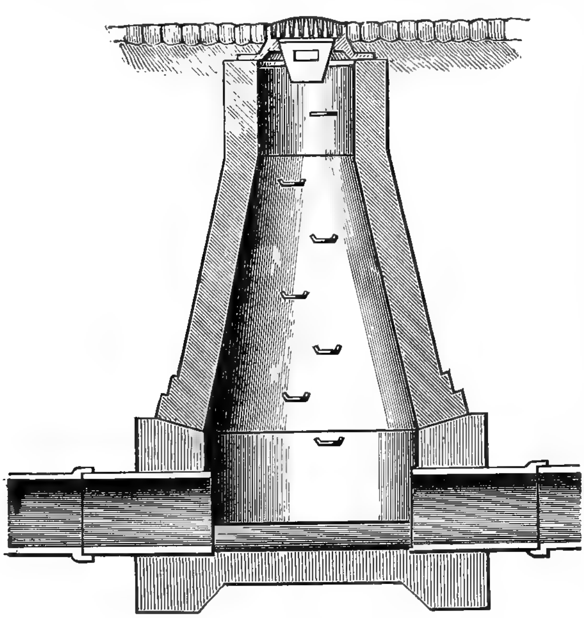

FIG. 3500.—Man-hole Connected with Pipe-sewer.

Lamp-holes are still smaller; they are generally constructed at no great distance from the man-holes, and are for the purpose of literally throwing light upon the intervening portion of sewer. The absence of light will indicate complete obstruction.

Sometimes cleansing- and flushing-openings are made to enter the sewer at obtuse angles with the portions below them. In this way a flushing-hose or cleansing-tool may be introduced through a comparatively small and inexpensive opening.

In some of the older sewers of the combined system, pits have been left in the invert at the bottom of the man-holes, for the purpose of collecting, and periodically removing, deposit. This is not to be recommended, as it favors deposit, which, if neglected, forms a nucleus, and which by its decomposition gives off offensive and injurious gases rising into the street. Similar pits are also made, in the course of the small sewers of the separate system, below stables and other points where obstructions have, in the experience of the officers, been found to result from the habits of careless people. The writer has seen plans of these, with their contents graphically depicted, and labelled as "Sardines," etc. (the "Sardines" were empty boxes, of course). Care must be taken to have these pits frequently inspected and cleansed.

In some of the large Paris sewers trucks were made to run, with the wheels on platforms, on each side of, and above, the sewage-channel, while a sort of gate the shape of the sewer-channel dips into it; this is carried along by the sewage and shoves deposit in front of it, while it also carries along the truck to which it is attached. When the deposit in front obstructs the action of the gate, the dirt is scooped up into the truck.

Ventilation of Sewers.—I have endeavored to point out the methods in the construction of sewers by which we are to avoid the retention of decomposable material, and to so cleanse the sewers that foul gases will be reduced to a minimum. But it has at the same time been made manifest that we are still liable to their formation.

Among the gases more commonly evolved from sewers may be mentioned sulphuretted hydrogen, carbonic acid, carburetted hydrogen, nitrogen, and ammonia. Many cases of asphyxiation in sewers and cess-pits are on record; no less than eight deaths from this cause occurred in the sewers of Chicago in one year.

The rise and fall of sewage, with the alternate wetting and drying of the walls of the sewers, cause a continual evolution of vapor. It is no conclusive proof of the absence of sewer-gases that they cannot be perceived by the sense of smell. Some injurious gases reveal themselves unpleasantly to the nose, while others do not. These last are so insidious in their nature as to be doubly dangerous. As examples, the baneful results which ensue from living in houses under which water lodges and becomes stagnant may be referred to. There are few medical practitioners who have not witnessed these results. The miasmatic poison of ague is inodorous, or has no necessarily unpleasant odor. In like manner sewers have sometimes very little unpleasant smell. Sometimes there is a smell somewhat similar to that produced by those burning fluids into the composition of which fusel-oil enters. We must be very careful, therefore, how we accept negative evidence as to the presence of noxious gases. In the experience of most practitioners, living in sewered districts, instances are common of the occurrence of zymotic diseases, clearly traceable to the presence of sewer-gases, where there has been little or no unpleasant smell. I am not aware of any appreciable odor from the contagia of scarlatina and measles, and yet they act through the medium of the atmosphere. One or two specific instances, in proof of what has now been stated, may be mentioned when we come to speak of some particular defects in sewerage. It is evident, then, that every care must be used to establish a thorough ventilation of sewers, and to secure it in such a way that the gaseous contents shall not, in making their exit, come in contact with human beings. Too often, and by too many avenues, they find their way into dwelling-rooms. How this should be avoided has been pointed out in the article on Habitations. It falls within the scope of the present article to point out the means commonly employed for the ventilation of sewers, the pneumatic forces which are at work in them, and the means which, in the opinion of the writer, should be adopted to change the air in them as frequently as possible.

It will be found that most of the agencies at work in sewers are variable and alternating in their action, sometimes drawing air into the sewer, and sometimes expelling gas through the same opening. The principal of these agencies are, besides the natural diffusion of gases, the following:

Difference of temperature between sewer and external air, causing an interchange in accordance with the laws which regulate the movements of unequal weights of air.

Upward draught in houses, acting as a ventilating shaft, in the wake of which the sewer-air will follow if allowed; sometimes a full flow of water down into the sewer will cause a current of air to accompany it.

The expansion force created by the sudden accession

Sewerage.

of heat in the drain, viz., by pouring down hot soap-suds of boiling water. This expansion is equal to 1 volume in 491 for each degree of Fahrenheit. As air expands the pressure is increased. If the temperature of the air in the drain be raised from 50° to 150°, the result will be

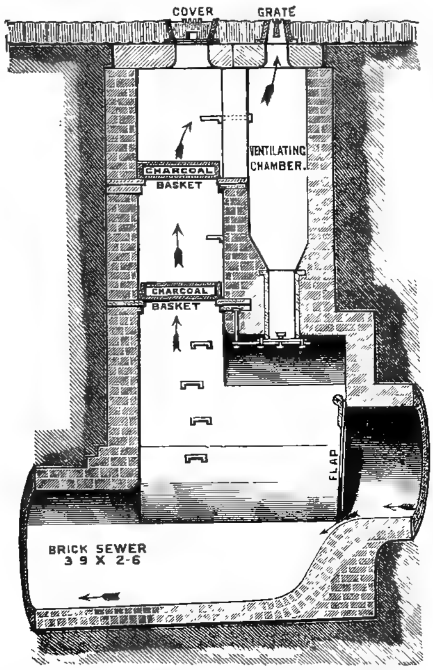

Fig. 3501.—Rawlinson's Manhole Charcoal Ventilator, and Tumbling-bay.

pressure equal to that of $6\frac{7}{10}$ feet head of water. And this rise of temperature is not at all an improbable one.

The flow of water into the drain causes an expulsive force. When water is poured into a drain it must, of course, displace its own bulk of air (less the small amount gained by compression), for two bodies cannot occupy the same space at the same time. Out of which end of the drain (supposing that it has no ventilator) this air shall pass will be determined by circumstances; it passes most readily where it meets with least resistance, always giving preference to an upward direction, owing to the greater gravity of the water. Storm-water suddenly filling the sewers acts powerfully in this way. This ebb and flow operate like a double-acting piston or syringe. Partial choking of the drain gives rise to confined air constantly increasing, expanding, and being displaced. Tides have a similar action. Wind blowing up the mouth of a sewer will drive gases before it; wind blowing across its mouth will often produce a down current.

From the rising of sewer-gases to the upper ends of sewers the higher, and at one time more healthy, portions of towns and cities have sometimes compared badly with the lower portions which have been improved *pari passu*.

Until lately the principal dependence for the ventilation of sewers has been on the ventilating gratings in the road-bed, both as inlets and outlets. Sanitary engineers, having experienced the necessity of deodorizing the air exhaled from the sewers, have invented and patented ventilators containing charcoal. One of these, Mr. Rawlinson's, is shown in Fig. 3501, which is copied from Dr. Ford's paper in Buck's "Hygiene." An inspection of the diagram shows the course taken by the sewer-gas. The man-hole has a tight cover to keep the charcoal dry. Below the ventilating chamber is a space for collecting the dirt which falls in, and which may be removed by unscrewing the plate at the bottom of the space. The flap-valve and bay are for the purpose of directing the gas up the ventilator, and the tumbling-bay is for the purpose of getting rid automatically of any deposit which may be caused behind the flap-valve.

Mr. Baldwin Latham gives a figure and description of a spiral charcoal ventilator (Fig. 3502), invented and thus described by him:

"The larger sizes combine in themselves man-hole cover, lamp-hole, and ventilator, while the smaller sizes fulfil the two last offices. Each of the large ventilators consists of four parts:

"1st. The frame *a*, for receiving the cover, and on the bottom of which hangs the dirt-box and charcoal ventilator.

"2d. The cover *C*, the centre part of which is solid, so as to form an efficient cover for the charcoal and protect it from rain, or the water used in street watering; *g* is the open grating in the cover by which air escapes or is drawn into the sewers. The openings of this grating are arranged concentrically, and are formed with the aperture wider below than at the street level, so that mud is not likely to adhere, or, if it does, is soon removed and falls directly into the dirt-box immediately below the grating. The cover in the illustration is shown filled in with wooden blocks (placed endways of the grain), for deadening the sound and giving an efficient foothold for horses. The covers, however, may be filled with any other suitable material, such as stone, concrete, or asphalt.

"3d. The dirt-box *d* hangs in a groove, *x*, made in the lower part of the frame *a*. The dirt-box is circular on plan, and the groove *x* is intended to be filled with fine sand. The weight of the dirt-box and ventilator pressing into the sand forms a gas-tight joint; *h*, *h'*, are handles attached to the dirt-box for raising or lowering it; *S* represents an open spiral trough which forms part of the dirt-box, and which is used for conveying away the overflow-water from the dirt-box to the sewer; *o* is a slot in the side of the dirt-box, communicating with the upper portion of the spiral trough, through which the water enters the trough.

"4th. The spiral trays *t*, for containing the charcoal, which are screwed into the ventilator over the spiral

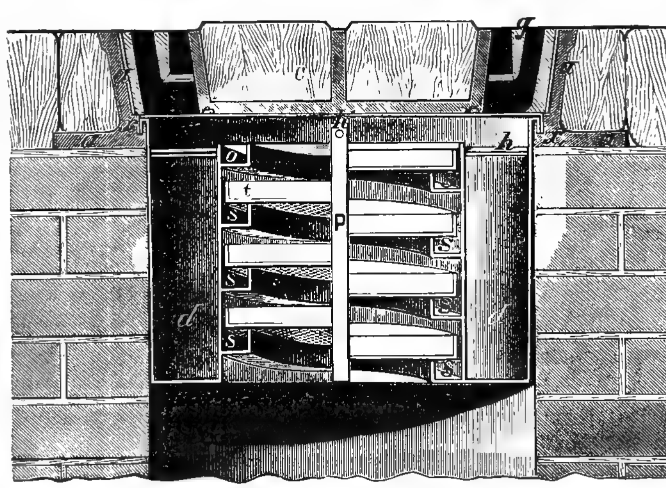

Fig. 3502.—Latham's Charcoal Ventilator.

trough *S*, by means of the handle *h*. Each tray consists of a central shaft *P*, which is square, and out of every face project arms of **T**-iron. These arms are attached at the extremities by a strip of iron coiled spirally, and the bottom of the trays is filled in with network.

"To recapitulate the advantages of this ventilator: 1. That, should the charcoal concrete in the tray, or if its pores are stopped with dust, no impediment is offered to

ventilation, as there exists a free communication between the sewer and the external atmosphere. 2. That the charcoal is completely protected from rain or water entering the ventilator or leaking through the joints of the cover, consequently it will retain its efficiency for a long period. 3. That the passage provided for the overflow-water from the dirt-box is not dependent upon traps, or any other uncertain device needing assistance to maintain it in perfect working order. 4. The escaping vapors are all brought in contact with the charcoal, it being impossible for any to escape by the sides of the tray or in any other way."

These charcoal ventilators are now mostly discarded as impeding the passage of air, and the contention of engineers often is that they are generally inlets; but the frequent stench, and the steaming exhalations from them in heavy winter days—exhalations through which our boys delight to run—do not support this contention, but rather go to show that the surface of the road-bed, amid the traffic of street passengers, is not a safe place in which to discharge these gases.*

As regards charcoal trays, even were the charcoal constantly dry, sewer-gas at times makes its exit too rapidly for the charcoal to exert any action upon it; so that, however useful an adjunct charcoal may be, it cannot be considered a preventive to the injurious effects of sewer-gas, and we cannot rely upon it as a germicide.

At one time it was a common practice to have the openings from the gutters untrapped; but as these openings were noticed to be very offensive, and were nearer to the foot-walks, they have been provided with traps. (See below.)

Laying aside the propriety of having such a point of escape for sewer-gases, it will be evident on consideration that the size of the street-gratings is insufficient, even when they are open; in our northern climate many of them are at times closed for weeks together, and they are often partially clogged with mud. But even when open, their interstices, if combined, would yield about forty-nine square inches, and if allowance be made for friction in the little openings, their carrying capacity would be about equal to that of a five- or six-inch pipe, and this to ventilate a length of six hundred feet (the distance given by Mr. Latham) of average street sewer.

Hence, it seems evident to me that the principle which is now being advised and adopted by leading sanitarians and architects, for the safety of the individual householder in regard to his house-drain, ought to be advised and adopted by sanitarians and engineers for the safety of the whole community in regard to the street sewers. A four- or five-inch pipe should be carried from every house-drain to the roof of the house which the drain is intended to serve, and should discharge the sewer-gas at a sufficient distance from all chimneys, windows, doors, or other openings into the house. Between this pipe and the sewer no trap should intervene. And this is the plan now generally adopted in Memphis and some other places, sewered on the separate system, there being no trap, save in exceptional instances, between the sewer and the soil-pipe extended above the roof. In the state of plumbing practice still in existence in many places, it would, in my opinion, be better to have a trap between the pipe and the house, provided that, in addition to the extension upward from the soil-pipe there is another four-inch pipe, forming a counter-opening and allowing a current of air to circulate freely through the house-drain and its connections and vents; but wherever good plumbing and rigid inspection are insisted upon, this multiplicity of pipes and traps could, and should, be done away with. There would then be a direct passage from the sewer to a point above the roof, carefully removed from chimneys, doors, windows, and all other openings into the house. Colonel Waring is a strong advocate for the abolition of traps on house-drains, contending that they impede ventilation and are themselves sources of danger.

It must be borne in mind that by the plan advocated the air allowed to escape through the soil-pipe (or outside vent-pipe) is not the same concentrated foul gas that often arises through street-gratings, for the number of openings, each of them almost of the same capacity as a (subdivided) manhole-grating, is so great that the gas is very much diluted; in a closely built street, with houses on each side of from twenty-five to fifty feet front, there will be one such opening for every twelve to twenty-five feet—instead of every six hundred feet, the limit for street-gratings given by Mr. Latham. Of course, this system, when adopted, should be made general. In places already sewered it could be introduced by the corporation authorities putting in ventilating pipes at such distances as would give some relief, and passing a law requiring that every new house-drain, and every drain that shall need to be reopened, be ventilated in this way, and that within a reasonable time the same shall be the case with all house-drains.

It has been objected that, inasmuch as house-drains do not usually enter the sewer at the highest point of the latter, there is a space in the crown of the street sewer that cannot be ventilated through the house-drain when the water in the sewer is higher than the mouth of the drain. To this I would answer that the air being confined to the crown of the sewer, its temporary stagnation during the time of flood-water will do no harm to anybody; if the pressure becomes very great the gases will be dislodged and will be carried off at a point higher up the line of sewer, where the drains are not water-locked; it is only at times that the house-drains will be so full as not to allow of counter-currents and through-drafts; and there is nothing to prevent the house-drains from entering sewers close to the crown, if so designed.

It has also been objected that air will not enter the sewers down the long stand-pipes; so long as the gas, when it does move, moves off overhead, we need not so very much mind its remaining in the sewer for a short time. But, as a matter of fact, a careful consideration of pneumatic laws and of the forces acting in sewers will show that the objection does not hold. The columns of gas or air on opposite sides of the street, if they are of the same temperature and density, will counterbalance each other; but let the sun shine on one side, and immediately an ascensional action begins; or let a cold wind blow on the other, and a dense column begins to descend. Besides, the rising and falling of the liquid in the sewer will cause the gas to be expelled, or the air to be drawn in. Again, the air will blow up the sewers from their mouths; and, for this reason, flaps should never be placed on the mouths—free vents being made all along the course of the sewer—although the contrary practice is recommended by some engineers.

Various contrivances for propelling air into sewers and extracting gases from them, such as fans, pumps, steam-jets, and furnace chimneys, have been employed. They are costly, and, alone, are insufficient and unsatisfactory. When plenty of free vents and good traps exist they are unnecessary, and when these do not exist they are dangerous, inasmuch as such propulsion will force traps, and such extraction will empty them by suction where free vents do not exist.

The true plan seems to be to make plenty of breathing-holes, plenty of channels through which currents will continually pass, and which will discharge gases at a safe distance overhead.

In many of our larger cities sewer ventilation is quite insufficient and faulty, and much apathy—or rather a want of appreciation of correct principles—is found in regard thereto. It has therefore been thought a subject which should receive here a full consideration.

Yard- and Gully-traps.—In discussing the means to be adopted inside of houses to secure the exclusion of sewer-gases from dwelling-rooms, various forms of traps

* On the day after the above was written the writer was called to visit a patient living near the head of a street in one of the finest districts of the city. Persons residing in the neighborhood have made loud complaints regarding the stench arising from several man-holes in this street and a street which crosses the head of it. At times, when a south wind is blowing, windows are kept shut and children cannot be allowed out to play in the immediate locality. Complaints have been made to the Medical Health Office regarding the matter. Numerous other instances of this kind might be reported did space permit.

Sewerage.

have been described, and the methods and principles by which their efficiency is to be maintained have been dealt

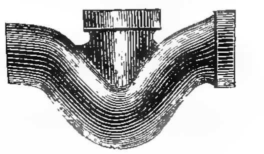

FIG. 3503.—Trap with "Hand-hole" in Centre; not suitable for drain with floating filth.

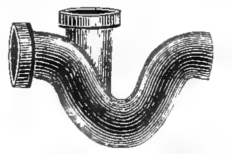

FIG. 3504.—Trap with Hand-hole on the Upper Side of the Seal.

with. (See Habitations: General Principles of Plumbing.)

In dealing with the means of excluding sewer-gases from frequented places out of doors, it only remains, therefore, to describe some forms of traps applicable to these places. Fig. 3503 shows a form of glazed-tile trap very suitable for a drain conveying rain or other water free from floating filth. Pipes may be brought from the hand-hole in the centre up above the ground-level, for the purpose of observing and removing deposit.

FIG. 3505.—Trap with Hand-hole below the Seal.

Filth in such a trap might remain floating for a long time in the hand-hole above the current, and hence it is not suitable for a house-drain.

Figs. 3504 and 3505 show traps more suitable for conveying floating filth. If the hand-holes are to be used merely for removing obstructions (should they occur), their sockets should be plugged and cemented; by means of pipes the openings may be brought up within a foot or two of the surface. But these hand-holes may also be used for purposes of ventilation, and for protecting the seals of the traps from accidents explained in connection with house-traps, due care being exercised as regards securing a sufficient supply of water.

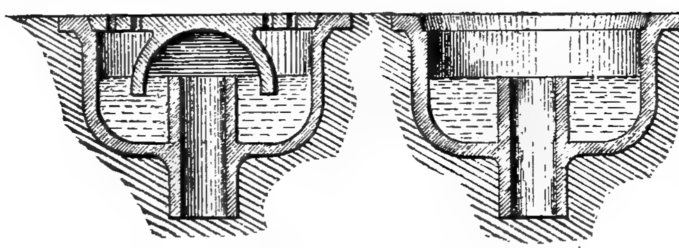

FIG. 3506.—Bell-trap Sealed and Unsealed.

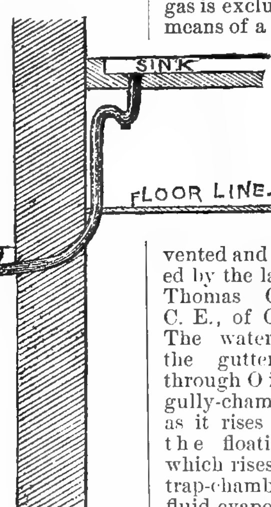
Fig. 3506 represents a "bell-trap;" to the left it is seen with the seal perfect, and in the centre the seal is broken, the "bell" (to the right) having been lifted out. This constitutes a great objection to the bell-trap; the grating becomes clogged, or the space below becomes filled with dirt, and the bell is taken out, and by careless persons not replaced. If it is so fastened down that it cannot be removed, the dirt in the box around the mouth of the descending pipe collects and decomposes. It is better to use the forms of traps already described, protecting them with a grating. Masonry or wooden traps may be constructed on the "mid-feather" principle, with partitions extending vertically across the drain and dipping down from the crown into the trap-chamber, between the points of entrance and discharge.



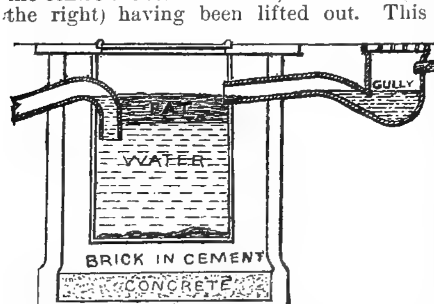


FIG. 3507.—Intercepting Grease-chamber, with Disconnecting Gully-trap.

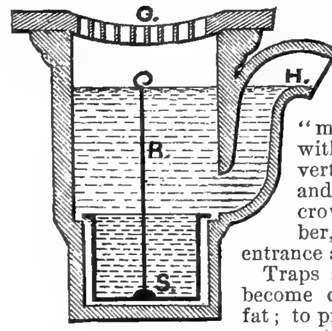

FIG. 3508.—Dean's Yard- or Gully-trap.

Traps and drains are liable to become choked with congealed fat; to prevent this, grease-traps are sometimes employed. A form of grease-trap is shown in Fig. 3507, copied from a paper in "Our Homes," by Mr. William Eassie, an English engineer. To the left may be seen the grease-chamber, closed by a cover, which may be removed in order to skim off the floating fat. This chamber should be ventilated by a pipe or pipes, carried to a safe position away from openings into the house. In the centre is seen a gully-trap for taking surface-water from the yard, and also for disconnecting the sink-waste outside the house. This "disconnection" is, of course, unsuited to the climate of the northern portions of our continent, but in England it is common to disconnect the house-drainage just outside the house.

Fig. 3508, from the same work, shows Dean's yard- or gully-trap, which contains a box, S, for catching any dirt that may drop through the grating G. To the box is attached a rod, R, by which it may be lifted out when it is necessary to empty it. H is the discharge-pipe.

Fig. 3509 represents a street-gully, from which sewer-gas is excluded by means of a trap invented and patented by the late Mr. Thomas Guérin, C. E., of Ottawa. The water from the gutter runs through O into the gully-chamber C; as it rises it lifts the floating V, which rises in the trap-chamber A, and permits the fluid to escape. As the fluid evaporates, or if it leaks away, the plug falls back into its seat. The plug being conical in its lower portion, R (Fig. 3510, which is an enlarged view of the trap only), any backward pressure of gas drives it more firmly into its seat. It is made of wood tipped with brass, and is furnished with a small hook for lifting it out. The

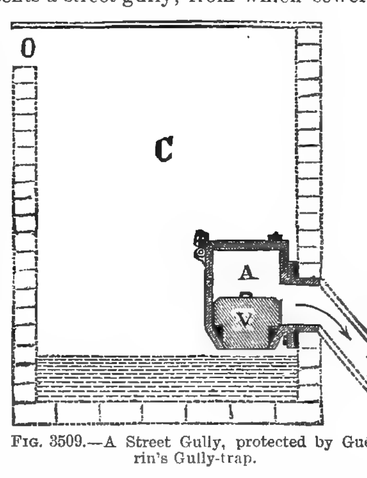

FIG. 3509.—A Street Gully, protected by Guérin's Gully-trap.

trap-chamber is of iron, and fitted with a tight movable cover, X. A trap of this kind will obviate the dangerous, and sometimes disgusting, vapor which we frequently notice from unsealed gullies.

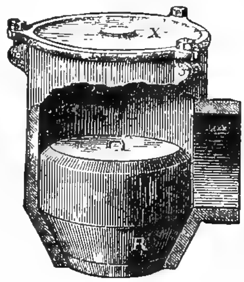

Fig. 3510. — Guérin's Gully-trap. (Larger View.)

Dry Traps.—The principle of dry traps is illustrated in Fig. 3511. Fig. 3512 represents the same style of trap, with a coupling clamp attachment. In these traps the flap is hung without bolt or pin, by being hooked on to two little projecting pieces above the circular opening which it is intended to close. The trap thus formed is inserted into the socket end of any pipe and kept in place by the spigot end of the next pipe above. Its place in a system of sewerage may be tersely described by a certificate given by the writer in 1878, and which he hardly expected would be deemed sufficiently meritorious for publication. Perhaps the patentee valued it as bearing a stamp of dubious honesty on the face of it :

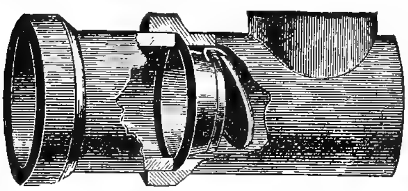

Fig. 3511.—Palmer's Trap.

"The best method of preventing reflux of sewer-gas is, in my opinion, a good water-trap, with sufficient seal, sufficient vent and ventilation, and frequent change of its fluid contents. Where these conditions cannot be obtained, then resort must be had to a *dry trap*, and the very best of these I have ever seen is Palmer's trap."

I am glad to be able to refer now to what escaped me at that time, viz., its power of preventing reflux of back water from sewers into cellars in low-lying districts. One great reason for the preference of water-traps over dry traps is the tendency of the latter to become foul and clogged with deposit, and the liability of their mechanism to become ineffective by reason of rust, dirt, and the interference of solid bodies.

Weeping drains, for draining the subsoil of houses, should not be laid inside the foundation, if it can possibly be avoided. The subsoil of houses, or blocks of houses, can generally be drained by porous tiles laid outside, so as to surround the foundation-walls at a sufficient depth below the level of the cellar floors. When the builder or owner of any particular house cannot accomplish this, he should be careful to provide the trap interposed below the weeping drains with some slight automatic water-supply, so that its contents shall be frequently changed. Sickness arising from want of attention to this particular is common ; the supply of subsoil water ceases, the traps become dry, and sewer-gas passes up into the house. Two examples may be cited. Becoming convinced that there was something wrong with the drainage of a house in which I was attending several members of a family showing symptoms of low fever, I requested a thorough examination to be made. There was no smell of sewer-gas, but on raising the board cover of a trap in the furnace-cellar over which the weeping drains emptied, a blast of air shot upward. Five members of this family were prostrated by typhoid fever. The other instance was in a house where diphtheria persisted in remaining, and recurring ; the weeping drains were found to connect with the sewer (a very foul one), without any traps.

Out-door Closets and Latrines. — That out-door closets and latrines, in connection with the water-carriage system, can be used even in the northern part of this continent, is now established by experience. In the case of careful individuals a hopper-closet, washed while in use by an automatic swirl of water from a valve set below the frost line, may be used ; but when numbers of persons of various classes have to use closets, they cannot be relied upon for care and cleanliness. Latrines should therefore be used to supersede the privy-pit in the densely populated districts in which the water-carriage system is established, unless it is resolved to use the dry system under corporation management. In many places the change from the old system to the new is being gradually made. No new pits are allowed to be dug ; and when any existing one becomes a cause of complaint, it is ordered to be cleaned and disinfected, and filled with fresh earth. These latrines can be controlled by some servant of the corporation, or other person, who shall, from time to time, change their contents and supply them with water. Of the various forms of latrines, the following may be mentioned :

So-called *iron sinks* are manufactured in various cities on this continent, and are being largely introduced. One of them, Mott's Latrine, is shown in Fig. 3513. The hopper, or receptacle, and its corresponding section of drain, are made in one piece, and the several portions of the drain are then connected. The contents are run off periodically by raising a plug at one end of the drain, and the drain and latrines are refilled. When these are situated out-doors, slight artificial heat must be used in winter. These latrines are very moderate in price.

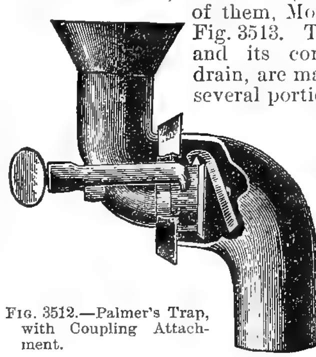

Fig. 3512.—Palmer's Trap, with Coupling Attachment.

The *Liverpool trough-closet* "may be described as consisting of a series of closets communicating with a long trough (*W*), situated beneath and behind the seat, which receives the excreta from each closet in the series. The lower end of the trough communicates with a drain (*D*, Fig. 3514), leading to the sewer by an opening which is closed by a plug (*P*). Behind the back wall of the closet there is a small space to which no one has access but the scavenger, and from which alone the plug can be raised by means of a handle. The scavenger visits the closet daily, empties the trough, washes it out with a hose (*A*) connected with a hydrant, and again charges it with water. As much water is let in as will cover the excreta received during twenty-four hours, and so prevent any smell. The closets are kept clean by the users." *T* represents a trapped overflow from the closet-trough to the drain, to prevent any accident from leakage of the hose-pipe.

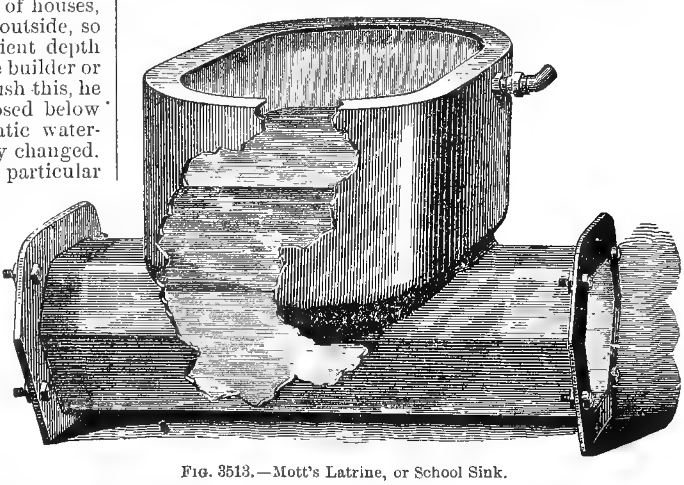

Fig. 3513.—Mott's Latrine, or School Sink.

The Bristol Eject.—This consists of a strongly constructed dip-trap, interposed between the privy-trunk, as the receptacle is termed, and the drain. It thus admits of the ready extraction of foreign matters which may be thrown in; it is not easily broken; and, as it is flushed and kept clean by the servants of the corporation, it is found to answer much better than ordinary water-closets among the poorer classes of large towns.

Other forms of latrines, on the same principle, are thus spoken of in Wilson's "Handbook of Hygiene:" "For barracks, prisons, etc., water-latrines of a much simpler construction than either of the above answer exceedingly well. An open metal trough, roofed in, and with the necessary partitions and doors, receives the excreta, while its anterior upper margin constitutes the seat. In order that the excreta may be constantly covered, the trough should be kept one-third full of water. It should also be well flushed at least twice daily, and the contents allowed to run off into a drain connected with a sewer. A plug, or flap-door, at the lower end of the trough, will be required to prevent the water from draining off at intervals.

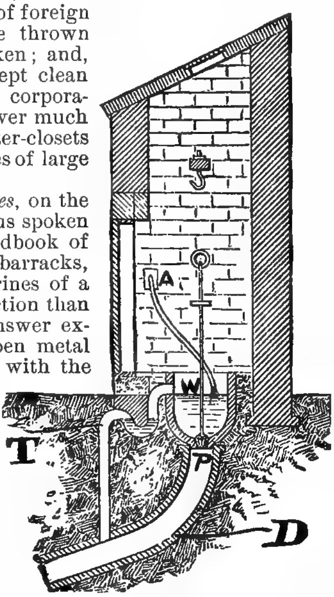

FIG. 3514.—Liverpool Trough-closet.

"There is a further advantage, common to all closets of the trough system, which may here be pointed out. In the event of an epidemic of cholera or enteric fever raging in the crowded courts where these closets are in use, it will be an easy matter to throw disinfectants into the troughs and thus destroy the infectious power of the alvine discharges."

In some latrines water does not stand in the receptacle, but is admitted daily to sweep out the contents with a sudden flush. Those in which fæces are received into the water, the whole being suddenly let off and flushed, are to be preferred.

If a moderate artificial heat were introduced with the use of such latrines a double gain would be secured. The exposure to severe cold is sometimes very injurious. Not to enter deeply into the subject, let us take the case of a school-child just recovered from scarlet fever, the peeling of the skin having been accomplished; exposure of the skin to severe cold may produce fatal disease of the kidneys. If, however, these conveniences cannot be heated, we must place the water appliances deeply, as is done now with our water-pipes, hydrant-services, and drains, always remembering that the open troughs are more exposed to atmospheric changes of temperature. In this regard great care needs to be exercised.

URINALS become offensive through want of proper provision for preventing the incrustation of them with deposits from the urine, and of proper means of frequently cleansing or removing surfaces which collect the droppings. A tray of ashes or sawdust in front of and beneath the urinal will meet this latter requirement, the contents of the tray being frequently changed. The urinal should have in front a narrow projecting lip. For the first mentioned cause of offensiveness it seems necessary to have a flow of water washing the urinal while in use. For this purpose various automatic contrivances have been arranged, such as the opening of a valve-tap, when a person stands upon a platform in front of the urinal.

INTERCEPTING SEWERS may be divided into those which intercept or receive the whole of the contents of other sewers, and those which intercept only a portion of the contents, allowing the rest to flow on. There is nothing peculiar in the construction of the former. They may be used under various circumstances. For example, a city may be so situated that the sewage of the upper district would flow by gravity to the intended outfall, while that of the lower districts would not; in such case the sewage of the upper district would be collected and carried off to the outfall by an intercepting sewer, the sewage of the lower district being pumped either to the intercepting sewer on the higher level, or directly to the outfall. Or the configuration of the place may be such that the natural drainage of the streets has a very long fall, while there may be a water-course lying at a comparatively short distance to one side; in this case a great saving in the size of the sewers may be effected by intercepting and beginning anew below the intercepting sewer. Or the city may be built on knolls, so that an intercepting sewer becomes a necessity, unless Shone's system (see below) is employed.

Sometimes it is desirable to collect only the more concentrated portion of the sewage, and allow the less impure to flow on, either because the former has to be utilized or pumped, or in order to save expense in the size of the intercepting sewer. How this object may be accomplished is shown in Fig. 3515. The intercepting sewer is seen below the divided invert, *C*, *E*, of the sewer, the concentrated sewage of which is to be intercepted. The ordinary fair-weather flow, and the first impure flush of a rainfall, will drop through the opening *B*,

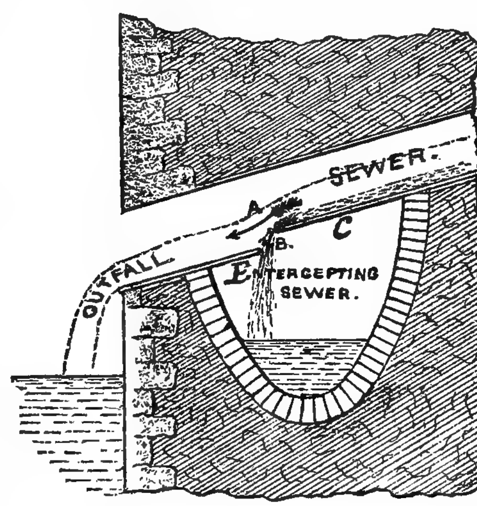

FIG. 3515.—Intercepting Sewer, with Overflow.

while a heavy flow or flood of water will shoot over, as represented by the dotted line *A* in the diagram.

Another example of intercepting sewer is shown in Fig. 3516. The description is taken from an "Account of the Trunk-sewer of Buffalo," by Col. George L. Waring, Jr.: "The connection of the trunk-sewer with the city sewers is shown in Fig. [3516], representing the Porter Avenue interception. The dry-weather flow of the sewer is delivered at an angle of forty-five degrees with the course of the trunk sewer, through a cast-iron pipe two feet in diameter. The bottom of this pipe is one foot above the bottom of the sewer, and its top is one foot below the middle of the sewer.

"For dry weather and light rains this would suffice. In order to secure the introduction of as much as possible of the discharge of the city sewers during heavy storms, it was arranged that its flow should be somewhat stilled in a well over the mouth of the inlet-pipe, to allow the escape of the large volume of air sometimes involved in the rapid current of steep sewers during storms. This is so done as to bring the full head of the intercepted sewer to bear on the inlet.

"So much of the flow as cannot gain access to the

trunk-sewer through the lower inlet, passes on over the vertical well and runs into it through a three-foot opening in its crown. Should the sewer be so full that the entire flow of the intercepted sewer cannot gain admission, the surplus passes on to the canal."

Tidal variations cause much difficulty in connection with outfall sewers; by the ebb and flow of the sewage-laden tide a serious and wide-spread nuisance is often created. And in this connection it should be borne in mind that sewage oxidizes more slowly in

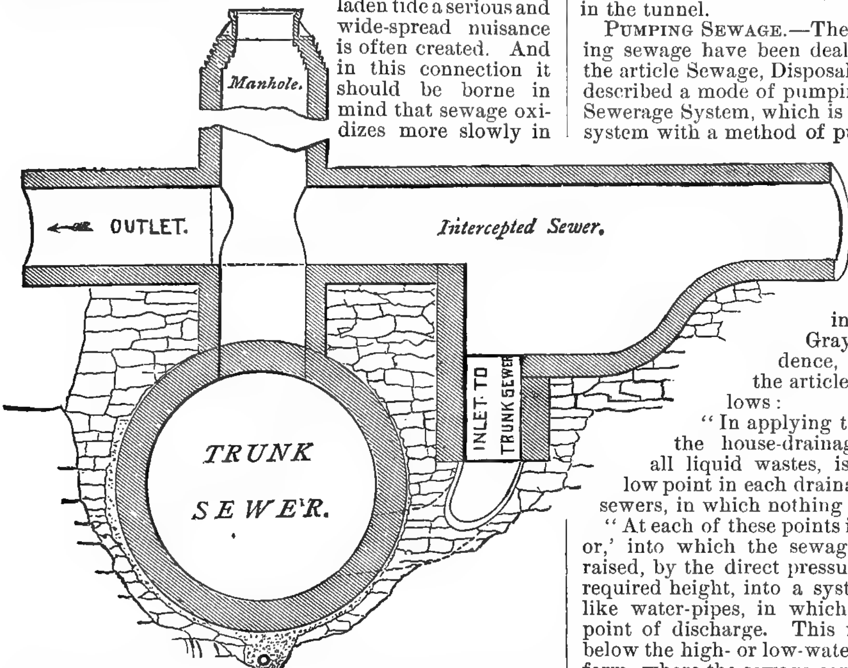

Fig. 3516.—Intercepting Sewer, Porter Avenue, Buffalo, with Overflow.

sea-water than in fresh water. If the sewer discharges continuously on the shore at or near high-water mark, the nuisance is intensified; if it discharges below low-water mark, the rising tide causes a backing up of the sewage and deposit of its solid portions, with all the evils incident to such a condition. It will also, by rising in the sewer, force backward the gases therein contained. To prevent this, flap-valves are often placed on the mouths of such sewers. It is more desirable to make ample vents for discharging the sewer-gases, as before described when speaking of the ventilation of sewers.

Fig. 3517, copied from "Suggestions as to Plans for Main Sewerage," by Robert Rawlinson, C.B., C.E., of the Local Government Board of Great Britain, is a "suggestion" for an outfall adapted to tidal variations. Its

pumping-station, where it is raised to a sufficient height to enable it to flow through a tunnel, over a mile long, beneath Dorchester Bay, to Squantum, and thence through a flume, for another mile, to Moon Island; here it is held in reservoirs and periodically discharged into the outgoing tide. At the pumping-station such straining and subsidence are effected as may be necessary to obviate deposit in the tunnel.

Pumping Sewage.—The ordinary methods of pumping sewage have been dealt with, as far as needs be, in the article Sewage, Disposal of; there now remains to be described a mode of pumping, called Shone's Pneumatic Sewerage System, which is a combination of the separate system with a method of pumping sewage by the direct action of compressed air, the reverse of that employed in the Liernur and Berlier systems. It is the invention of Mr. Isaac Shone, a mining and civil engineer of Wrexham, Wales. It is well described in the report of Mr. Samuel Gray, Civil Engineer, of Providence, R. I. (already referred to in the article on Sewage Disposal), as follows:

"In applying this system to a city or town, the house-drainage, comprising excreta and all liquid wastes, is conducted by gravity to a low point in each drainage district, through ordinary sewers, in which nothing else is permitted to flow.

"At each of these points is situated a 'pneumatic ejector,' into which the sewage flows, and by which it is raised, by the direct pressure of compressed air, to any required height, into a system of cast-iron pipes jointed like water-pipes, in which the sewage is forced to the point of discharge. This may be at the sea-shore, far below the high- or low-water level, or may be at a sewage farm, where the sewage can be applied to the land. Another arrangement is to deliver the sewage from the ejectors into an upper tier of gravity-sewers leading to the outfall. The choice between these two methods depends upon the topography of the locality.

"The air, which forms the motive power of all the ejectors, is compressed at some convenient place by a compressor operated by steam or water power. Thence the compressed air is supplied to the ejectors through small iron pipes laid through the streets.

"The system is confined to the removal of house-

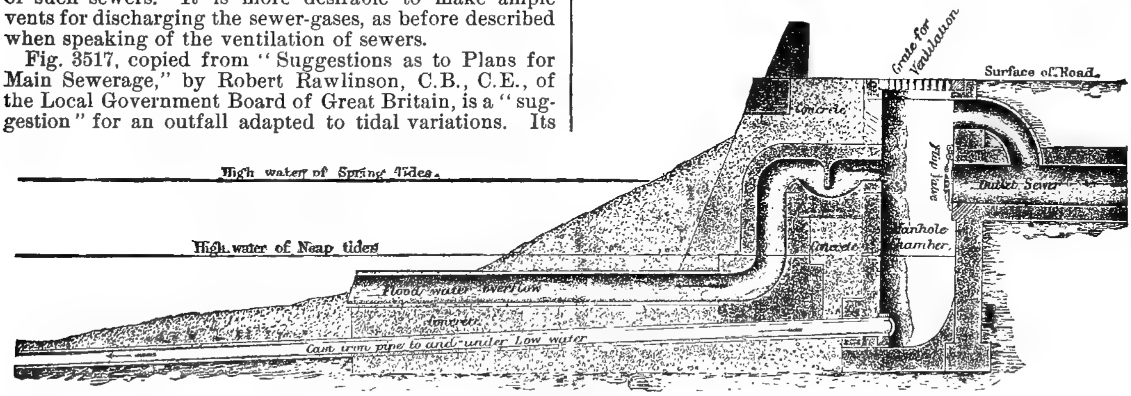

Fig. 3517.

construction is explained by descriptions on the cut itself. It will be noticed that the pipe leading "to and under low-water" is of smaller size and steeper gradient than either the "Outlet Sewer" or "Flood-water Overflow;" the tendency of this would be to prevent deposit.

In Boston the difficulty has been met by building a main sewer (with elaborate overflow and other appliances) which conducts the sewage over three miles to a

sewage, both to prevent its dilution and to render more uniform the volume of liquid to be raised by the ejectors; it being evident that, should storm-water and subsoil drainage be admitted, the ejectors would either be unable at times to perform the work required of them, or would need to be so large that they would not work economically under ordinary conditions. Storm-water and subsoil drainage are therefore expected to be con-

veyed in a distinct system of sewers." . . . "The sewage is discharged from the gravity-sewers into a receiving chamber, from which it passes into a separating chamber, where all floating substances are arrested, and thence into the ejector. Sometimes the sewage passes directly from the gravity-sewers into the ejector." . . . "The action of the ejector is seen in Figs. [3518] and [3519]. Fig. [3518] shows the ejector while it is filling. At the top of the ejector is an automatic-valve apparatus, controlled by a weighted lever. A rod connected with one end of this lever passes through a stuffing-box, and into the interior of the ejector. On this rod is a reversed cup or 'bell,' and connected with its lower end is a weight or 'cup.' While the ejector is filling, the valve marked 2 is held to its seat by the pressure from the rising main, and the valve marked 1 is lifted by the pressure of the inflowing sewage. The air within the ejector passes out through an exhaust-port and pipe to the man-hole or sewer. When the ejector is full, the 'bell' is affected by the buoyancy of the water, and the weighted lever falls, closing the exhaust-port; and immediately afterward opening the inlet-port, admitting compressed air to the interior of the ejector. This action upon the surface of the sewage causes the valve 1, Fig. [3519], to close, and the valve 2 to open and permit the passage of the sewage to the pressure-main in the street at a higher level, to which it is raised by the force of the compressed air. When the sewage has fallen to the bottom of the 'cup' suspended from the valve mechanism, its buoyancy has been withdrawn and the 'cup' falls and reverses the valves, closing the inlet-port and immediately afterward opening the exhaust-port through which the compressed air within the ejector escapes by a pipe leading to the man-hole or to the sewer. The atmospheric pressure being restored within the ejector, the valve 2 closes, and it begins to refill with sewage.

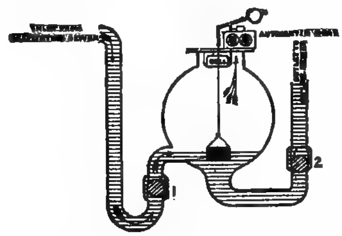

FIG. 3518.—Shone's Ejector, Filling.

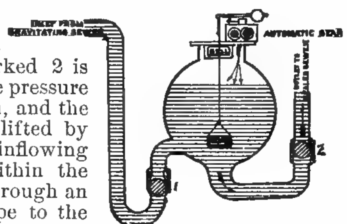

FIG. 3519.—Shone's Ejector, Discharging.

"From this description it will be seen that the Shone system is essentially a method of pumping sewage in detail by means of small pneumatic pumping engines, situated in different parts of the city, all of which are operated by power generated at a single station. The system may be applied to the entire sewerage of a city, or may be confined to special districts, according to circumstances.

"The Shone system is particularly valuable in the sewerage of towns where fall sufficient to produce a proper velocity of flow cannot be obtained, and where it is impracticable to convey the sewage to one general pumping station, since in this system it is not necessary to follow the general topography; but the sewers may be given such grades as may best promote the rapid discharge of the sewage. An ejector may be placed wherever these grades cause the depth of the sewer to be excessive, and the sewage may be raised to a height from which it may flow to the outfall, either under pressure or by gravity. The cost of an equal number of small steam-pumps, with their appurtenances, to do the work done by the ejectors, would be very great."

RELATIVE VALUE OF THE SEPARATE AND COMBINED SYSTEMS.—Of the separate and combined systems of sewerage, the distinctive features and some of the relative merits have, of necessity, been described and discussed under the various details of Sewerage and Sewage Disposal. A brief comparison will therefore be all that is necessary here.

In behalf of the separate system it may be urged:

From a sanitary standpoint, the smooth glazed pipes are less liable to deposit and to acquire a slimy lining.

They can be more fully and readily flushed at will and periodically.

Their smaller size leaves less surface for the exhalation of vapor, less space for its collection, and greater facility for its change by removal.

From an economical standpoint, its cost is very much less, say from $0.75 to $2.00 per foot, as compared with that of the combined system, say from $5.00 to $10.00 per foot, which figures are given by Messrs. Staley and Pierson.

The advocates of the separate system state that street and surface filth should be swept up and removed by some dry method.

That even when the combined system is used for the safe conduct of surface water the sewers are insufficient in time of unusual flood, and flooding of cellars takes place.

By those who hold that the combined system may, under certain circumstances, be the most advisable, it is represented:

That inasmuch as it is well known that excreta only form a small percentage of the filth of sewage, and that street and surface filth form a large percentage, it is necessary to provide for the removal of the latter, and water-carriage is the cheapest and best method of removal.

That in places where the natural drainage fall is lengthy, the volume of water will become so great that subsurface conduits become necessary; and it is only once in years that these volumes become so excessive that flooding of cellars takes place, the fall in the sewer and over the surface generally provided being sufficient to prevent flooding. That flooding is more likely to take place by overflow from the surface, and hence is more liable to occur with the separate system.

That some cities are so flat that surface water would stand in ponds.

That the cost is increased by providing two systems, one for rain- and storm-water, and another for household sewage.

That obstructions in the small pipes of the separate system necessitate frequent excavation down to the sewer.

That in deep cuttings the pipes are liable to be crushed (unless made of iron) and obstruction thus take place.

That two systems of sewer-pipes in the same street are liable to give rise to confusion in making connections and repairs.

There is much force in the arguments for both systems, and perhaps we should not look upon them as opposed arguments on behalf of rival systems, so much as points to be considered in connection with the sewerage of any particular place.

There can be no hesitation in saying that in a place where the surface water can be left to flow off over the surface without flooding houses or impeding traffic, and where it will not cause pollution, the separate system is the best.

Nor can there be much hesitation in saying that in other cases, if we can compass the cost of sewage and storm-water conduits separately, it had better be done.

But it is evident that in each community it is necessary to make a study of all attending circumstances, and we cannot lay down a dogmatic decision to apply to all; we must be guided by principles as applied to the particular circumstances.

There may, too, be a happy medium, as there is in most things; the mode of intercepting only the more concentrated portion of the surface water, that which first flows in, has already been referred to. Another plan, that might with advantage be adopted in places where the surface water is liable to form streams too large to flow over ground all the way to the outfall, would be to admit it in the higher districts into the (combined) sewers, and to exclude from them that in the lower

districts. The advantages of this would be that the upper parts would receive the flushing which they more especially need, the size of the sewer would not increase below to the great extent that it now does, and the volume of surface water from the lower districts only would not be so great.

THE PRESERVATION OF DRAINAGE AND SEWERAGE PLANS is a matter to which I would refer as one of very great importance. Often they are lost or do not pass into the possession of those most interested, the owners of the properties concerned; and a vast amount of time is lost, property destroyed, and mistakes committed, in delving and searching for hidden drains. When our health organizations are firmly established in the relations they should occupy in regard to the sanitary construction of houses, copies of all such plans and specifications should be obtainable from them. When they are not so, and perhaps in any case, these plans should be preserved in the registry offices along with the title-deeds.

In conclusion, I desire to express my thanks to the gentlemen whose names and work have been mentioned in this article, and to any others whose names have been overlooked, but from whom, as contributors to the general fund of information on this subject, I have derived assistance. *Wm. Oldright.*

SEWER-AIR (Sewer-gas). DEFINITION. — Sewer-air, as the name implies, is the air usually found in sewers. It is composed of atmospheric air containing certain gases, vapors, and micro-organisms resulting from the decomposition of sewage and excrementitious matters found therein.

In this article the definition will be extended to include the air of house drain-pipes, privy-vaults, cesspools, and other imperfectly ventilated places containing decomposing animal and vegetable matters.

The term "sewer-gas" is frequently used as synonymous with sewer-air, but it is objectionable, from the fact that it seems to imply that sewers contain a specific gas having a definite chemical composition. Such is not the fact; on the contrary, sewer-air is a mixture of air with other gases and vapors in ever-varying proportions.

COMPOSITION.—In order to understand the composition of sewer-air we must call to mind the composition of sewage, and how the air is contaminated by it. Sewage of cities and large towns consists of water flowing slowly through an underground conduit, and holding, partly in solution and partly in suspension, the excreta of men and animals, refuse from kitchens, grease, soap, the drainage from slaughter-houses, stables, factories, laundries, streets, etc. It is therefore a complex mixture of organic and mineral matters, very prone to putrefactive decomposition. This decomposition is brought about by the agency of the usual putrefactive bacteria, and with the development of carbonic dioxide (CO_2), marsh-gas (CH_4), nitrogen, ammonia, and sulphuretted hydrogen (H_2S).

Letheby found that sewage-water containing 128.8 grains of organic matter per gallon, and excluded from air, evolved, for nine weeks, 1.2 cubic inch of gas per hour, or 28.8 cubic inches per day. The analysis of this gas gave, in 100 parts, by volume:

Marsh-gas	78.83 parts.
Carbon dioxide	15.90 "
Nitrogen	10.19 "
Sulphuretted hydrogen	0.08 "

Similar experiments with sewer-mud in the Seine, by Durand-Claye, gave a gas of the following composition:

Marsh-gas	72.88 per cent.
Carbon dioxide	13.30 " "
Nitrogen	4.58 " "
Carbon monoxide	2.54 " "
Sulphuretted hydrogen	6.70 " "

Such mixtures are never found in an ordinary sewer, as the gases are always mixed to a greater or less extent with air. The quantity of these gases to be found in the air of a sewer will depend upon the composition and the velocity of the movement of the sewage, as well as upon the ventilation of the sewer.

Dr. Letheby gives the following as the average percentage composition of the air of London sewers:

Oxygen	19.51
Nitrogen	79.96
Carbon dioxide	0.53
Marsh-gas	traces
Ammonia	traces
Sulphuretted hydrogen	traces

Professor W. R. Nichols, of Boston, analyzed the air of a badly ventilated sewer in that city, with the following maximum and minimum percentages:

	Maximum.	Minimum.
Oxygen	20.90	20.48
Nitrogen	79.26	78.89
Carbon dioxide	0.50	0.40
Sulphuretted hydrogen	trace	trace

In extreme cases the oxygen has been found as low as 13.79 per cent., the carbon dioxide as high as 3.4, and sulphuretted hydrogen as high as 2.99 per cent. Besides the gases here mentioned, sewer-air always contains bacteria and volatile organic matters, sometimes in large amount. The exact nature of these organic matters is not well understood. Some of them seem to belong to the class of bodies known as compound ammonias, or amines. When sewer-air is shaken up with a dilute solution of potassium permanganate, the organic matter undergoes oxidation at the expense of the oxygen in this salt.

We may form an idea of the amount of organic matter present by the amount of a standard permanganate solution decolorized by a measured volume of the air. Dr. Angus Smith found that the air of a cesspool destroyed two thousand eight hundred and forty times as much permanganate as the same volume of pure air. The air of a house into which sewer-air had penetrated destroyed twenty times as much permanganate solution as the same volume of pure air. These organic matters are probably much more deleterious constituents than those shown by the chemical analyses above quoted. These gases seem to possess considerable diffusive power, and will pass easily through walls and porous earthenware, or brick sewers. In this way these gases frequently find their way into the cellars of houses, especially in the vicinity of a broken sewer or improperly constructed cesspool. Fungi readily grow in such air, and articles of food, such as meat or milk, soon become tainted and decompose when exposed to it. Experience has shown that stagnant sewage gives off more gas, and is more dangerous, than that which is kept in motion. Sewer-drains which have a steep grade are, therefore, to be preferred to those having a slight grade. Where sewers are frequently flushed with water, and where there is no chance for stagnation, with a reasonably good ventilation, the danger from sewer-air is reduced to a minimum.

There are very strong reasons for believing that the specific poisons, or germs, of a number of the contagious diseases may be transmitted by sewer-air. That dysentery, diarrhœa, and periodic fevers are frequently produced by sewer-emanations cannot be doubted. It is also believed that the poisons of typhoid fever, of cholera, and of yellow fever, have been transmitted from house to house by the medium of the sewers. Indeed, the evidence of such transmission amounts almost to a positive proof.

PHYSIOLOGICAL EFFECTS OF SEWER-AIR.—The effects of breathing sewer-air depend upon its composition and upon the degree of dilution. Poisoning by this gas, or mixture of gases, may be acute and rapidly fatal, or chronic, only manifesting itself after weeks or months of exposure. Acute poisoning from breathing sewer-air, or the air of cesspools, privy-vaults, etc., occasionally leads to fatal results. These effects may usually be traced to one of two causes: 1. The air may be deoxidized, or deficient in oxygen, and contain excess of carbon dioxide. 2. It may contain a poisonous quantity of sulphuretted hydrogen (H_2S).

According to Thénard, asphyxia of persons by breathing sewer-air is often due to breathing an air containing a deficient supply of oxygen, rather than an excess of

carbon dioxide. Experiment has repeatedly shown that an animal can endure for hours a greater proportion of carbon dioxide than is ever found in ordinary sewer-air, provided that the proportion of oxygen is kept up to the normal amount, or is in excess of the normal. The poisonous properties of carbon dioxide are very slight when the oxygen of the air is increased above the normal proportion. Thus, an animal may live for hours in an atmosphere composed of forty per cent. of oxygen, twenty per cent. of carbon dioxide, and forty per cent. of nitrogen. An addition of five per cent. of carbon dioxide to normal air may be endured for some time without fatal poisoning. As sewer-air seldom contains more than four per cent., it is evident that unless the oxygen be reduced below the normal, the mixture could not prove rapidly fatal from carbon-dioxide poisoning. A case of asphyxia from breathing sewer-air, then, is oftener due to a deficiency of oxygen than to an accumulation of carbon dioxide; or, perhaps, to the combined effect of this with an excess of carbon dioxide. In such cases resuscitation is likely to prove successful, if pure air can be supplied in time.

In certain cases sewer-air may contain enough sulphuretted hydrogen (H_2S) to become poisonous. A number of cases of fatal poisoning by sewer-air containing sulphuretted hydrogen are on record. Woodman and Tidy[1] mention twelve cases of sewer-gas poisoning. They seem to attribute the poisoning to H_2S in most, if not all, of these cases. It must be admitted that it is only in exceptional cases that this gas accumulates in sewers in sufficient quantity to give rise to acute poisoning.

A discharge of a considerable quantity of mineral acid into a collection of sewage-matter containing an abundance of sulphides may cause an evolution of H_2S, which, in a poorly ventilated and flushed sewer, may accumulate in fatal quantity. A liquid charged with sulphuretted hydrogen or ammonium sulphydrate, like gas-liquor, may be discharged into a sewer so as to temporarily poison the air. By far the largest number of these cases of acute poisoning occur to workmen engaged in handling night-soil, the contents of privy-vaults and cesspools, or the mud of sewers. In such cases the pent-up gases may escape in poisonous quantities, and overcome the workmen before it has had time to diffuse itself. Sulphuretted hydrogen is a deadly poison, even when mixed with large quantities of air.

The results of experiments upon animals show that:[2]

1 part of H_2S in 1,500 of air killed	small birds	Parent du Chatelet.
1 " " " 290 " " "	rabbits	
1 " " " 250 " " "	horses	
1 " " " 1,800 " " "	birds	Dr. Barker.
1 " " " 210 " " "	dogs	
1 " " " 2,000 " " "	birds	Dr. Letheby.
1 " " " 200 " " "	dogs	

Dr. Letheby considers that one per cent. of the gas in air would destroy human life. As $\frac{1}{100}$ per cent. (1 part in 10,000 of air) can be detected by the odor of rotten eggs which it imparts, there can be little danger of being acutely poisoned by it unawares.

It is more than probable that the fatal effects, above referred to, are as largely due to deoxygenated air as to the poisonous action of the sulphuretted hydrogen, or of the ammonium sulphide.

TREATMENT OF ACUTE POISONING BY SEWER-AIR.—The treatment of this form of poisoning may conveniently be divided into preventive and remedial.

The prevention of acute poisoning by the air of sewers, cesspools, etc., is very simple. In sewers thorough flushing and ventilation is all that is needed. In cesspools and vaults it is important to stir their contents before emptying, in order to allow the greater part of the gas to escape. If the generation of hydrogen sulphide is rapid, it may be necessary to throw down a little chloride of lime, a day or two before going into the vault, or to generate chlorine in the vault by means of chloride of lime and dilute acid. The test of lowering a candle into such places is not always a safe test to depend upon. The remedial treatment of asphyxia from sewer- or cesspool-air consists in the admission of fresh air, and the use of cold affusions. Warm brandy or whiskey and water may be given freely, to sustain the heart.

Dr. Eskbridge has used, with success, intravenous injections of aqua ammoniæ fortior in a case of acute poisoning. He proposes to use this solution, diluted with two parts of water, at a temperature of 110° F.

Commonly, the simple removal of the person into pure air, if done without delay, is sufficient to restore him. Woodman and Tidy recommend the breathing of air containing a trace of chlorine, formed by putting chloride of lime in a bottle. The object of this treatment is to decompose the hydrogen sulphide that may be in the residual air of the lungs, or, possibly, in the blood.

SYMPTOMS AND POST-MORTEM APPEARANCES.—The symptoms of acute poisoning by sewer-air, the air of cesspools, or the gases evolved by night-soil, are usually those of asphyxia, or of poisoning by hydrogen sulphide. The surroundings of the person at the time of the accident can usually be determined, and thus the cause of the symptoms, or death, inferred. The first effect will probably be nausea, faintness, or dizziness; cold, clammy skin; frequent pulse, and irregular or jerky respiration.

Later, or if the sulphuretted hydrogen be more abundant, the person loses the power of motion, and becomes insensible. His lips become livid, and a bloody, frothy mucus may exude from the mouth or nose. The pulse becomes weak, rapid, and irregular. The respirations now become rapid, laborious, and irregular. The voluntary muscles are relaxed, with occasional twitchings, or even tetanic convulsions. Death may occur suddenly, or the patient may slowly regain consciousness on exposure to pure air.

The post-mortem appearances are usually those observed after poisoning by hydrogen sulphide. The blood will everywhere be found to be of a very dark color, sometimes almost black, and fluid. The right side of the heart is usually found filled with blood. The body emits an offensive fecal odor, and rapidly undergoes putrefaction. When the cause of death is sulphuretted hydrogen, the mucous membrane of the bronchial tubes is smeared with a dirty-brown mucus, easily rubbed off. This appearance is very characteristic, and may serve to distinguish between suffocation by deoxygenated air and sulphuretted-hydrogen poisoning.

CHRONIC POISONING BY SEWER-AIR, AND THE DISEASES PRODUCED BY IT.—This is a subject upon which a great deal of attention has been spent, without entirely satisfactory results. Opinions differ as to the effects of sewer-air upon the human economy, when breathed for a considerable time in a highly diluted condition. While some physicians believe that it is not deleterious to health under these conditions, others claim that it is a cause of many cases of serious illness, and a frequent carrier of such diseases as typhoid fever, dysentery, cholera, yellow fever, diphtheria, scarlet fever, measles, etc. While it is not easy to obtain reliable data upon this point, the weight of evidence, as well as reason, seems to declare that there is some connection between sewer-emanations and some of the diseases mentioned. It would carry us too far for the limits of this article to discuss at length the evidence that must lead us to this conclusion.

It is certain that there are well-established observations, which seem to prove that sewer-air, even when largely diluted, produces a very deleterious effect upon the health of persons who breathe it for a considerable time. The teachings of writers on toxicology, the clinical experience of hundreds of physicians in our large cities, the experience of sanitarians and of sanitary engineers, all lend weight to this opinion. It is equally certain that these effects cannot be due alone to the gases which have been described as entering into its chemical composition.

Mixtures of air with carbon dioxide, marsh-gas, sulphuretted hydrogen, and ammonium sulphydrate, when prepared in the laboratory, in the arts, or in metallurgical operations, have never been known to produce typhoid fever, dysentery, malaria, or any other of these specific

Sewer-Air.

diseases. Indeed these gases, with the exception of H_2S, are known to be harmless when highly diluted. Sulphuretted hydrogen has lately been recommended and used by inhalation in the treatment of phthisis. The author has so used it, with no apparent ill effect.

Some other cause for the well-known effects of sewer-air must be found than is revealed by the analyses above quoted. This must be in the organic matters or micro-organisms that have been described as present in sewer-air. The air of sewers has been found to contain large quantities of bacteria. This may be easily shown by exposing in a sewer a glass slide moistened with glycerine, and then submitting the slide to microscopical examination.

Professor Frankland[3] has shown that few solid or liquid particles are evolved from sewage unless it be agitated. He found that the ordinary flow of the sewer-water did not scatter any particles into the air; but when it began to ferment and evolve gases, the bursting of these bubbles sent small portions of the liquid into the air. From this fact he argues that sewage pollutes the air with dangerous germs only when it is giving off bubbles of gas. If we take proper measures to carry off the sewage before fermentation takes place, the danger will be reduced to a minimum, or entirely obliterated. If, as above stated, the putrefactive bacteria are thus disseminated through sewer-air, there is no known reason why pathogenic microbes, when present, should not be scattered in the same way.

A case in which sewers probably played a part in the spread of cholera, is given by Dr. Parkes, in his report to the officer of the Privy Council on the cholera in Southampton, in 1866. There is good evidence that the contagious principles of yellow fever and typhoid fever have been disseminated by sewer-air.

In the city of Brooklyn, N. Y., in 1885, there were a large number of cases of typhoid fever in two pretty well-defined localities, both situated on high ground. After a thorough investigation of the cause of the localization of the cases, the conclusion was reached that the sewers were infected by the discharges of a few imported cases; that the poison was disseminated by the sewer-air tending always toward high levels, and gained an entrance into houses in the immediate vicinity through defects in the plumbing. In a very large number of the houses where cases occurred, such defects were actually found on inspection.

Upon this subject Dr. John Simon, Chief Medical Officer to the Privy Council of Great Britain, in his essay on "Filth Diseases," while speaking of morbific ferments, or contagia, says: "The ferments, so far as we know them, show no power of active diffusion in dry air; but, as moisture is their normal medium, currents of humid air (as from sewers and drains) can doubtless lift them in their full effectiveness, and if into houses or confined exterior spaces, then with their chief chances of remaining effective."

Dr. Parkes[4] says: "The air of sewers passing into houses aggravates most decidedly the severity of all exanthemata—erysipelas, hospital gangrene, and puerperal fever (Rigby); and it has probably an injurious effect upon all diseases." "Two special diseases have been supposed to arise from the air of sewers and fecal emanations, viz., *diarrhœa* and *typhoid* (enteric) *fever*." That typhoid fever may, and frequently does, arise from sewer-emanations is a doctrine certainly well supported by facts. The writer's experience has furnished examples of this fever that were apparently contracted from sewer-air. There are several cases on record where typhoid fever has constantly recurred in houses exposed to sewer-emanations, and in which proper attention to sewer-defects has completely prevented further outbreaks.

Water has been known to become contaminated by sewer-gases, and afterward to produce typhoid fever in those who drank it. Dr. F. de Chaumont[5] cites a case where a cistern was thus poisoned by sewer-air passing into it from the sewer through the overflow-pipe. An analysis of this water showed it to contain a considerable excess of "albuminoid ammonia," derived from the absorbed gases. A similar case is recorded by Dr. Robert King, in the *Medical Times and Gazette* for August 2, 1879. These, and other similar cases, add an interest to the question of overflow-pipes to wells and cisterns, and of the efficacy of water-traps, not usually appreciated.

Mr. William Budd cites instances in which those members of a particular household, who used one closet into which the dejecta of a typhoid patient were thrown, contracted the disease, while other members of the same household, who were in close personal contact with the sick person, escaped.

From what is here said, it will be understood that the results of breathing sewer-air are not always the same. The effects will depend upon the quality much more than upon the quantity of the air breathed. A small amount, at one time, may cause a fatal contagious malady, and at another time a much larger amount may produce only a slight malaise. A small quantity laden with the germs of a specific disease is more dangerous than a large quantity of gas from an uninfected sewer.

Symptoms of Chronic Sewer-Air Poisoning.—As already remarked, the symptoms of sewer-air poisoning are usually insidious in their development, and by no means always constant. I am disposed to believe that the effects may even remain unnoticed for months, as long as the sewer is not infected with harmful germs, and may develop with certainty whenever such infection does occur.

In adults the symptoms, when no specific disease-germs are at work, are malaise, headache, loss of appetite, with even dyspeptic symptoms, drowsiness, and slight feverishness. There is a marked tendency to anæmia and general debility. These symptoms are frequently grouped under the name of "malaria." In children, to these symptoms may be added a smooth or glazed, broad, flabby tongue, with a marked tendency to digestive trouble, as vomiting, diarrhœa, dysentery, and attacks of gastric catarrh and catarrhal tonsillitis.

The tendency of sewer-air poisoning, then, is to derange the organs of primary assimilation, rather than the lungs; as, for example, gastric catarrh, duodenitis, hepatitis, spleuitis, diarrhœa, enteritis, and colitis. Besides these effects, the debilitating influences of the polluted air render the persons so effected an easy prey to any intercurrent malady.

In times of epidemic diseases these are apt to assume a severe or malignant type. There is less tendency to periodicity, and more variability in sewer-air poisoning than in marsh-miasm. The effects seem to depend largely upon the bodily vigor and activity, at the time of exposure, and are therefore greater in night exposure than during active working hours. Hence workmen engaged in ventilated sewers and vaults seldom suffer any particular harm. Numerous inquiries upon this subject have been made, and, although there has been some difference of opinion, the weight of evidence would seem to indicate that sewer-workmen suffer no more from disease than do other men, aside from a few accidental cases of asphyxia. Those who suffer most from sewer-gas poisoning, or sewer-malaria, are women and children who spend most of their time in the house, especially in poorly ventilated apartments. As might be expected, an exposure to sewer-air during sleep is more dangerous than during waking hours, and during a period of active exercise.

While we admit the injurious nature of air contaminated with sewer-air, we must admit that we occasionally meet with cases where persons have lived in houses for years, where traps were unknown, and have suffered from no apparent bad effects. These facts have led some sanitarians to deny the relation of sewer-air to any form of disease. It will not be claimed that the specific germs of disease are always present in any given sewer, especially if it is well ventilated, and if the sewage is constantly in motion. The air of a badly ventilated and stagnant sewer is always to be regarded as more dangerous than that of one where these conditions do not prevail. It has repeatedly been shown that the conditions under which the various microzymes grow, have a great influence upon their virulence in producing disease. It is

quite possible that the ordinary putrefactive bacteria, when germinating in pent-up sewage, may be the cause of the catarrhal sore throats and diarrhœas produced by sewer-air. The virulence of many of the microzymes of the specific diseases, when present in sewers, is increased by germination in closely confined and stagnant sewage. It will be admitted that these disease-germs are not always present in sewers, and under favorable conditions, such as rapid flow and free ventilation, would do no damage when they were present. The importance of securing these favorable conditions in sewers is therefore very apparent.

Treatment.—The treatment of chronic sewer-gas poisoning is partially remedial and partially preventive. In the former, fresh air is of first importance. Pure outdoor air acts as a tonic, and, at the same time, a diluent and disinfectant of the sewer-air. As the tendency of sewer-air, aside from the specific disease-germs, is to produce a lowered vitality and anæmia, quinine, arsenic, salicin, iron, and the mineral acids are indicated. A change of location is often of the greatest benefit. It should be remembered that the effects of sewer-air are frequently seen only in their aggravation of other maladies. Thus, a simple sore throat may, under its influence, assume a very serious and aggravated form. A simple gastro-intestinal catarrh, in children exposed to sewer-air, is often found to be most intractable, until a change of location is secured. The author has seen cases of summer diarrhœa very greatly benefited, and even cured, by a removal for the distance of a few blocks in the city. The effects of a removal to the country are too well known to demand discussion. Many of the cases of infantile cholera are undoubtedly due to the combined effect of a polluted air and high temperature. Fresh air is curative in a large number of these cases.

The effect is the same whether the fermenting sewage is contained in sewers or has soaked into the ground about the house. Both may pollute the air with the same gases, and may produce like effects. When furnace-fires are used in the house, the gases from a sewage-soaked soil may be drawn into the cellar and thence into the rooms above, giving rise to all the injurious effects of sewer-air.

The prevention of sewer-air poisoning is of more importance than is its treatment. The principal requisites for a system of sewers are, free ventilation of all drain- or waste-pipes, and sufficient grade or inclination in outlet-pipes to secure a somewhat rapid current of the sewage. To secure thorough ventilation of the pipes in the house, it is now customary and proper to carry a ventilating pipe, from the sewer side of all traps, to a larger pipe leading to and above the roof of the house; also, to carry a pipe from the house side of the trap, between the house- and street-main, to the open air. This last pipe allows the air to enter the house-system, whence it finds its way, in a constant current, through the pipes and out of the ventilating pipe above the roof. By this arrangement there can be no stagnant air in the pipes of the house, and they are constantly purified by a current of out-door air. When this is secured, and there is no leakage in the pipes, we need fear no trouble from sewer-air.

Detection of Sewer-Air.—The detection of sewer-air is not always an easy matter. The chemical tests depend upon the detection of sulphuretted hydrogen (H_2S) or ammonium sulphydrate. If a piece of filter-paper be dipped in a solution of lead acetate, and be exposed to an atmosphere containing either of these substances, it turns dark-brown, and finally black. A paper dipped in a solution of nitro-prusside of sodium assumes a crimson, and turmeric paper a brown color with ammonium sulphydrate. White-lead paint is darkened by both the above compounds, while zinc white is not changed in color.

The peculiar odor of H_2S may be easily detected, when the proportion reaches 1 part in 10,000 of air. On closing a room tightly for some hours, and then going into it from the open air, a musty or oppressive odor is detected when sewer-air or emanations from decomposing animal matters have found their way into it. If any circumstance should lead to the suspicion that sewer-gas is entering a room or house, it would be best to test the drain-pipes by the "smoke test" or the "oil-of-peppermint test."

A suspected joint in a sewer- or drain-pipe may be tested by wrapping it with a single layer of white muslin moistened with a solution of acetate of lead. As the gas escapes through the meshes of the cloth, it will be blackened by the sulphur-compounds.

As above stated, all these tests may fail in certain cases, when the amount of sewer-air is small in comparison with the air with which it is mixed. It is therefore to be recommended that the plumbing of houses be examined by an expert at least once a year. *E. H. Bartley.*

SEX is a term employed with two significances, which are often confused, but which it is indispensable to distinguish accurately. Originally sex was applied to the organism as a whole, in recognition of the differentiation of the reproductive function. Secondarily, sex, together with the adjectives male and female, has been applied to the essential reproductive elements, ovum and spermatozoon, which it is the function of the sexual organisms (or organs) to produce. According to a strict biological definition *sexuality* is the characteristic of the male and female reproductive elements (genoblasts), and *sex* of the individuals in which the reproductive elements arise. A man has sex, a spermatozoon sexuality.

Sexuality, then, is primitive and essential, and sex is dependent upon it. We consider, therefore, 1, the nature of sexuality; 2, the nature of sex. In a third section a few words will be added on the origin of sexuality.

1. Nature of Sexuality.—The essential facts of sexual reproduction are: that two bodies, partaking more or less plainly of the character of cells, fuse together into a single body, which seems in every respect homologous with a cell, and which undergoes a series of divisions from which result a number of new cells. In all the higher plants and animals the two bodies are obviously different. In all metazoa one body is large, contains a store of nutritive material, and has a special envelope of its own (see Ovum); the other is small, and provided with means of active locomotion (see Spermatozoa); the details of the process of their union are described under Impregnation, *q.v.*

The only hypothesis, as to the nature of the sexual elements, which rests on much basis of fact, is that of Minot.[1] This hypothesis is based upon the consideration of three categories of facts: 1. Sexual reproduction is effected by the union of a male and a female element, which produces a cell; this cell is, therefore, hermaphroditic, or, perhaps, one should say asexual, since it is neither male nor female. It produces other cells by division, and it is probable that the new cells are likewise hermaphroditic or asexual.* 2. When the cell which gives rise to the female element matures into an ovum, it undergoes a remarkable process of unequal division, known as the extrusion of the polar globules. In other words, the cell separates into two kinds of bodies, *a*, several polar globules; *b*, a single female element. 3. Although our knowledge of the development of spermatozoa is extremely unsatisfactory, and although no successful attempt has been made to elucidate what is essential, yet there are reasons for thinking that the parent cell, which generates the male elements, divides during the process into two kinds of bodies, first, a number of smaller corpuscles (spermatoblasts), and second, a single larger structure (mother-cell). The deduction from these premises is evident. In the cells proper both sexes are potentially present; to produce sexual elements the cell divides into its parts; in the case of the egg-cell the male polar globules are cast off, leaving the female ovum; in the case of the sperm-cell the male spermatoblasts, which

* Van Beneden has attempted to give an elaborate proof of this in his paper on Ascaris, but unsuccessfully, as his observations were defective.

by this hypothesis are homologous with the polar globules, are further specialized and employed while the mother-cell atrophies; the mother-cell is homologous with the ovum after the extension of the polar globules.

The hypothesis just outlined is purely morphological, and offers at present no insight whatever into the physiological aspects of sex. It has, however, been adopted provisionally by many writers, Sabatier has carried it somewhat further, having attempted to demonstrate that the central portion of the cell is female, the peripheral portion male. For a more exact statement of these views the reader is referred to Sabatier's original memoirs. In opposition to Minot's view, it has been suggested that the formation of polar globules is merely an atavistic remnant of the process of cell division (Whitman), but this suggestion offers no explanation of the universal fact that the polar globules are always present,* and always entirely different from the ovum proper. Similarly, it has been suggested that the multiplication of the spermatoblasts was an atavistic cell-divisional process (Bütschli), but the evidence in favor of this view is inconclusive. A fanciful comparison between the multiplication of spermatoblasts and the segmentation of the ovum has found favor with some writers, notably with Geddes, but I am unable to recognize any evidence in favor of the comparison.

In regard to the physiological relations of the sexual elements, all sorts of credible and incredible hypotheses—especially the latter—have been advanced. None of them appears to me to deserve mention, unless it be Geddes' speculation that the spermatozoon is the outcome of katabolic changes, and the ovum of anabolic changes; but does not such speculation pass far beyond the present possibilities of science?

According to Minot's hypothesis, then, sexual reproduction consists in the splitting up of cells into sexual elements, and the reunion of a male and a female element to make a new asexual cell. We know from empirical observation that such a new cell has an increased power of growth. It is inevitable, therefore, to suppose that the object of sexual reproduction is just this renovation, or the formation of a new young organism. Why there should be such renovation?—By what physiological change it is accomplished?—are questions to which no answer can be given yet. Weismann has brought forward the important thought that the union of the sexual elements mingles two hereditary tendencies, and so produces variability, and thus helps natural selection. Weismann thinks that this is the only object of sexual reproduction, but I cannot follow him in that.

Parthenogenetic ova develop without impregnation, that is, without the addition of a male element. In accordance with Minot's hypothesis of sexuality, it might be assumed that in parthenogenetic ova the male element was retained, and that the cell remained a true asexual cell and did not become a sexual element. Blochman and Weismann have shown that this is the case by their discovery that in parthenogenetic ova only one polar globule is formed, while there are always two in ova which are impregnated; hence it is probable that one polar globule (by hypothesis male) is retained.†

There are reasons for thinking that the physiological cause of the formation of the sexual elements is defective nutrition. There are numerous observations on plants which indicate this conclusion. Among animals the coincidence between the diminution of growth and sexual maturity may be brought forward as a similar argument. The fact, too, that puberty arrives earlier among the poorer classes, points in the same direction. There is certainly enough evidence in favor of the conclusion that there is a causal relation between impeded nutrition and the development of the sexual elements to more than justify a thorough investigation of the subject.

We may describe the life-cycle as beginning with the union of the sexual elements, resulting in a cell with a great power of growth and multiplication; as multiplication continues the cycle of cells is continued, but the power is gradually exhausted. After a time the exhaustion (impeded nutrition) *causes*, according to the hypothesis just advanced, the formation of sexual elements, and so creates the possibility of a new cycle. The problem of life-cycles has already been discussed in the article on Growth.

2. Nature of Sex.—As a matter of speculation, we must assume that originally the cells could produce both sexual elements in an efficient form at once, but, as a matter of fact, we see that in all (?) known cases only one kind of sexual element is brought to development from one cell. Very early in the evolution of plants and animals, certain cells or groups of cells assumed the special function of producing the sexual elements (genoblasts). Sexual organs were differentiated very early. In the metazoa, originally, the same individual produced both male and female genoblasts, and was therefore hermaphroditic. As evolution continued hermaphroditism was replaced by a new differentiation, in consequence of which the individuals of a species were, some, capable of producing ova only; others of producing spermatozoa only. Individuals of the former kind we call females, of the latter males, and they are said to have sex. In connection with this differentiation there have been evolved manifold secondary modifications, so-called sexual characters, the origin and importance of which were first brought out clearly by Darwin.

The reason why some individuals become male and others female is unknown. Van Beneden advanced the theory that there was a sexual difference between the germ-layers, all male elements arising from one, all female elements from the other. Weismann has shown that this theory was a speculation based upon insufficient observations. In vertebrates the sexual organs (ovaries and testes) arise from the middle germ-layer and out of the genital fold (see Fœtus). At first it is impossible to tell whether the fold is to give rise to an ovary or a testis; on the contrary, the beginnings of the two organs appear identical. This observation leads naturally to the supposition that the sex of the individual embryo is at first non-existent and is determined during the course of development. It is, therefore, noteworthy that nearly all attempts to discover the causation of the sex of an individual seek the cause at the moment of impregnation. Thus we find many hypotheses assuming that the relative condition of the ovum and spermatozoon at the time of their union decides the sex resulting. For example, Hofacker (1828) and Sadler (1830) maintained that when the father was older than the mother there were most sons, but when the mother was the older, then most daughters. Thury thinks that the time of fertilization is important, and that females result if ova are impregnated when freshly matured; males when impregnation is retarded. This view has many advocates, notably Stieda, Berner, Düsing, Girou, and others. Another favorite doctrine is that of relative potency or comparative vigor, according to which the most vigorous of the elements determines the production of its own sex, or, according to some, of the opposite sex. This doctrine has been further elaborated by the assumption that the potency of the sexual element depends upon that of the organism at the time of producing it (Starkweather). Another set of explanations is offered by those who see the *vera causa* of sex in the nourishment of the developing young. Good nourishment is supposed to promote the production of females, poor nourishment that of males. For plants this has been advocated by Girou, Haberlandt, Meehan, and others; for insects, by Gentry and Mrs. Treat; for amphibia, by Yung; for mammals, by Girou, Düsing, etc.

The whole subject urgently calls for a thorough critical revision, based upon proper experiments. At present all we can say is, we do not know why or how sexual individuals are produced.

The *proportion of the sexes* in man has been very carefully studied. The statistics compiled by Oesterlen of

* See discussion in article Ovum.

† Weismann seems to have overlooked this interpretation, which appears obvious and natural, and has endeavored to strain his important observations into an argument against Minot.

59,350,000 births in Europe show that for every 1,000 girls there are 1,063 boys. The result may be confidently accepted, as the proportion of boys in the single countries varies only from 1,052 to 1,072. In animals the proportion varies greatly according to the species; in many mammals females are in excess—thus for 1,000 mares there are only 994 stallions (Darwin); in plant lice the excess of females is enormous, and of some copepods there are plenty of females, but the males are unknown. I do not recall any instance of a *great* excess of males. The best authority on the determination and proportion of the sexes is Hensen (Hermann's "Handb. der Physiol.," Bd. vi., 2 Th., pp. 203–211). Düsing's memoir* is an elaborate and useful compilation.

3. Origin of Sexuality.—It is still uncertain whether sex is co-extensive with life; Weismann maintains that it is not, but was evolved on account of its value in increasing variability; but Weismann disregards some considerations which, I think, have an essential bearing upon the problem. It is, however, certain that the conjugation of unicellular plants and animals is identical with the conjugation of the spermatozoon and ovum (see article on Reproduction, in the Appendix). Indeed, we must assume that sexuality arose before the evolution of life had progressed to the differentiation of animals and plants; since sex occurs in both kingdoms, it is probable that it existed before they were separated and is a common inheritance. This carries sex very far back indeed, and makes it more prudent to recognize the crudity of our knowledge concerning the lowest forms of life, than to attempt premature conclusions about the origin of sex. The evolution of sex in plants has been much studied, and is treated in many text-books of botany—those of Sachs and Goodale may be specified as excellent in this respect. Zoologists have neglected the subject unduly. There is, so far as I know, no good comprehensive treatise on the evolution of sex in the animal series.

Charles Sedgwick Minot.

Therapeutic Properties.—These are celebrated sulphur waters. They are used internally and externally in chronic skin affections, gout, rheumatism, and catarrhal states associated with lymphatic conditions. There are no better waters of this class.

Sharon Springs is situated in a valley, about eleven hundred feet above sea-level, and sixty miles west of Albany. The scenery of the surrounding country is charmingly diversified with hills and vales, while in the distance the peaks of the Adirondacks are visible. The accommodations for guests are ample and of the best, consisting of the main building, "The Pavilion," and twelve cottages situated on a shaded lawn of fifty acres. The bath-house is new and contains all the modern appliances for comfort and convenience. Billiards, bowling, and other forms of amusement are provided for. There are various points of interest within driving distances.

G. B. F.

SHELDON SPRINGS. *Location and Post-office,* Sheldon Springs, Franklin County, Vt.

Access.—By the New York Central & Hudson River and Central Vermont Railroads; or from the east to Lowell, thence by the Central Vermont to St. Albans. From St. Albans the Missisquoi Railroad runs direct to the Springs.

Therapeutic Properties.—This is a delightful alkaline-saline water. It is employed in gastric, uterine, and cystic catarrhs.

* Düsing's article appeared in the Jenaische Zeitschrift, 1884, and has been republished separately.

Analysis (S. Dana Hayes, M.D.).—One gallon contains:

	Grains.
Potash	0.096
Sodium	0.148
Soda	4.012
Ammonia	trace
Lime	1.077
Magnesia	0.166
Protoxide of iron	0.010
Sulphuric acid	0.508
Silicic acid	4.587
Carbonic acid combined	2.115
Crenic acid and organic matter	2.867
Chlorine	0.166
Total	15.752

These springs are situated in the northwestern corner of Vermont, ten miles from St. Albans, on the banks of the Missisquoi River, in a beautiful pastoral country of hill and dale, with Mt. Mansfield and other peaks of the Green Mountains within sight. From a hill near the hotel Lake Champlain can be seen. The hotel, "Congress Hall," stands on the banks of the river, and is fitted with all conveniences for the comfort of its guests. The bath-house is supplied with water from the Sheldon Spring, which flows fourteen thousand gallons per twenty-four hours. In addition to the above spring there are the Central, the Missisquoi, and the Vermont, within a distance of two miles along the Missisquoi River.

G. B. F.

SHENANDOAH ALUM SPRINGS. *Location and Post-office,* Shenandoah Alum Springs, Shenandoah County, Va.

Access.—By the Baltimore & Ohio (Harper's Ferry &

Valley Branch) Railroad to Mount Jackson, thence by stage twelve miles to the Springs.

ANALYSIS.—A qualitative analysis shows the Alum Spring to contain this ingredient in very marked proportion, together with the usual salts and a trace of iron.

THERAPEUTIC PROPERTIES.—As an astringent and alterative this spring is resorted to with success by those suffering from catarrhal diseases of the alimentary tract and urinary apparatus.

This group of springs, eight in number—three alum, a chalybeate, a healing, a sulphur-iron, an arsenic, and a lithia well—are situated in the Shenandoah Valley near the North Mountain, amid the grand and picturesque scenery of that region, at an elevation of over 2,000 feet; there are numerous drives to various points of interest in the surrounding country, over good roads. Hotel accommodations are good. *G. B. F.*

SHOCK. Shock, or collapse, is a sudden, and more or less profound, depression of the vital powers, characterized by general prostration, a feeble pulse, clammy skin, cold extremities; pale, wrinkled, pinched, and shrunken features; faint and sighing respiration, and often more or less impaired consciousness.

The terms "shock," and "collapse," are very properly used synonymously, and yet, while the symptoms are similar or identical, there is often a difference in their application. That condition which is the result of an injury or of an operation, is called shock; while the same group of symptoms arising in the course of some other affection, as peritonitis, strangulated hernia, or hæmorrhage is called collapse. The moribund state is an extreme collapse. It is not practicable to make a distinction in the application of the terms, and no effort will be made to do so in this article.

Syncope resembles collapse in that it comes on suddenly, is attended by weak pulse and respiration, and complete prostration. But in syncope the cause is often mental rather than physical, and the cerebral symptoms are by far the most prominent. Consciousness is lost, as it is not usually in collapse from injury, except in the most serious cases. Furthermore, the symptoms in syncope are generally of a much shorter duration and of a much less dangerous character. On the other hand, the symptoms of collapse are more severe, the danger is greater, and they may be followed by more or less permanent after-effects.

CAUSES.—Among the causes of shocks which call for consideration are the following: injuries, operations, burns and scalds, lightning and electricity, hæmorrhage, poisons, pain, and mental emotions. It goes without saying that the more extensive the injury, the greater will be the shock, and also that the greater the power producing the injury, the more serious will be the result. These facts are noticeable in railroad accidents, and in falls from great heights. A man who has been struck by a locomotive, for instance, will experience a far greater degree of shock than had he been run over by a wagon. The immediate disturbance resulting from a high fall, by which the whole system is jarred and shaken, will be much more severe than that which ordinarily follows a blow from some falling body. Hence the manner of receiving an injury is an important element in the prognosis and treatment.

Injuries to different parts of the body are followed by varying results. A crush of the upper extremity is less dangerous than one of the lower, and is usually attended by less shock. Injuries to the head are proverbially dangerous, and the symptoms of shock are often masked by those resulting from cerebral lesions. Contusions and perforating wounds of the abdomen and its contents, liver, kidneys, intestines, etc., are especially prone to be followed by serious collapse. So are cases of peritonitis from whatever cause, intestinal obstruction, and strangulated hernia. The painful effects resulting from a blow upon the pit of the stomach are familiar to most people. A crushing or laceration of the testicle generally gives rise to profound shock, and a smart blow upon the breast of a woman is apt to be followed by a similar condition.

Severe or prolonged surgical operations are very generally followed by more or less collapse, especially if the operation be attended by much hæmorrhage. This condition is more marked after primary operations for injury, as the shock of the injury is augmented by that of the operation. Secondary operations, performed upon persons of a fairly sound constitution, are much less likely to be followed by severe collapse or shock, from the fact that the system seems to have become habituated to the altered condition. It is a matter of common observation, that a febrile attack, or an acute inflammation, will in many instances protect the system for a certain time, so that an operation of severity may be performed with a fair prospect that the immediate inflammatory disturbance will be comparatively mild. In critical cases it would seem to be wiser to do two operations of moderate severity, than to risk the greater danger attending a single more severe one. The writer has performed amputation at the hip-joint in several instances, by first removing the limb at the middle third of the thigh, and in a few weeks completing the work by disarticulating and removing the remainder of the femur. The shock is thereby distributed, or divided, and while there may be more in the aggregate, yet it does not all come upon the system at once, and hence there is less danger of its overwhelming the vital powers. The extent of shock following an operation depends not alone upon its severity, or upon the idiosyncrasy and condition of the patient, but also upon the time consumed in its performance, upon the amount of hæmorrhage, the length and degree of anæsthesia, the exposure to cold, etc. These matters will receive further attention under the head of prophylaxis.

Burns and scalds involving a great extent of surface, even if superficial, are more prone to produce collapse, than are those of limited area which extend deeply into the tissues. The immediate effects of injuries of this kind to the chest and abdomen are particularly severe. The prostration and pain resulting from inhaling steam or flame are very great, and very frequently the victims die from shock. Similar results are often produced by swallowing caustic or other irritating poisons, as arsenic, corrosive sublimate, oxalic acid, caustic potash, etc.

As might be inferred from the nature of the agent, injuries from electricity are especially severe and dangerous. Lightning often kills instantly, as does the current from the wires used in the modern electric lights. The collapse which results from these injuries, when immediate death does not follow, is often more severe and more prolonged than that following the more common accidents.

Hæmorrhage not only aggravates collapse, but when sudden, severe, or prolonged, it may produce the condition in any degree, from the mildest to the most grave. The more sudden the loss of blood, the greater will be the immediate prostration, and the less are the chances of recovery. A small quantity of blood abstracted from the circulation suddenly will produce more serious effects than a larger quantity taken slowly.

Severe and long-continued pain will aggravate, or may even produce, collapse, as is occasionally seen in some of the neuralgias, like intestinal colic. There can be no reasonable doubt that pain conduced to a fatal result in a case of peritonitis which recently came to the knowledge of the writer. A young lady suffering from this affection was attended by a physician who did not approve of opiates. The result was that the patient tossed upon her bed, and even rolled upon the floor, in her agony, until she finally sank into a comatose state, and died at the end of five days.

Death from shock produced by mental emotion alone must be a rare event. A remarkable case is related by Lauder Brunton, in which some medical students, becoming displeased with a janitor, seized him, and made him believe that they were about to execute him. He was blindfolded, made to kneel before a block, and was then struck a smart blow upon the back of the neck with a wet towel. To their amazement and horror, on removing the bandage the man was dead, literally frightened to death.

The minor effects of strong mental excitement upon the whole system, as well as upon various organs, are matters of every-day observation. Miscarriages attended by severe or even alarming prostration, are occasionally due to mental causes, such as fright, grief, anger, etc. Hysteria, catalepsy, and other affections of the nervous system are familiar examples of psychical disturbances. The unfavorable and even dangerous effects of bad news and other depressing influences upon very sick or very sensitive people are well known to all physicians. Such a shock is as real, and at times as profound, as is that which depends upon some physical lesion, and, moreover, it may be followed by permanent impairment of some function or organ. Deafness has been caused by fright. The normal balance of the nervous system has been permanently impaired in many instances by various powerful emotions, and the patient has been thereby rendered an invalid during the remainder of life.

The degree of shock or collapse resulting from injury, disease, or any cause whatsoever, is influenced more or less by age, and by the physical or mental condition. Some persons are prostrated by comparatively slight injuries, while others sustain very severe ones without having any symptoms of shock. This depends, among other things, upon the natural powers of resistance, upon the frame of mind the patient was in at the time of receiving the injury, and upon the surroundings. Wounds received in battle are often ignored until the excitement of the conflict is over. It is doubtful if sex has much to do with the susceptibility to shock, except in those cases which have some mental disturbance for an exciting cause. It is a common opinion that women bear pain with more patience and fortitude than men, yet it is not certain that they can endure pain of a greater degree, or for a longer time, than men. For example, it is seldom that a man dies from the shock and exhaustion of a fractured hip, but old women not infrequently succumb to this injury.

Weak and debilitated people, and those having a "lax fibre," both mentally and physically, suffer from shock to a greater extent than the strong and robust. The victims of alcoholism withstand shock, as well as most affections of the nervous system, poorly. They frequently, in such cases, suffer from delirium tremens, mania, or other complications; while the rallying power is diminished, the convalescence is prolonged, the prognosis is more unfavorable, and the effects of all kinds of treatment are often anything but satisfactory. The very young and the very old are peculiarly susceptible to shock and collapse. The symptoms are more pronounced in the former, but more lasting and more dangerous in the latter. A temporary collapse is very common in children after many operations and injuries of no great severity. While it is not a very dangerous condition under most circumstances, yet it is to be looked for, and is to be carefully watched until it disappears. Quiet and artificial heat are all that will usually be required in the way of treatment. On the contrary, in the aged the symptoms of shock are frequently mild in character, but they do not pass away, as might be expected. They are apt to persist, and finally to merge into some more serious and perhaps fatal condition.

Symptoms.—The symptoms of shock or collapse are strikingly characteristic, and once seen they are not easily forgotten. The vital powers are profoundly prostrated. The patient lies perfectly still upon his back, too weak to move, and almost too weak to breathe. The pulse is feeble, quick, irregular, or absent; the sounds of the heart are indistinct, or perhaps inaudible; the inspiration is faint, sighing, and slow; the features are pinched and shrunken; the lips pale and livid; the eyes dull, sunken, and often turned upward; the pupils dilated and sluggish; the skin is pale, cold, and clammy; the sweating is at times profuse; the extremities are cold, and the nails purplish. The temperature falls in proportion to the severity of the shock, the depression sometimes exceeding two degrees. Except in the most unfavorable cases, or in those complicated with injuries to the head, the intellect is usually clear and unimpaired. The patient may be perfectly conscious, and yet be too weak to speak, or to notice his surroundings, or his own sensations, unless he be in severe pain. There may be vomiting, which is a sign of reaction, or hiccough, and the sphincters may be relaxed.

In other instances the patient is extremely restless, throwing himself about first in one position and then in another, but is easy in none. Tossing of the arms, gasping for breath, and calling for water are common and unfavorable symptoms attending a severe hæmorrhage. The mind under these circumstances is usually clear, the voice is strong, but vision may be lost. At times the patient suffers the most intense agony from fear of impending death. Travers, in his valuable work on "Constitutional Irritation," has called this restless stage "prostration with excitement," and the term exactly expresses the condition. It is to be borne in mind that, while in this state, the patient is on the brink of dissolution, and that great care is required in performing operations to prevent collapse. The power of resistance seems to be reduced to the lowest point, and a little additional shock suffices to turn the scale the wrong way.

A peculiar, as well as deceptive, form of collapse is occasionally seen in cases of strangulated hernia. The pain and vomiting, after persisting for a period varying from two to five or six days, finally subside, leaving the patient quiet and comfortable; he talks rationally, and with some strength. To a casual observer he seems to be convalescent. But he has no pulse at the wrist, or at best an extremely weak one. Patients in this condition generally die inside of twenty-four hours, and any operation performed to relieve the strangulation will only hasten the end.

The term "shock" has of late years been applied to a peculiar condition of the nervous system, which is usually the result of a railroad accident. A person is in a collision, for example, and receives a severe shaking up, perhaps in the form of a violent to-and-fro motion. He crawls out of the wreck apparently unhurt, with the exception of a few unimportant bruises. Perhaps he assists some of his fellow-travellers, or goes on his way to his destination. In the course of some hours or days after the accident he begins to feel nervous and restless; is easily frightened or excited; cannot sleep; has headache, pains in his back and in various parts of the body. He is depressed, hypochondriacal, loses his interest in everything and in everybody except himself and his own sensations; his appetite fails, and he grows thin; becomes weak both mentally and physically, and presents the appearance of premature old age. He is said to be suffering from "shock to the nervous system." The normal poise or equilibrium is for the time destroyed.

These symptoms, as will readily be seen, are entirely unlike—both in character and in the time of their appearance—those met with in the ordinary cases of shock following an injury. Their course, duration, and treatment are also very different. It is a singular fact that cases attended by symptoms of shock immediately after an accident, seldom develop the symptoms peculiar to "shock to the nervous system." This peculiar affection is so frequent after railroad accidents, although not wholly confined to them, and so often involves a question of suit at law for personal damages, that the various complaints have received the name of "litigation symptoms." Experience proves, however, that they have a real existence, and that they may persist for a long time, or may even result in some permanent affection. Yet the tendency, in the great majority of cases, is toward recovery.

Experimental physiology has demonstrated that in shock there is a reflex paralysis of the heart and abdominal vessels through the medium of the vaso-motor system. "The slow, feeble, or almost annihilated pulse, the pallor of the lips and coldness of the extremities, the mental hebetude, the anæsthesia of the surface, the relaxation of the sphincters, the lessened secretion of the urine, the impaired muscular action,"[1] all indicate the effect of a more or less severe paresis of the heart and vessels, and its accompanying impression upon the whole nervous system.

"Shock is an example of reflex paralysis in the strictest and narrowest sense of the term—a reflex inhibition, probably in the majority of cases general, affecting all the functions of the nervous system, and not limited to the heart and vessels only." [2]

PROGNOSIS.—To arrive at a reasonable prognosis in a case of shock or collapse, the nature of the injury, the character of the symptoms, their course and duration, and the age and previous condition of the patient, must receive careful consideration. The longer the symptoms have persisted, the more unfavorable will be the prognosis. Should reaction be delayed more than eight or ten hours, in cases not complicated with head injuries, the outlook is very serious, although by no means hopeless, as many patients have recovered after a much longer time. The greater the force producing the injury, and the more profound the collapse, the greater the danger of a fatal result. Deepening of the stupor, or increased restlessness with diminished force of the pulse, persistence of the pallor and of the coldness of the surface, profuse sweats, inability to swallow, insensibility of the pupils, persistent vomiting, and relaxation of the sphincters, all betoken the greatest danger, and are seldom followed by recovery.

On the contrary, returning consciousness, "coming to himself," as it is commonly called, increasing interest in the surroundings, a stronger and steadier pulse, deeper and more regular breathing, warmer and drier surface and extremities, more natural color and expression, a brighter eye, an increasing muscular power enabling the patient to change his position at will, are all favorable symptoms. They indicate a healthy reaction, and promise a favorable termination so far as the immediate results are concerned.

In some instances reaction sets in well, progresses to a certain stage, and then stops, leaving the patient in a weak and unsatisfactory condition, which may persist for an indefinite period. Again, the symptoms of collapse may recur after having entirely disappeared, and the patient may be brought to even a worse condition than he was in during the primary shock. These secondary attacks of prostration should lead to the suspicion of some internal lesion, or of some organic change, which had not hitherto been discovered. Hæmorrhage, extravasation of urine, perforation of the intestine, embolism, or other internal injuries and affections must be thought of, and the proper means taken to determine their existence.

Temperament is an important factor in the prognosis of shock, especially in that form which follows surgical operations. The hysterical or neurotic temperament is a particularly troublesome one. Slight operations upon these persons are often followed by great nervous excitement and pain, which are out of all proportion to the severity of the treatment. The symptoms are persistent, and, as a rule, they are not very responsive to the action of drugs. The convalescence is not only longer, but the final result is more doubtful. The writer is cognizant of an instance in which a tenotomy of the tibialis anticus in a young lady was followed by the most alarming collapse, as well as by many months of severe prostration. In short, the patient has never been as well as she was before. Operations of expediency should be performed upon this class of people only after the most careful consideration, and with the expectation that the subsequent effects may be much more serious than they would be under ordinary circumstances. As a rule, patients who are courageous, cheerful, and hopeful do better than the irritable and despondent. Those individuals who ask for an operation for the cure of some surgical affection, have their minds prepared to a certain extent for the ordeal, and therefore they undergo the trial better than those who are suddenly struck down in robust health by an accident, and are compelled to submit to an operation. In the former case the system is somewhat prepared for the state of invalidism which the patient is obliged to lead for a time, and the change in habits is much less in degree, and hence is productive of much less disturbance both mental and physical.

TREATMENT.—In slight cases of shock little is required in the way of treatment beyond keeping the patient warm and quiet, and thus allowing the vital forces to regain their normal condition. Too much dosing with drugs and stimulants under these circumstances does more harm than good.

In the severe cases, however, much can be done, and much can be left undone, to aid the patient's recovery. The main indications for treatment are to preserve and supply heat to the body; to keep the heart going; to control restlessness; and to treat the complications, as hæmorrhage, etc., according to the indications and opportunities. A person suffering from shock should be placed in an easy position upon his back, with his head low. He should be surrounded by bottles of hot water, or hot bricks, or whatever is most convenient, care being taken that the skin is well protected from being burned, a not uncommon accident in these cases. He is to be warmly, but not too heavily, covered with blankets, and if such an article is at hand, by a rubber sheet. The patient is to be moved about as little as possible. The clothing should not be changed unless it is wet or unless there is some absolute necessity calling for the change. He should not be bathed nor "tidied up" for the sake of appearances. The physician's examination should be conducted as quietly and as gently as possible, and need be carried only far enough at the time to determine the danger, and to indicate the treatment immediately required. Unnecessary handling and moving, changing the clothes, etc., only tend to increase the exhaustion. Hæmorrhage should be checked in the speediest and most efficacious manner, and the wounds should receive as little treatment at the time as is compatible with the future well-being of the patient.

As the processes of digestion and absorption are more or less in abeyance during collapse, it is useless, and worse than useless, to give the patient a large quantity of food or stimulants by the mouth. The stomach in many instances will retain everything for a time, but no symptoms of reaction manifest themselves. Finally, vomiting sets in, and the ejected matters show that the stomach has been inactive, and incapable of performing its functions. Time has thus been lost, and the depression has been steadily increasing. It is better to delay the administration of food until partial reaction has taken place, but stimulants are indicated from the first in proportion to the degree of collapse. To get the speediest and surest effect from them they should be given hypodermically. A syringeful (ʒ j.–ij.) of sulphuric ether, brandy, or other liquor may be injected into the arm, or other convenient part of the body, at intervals of five or ten minutes, or less frequently, until signs of reaction manifest themselves, when the intervals are to be lengthened, and small quantities may then be given by the mouth and rectum. When a fair amount of reaction has become established, food, in the form of milk and lime-water, beef-tea, etc., should largely supplant the stimulants.

Restlessness and pain are best controlled by morphine given subcutaneously. The drug acts as a strong, steady, and continuous stimulant, and it is a most valuable agent to maintain the vital powers in shock, as well as to prevent this condition. The dose may vary from one-twelfth to one-fourth of a grain, according to the indications, always taking care not to repeat the dose often enough to get the narcotic effects of the drug. The stimulant action, and not the soporific, is desired under these circumstances.

Digitalis has been recommended for its stimulant effect upon the heart and circulation. It may be given under the skin or by the mouth, preferably by the former method to get the effects speedily. The dose is half a drachm of the tincture, which is to be repeated every hour until signs of improvement are apparent.

Transfusion, or what is more practicable, and probably fully as efficacious, an intravenous injection of salt-water, is indicated in collapse resulting from hæmorrhage, but not under other circumstances. The great advantage of the saline injection is that it is always at hand, and can be used with a fountain, or any other good syr-

inge which carries a steady stream, and which can be filled while in position. The solution should be warm, and the proportion of salt should be about a drachm and a half to the quart. The following formula, suggested by Mikulicz, may be used, if time is not pressing:

Sod. chloridi	ʒ jss.
Sod. bicarb.	gr. xv.
Aq. destillatæ	O ij.

M.

The solution should be raised to a temperature of 100° F., and it is to be injected very slowly, and in quantities varying from one to four pints. The pulse and respiration are to be carefully watched during the operation. The simplicity of this mode of treatment, as well as the favorable results which follow it, are strong arguments in its favor.[3]

It is more than doubtful if venesection is required in those cases of collapse attended by congestion of the surface and distended jugulars. "The heart is distended because it is paralyzed, and not paralyzed because it is distended."[4]

Authorities are pretty well agreed that surgical operations should not be performed while a person is in a profound collapse. The shock of the operation added to that of the injury augments the danger, and thereby diminishes the patient's chances for recovery. The claim put forward by some writers, that the stimulant effects of sulphuric ether counterbalance the depression of the operation, is not sustained by experience. It is true that the primary effect of ether is stimulating, but it is of short duration, and is not to be relied upon. If the anæsthesia be profound, or if it be kept up for any length of time, the subsequent prostration is frequently alarming.

The operation should always be delayed, if possible, until a fair reaction has become established. The exact stage of reaction which justifies a resort to operative procedures is to be decided by the condition of each individual case. A weak, irregular pulse, sighing and irregular respiration, cold extremities and cold sweats, contra-indicate an operation. On the other hand, an operation may be undertaken when the patient is fully aware of what is going on around him, when the pulse is regular and of fair strength, the surface is warm, and the breathing natural. No regrets need be entertained by the surgeon because a patient dies from shock without an operation. If he could not rally from the collapse alone, he certainly could not do so after an additional burden had been put upon him.

Unconsciousness from shock, not complicated with head injury, is an exceedingly grave symptom, and, as a rule, precludes an operation. Should it be necessary to perform one under these circumstances, no anæsthetic is required. It is not necessary to control pain, as the patient, being unconscious, feels no pain. Neither is the ether called for as a stimulant, because there are other and better methods of stimulation. Should the patient be sensible to suffering, a very little of the anæsthetic, administered at the commencement of the operation, is of great value. It quiets the nervous system, deadens or prevents pain, and if used rightly, it does not add to the shock and subsequent prostration.

Prophylaxis.—This subject is of so much importance, that a few concluding sentences may be devoted to its consideration. Very much can be done to prevent collapse after surgical operations by paying special attention to the following points: Temperature, time, hæmorrhage, degree of anæsthesia, and personal disturbance. It is a great mistake to suppose that the time consumed in performing an operation is of little importance so long as the patient is under the influence of an anæsthetic, and hence not conscious of suffering. There can be no doubt that the longer a person is subjected to an operation or to an examination, the greater will be the shock to the nervous system, and the greater will be the subsequent prostration. Deep or long-continued anæsthesia augments the unfavorable symptoms. The patient may seem to be going on well under an operation with full anæsthesia, when suddenly the pulse fails, the strength vanishes, profuse sweats break out, and the patient is in collapse. The operation is either hastily concluded or abandoned, and hours are consumed in efforts to keep the person alive. This state of affairs may often be avoided by giving just enough ether to deaden the pain of the primary incisions, and perhaps the dividing of the bones, and by being as expeditious as possible in all the manipulations. It is advisable to give a moderate dose of morphine (gr. $\frac{1}{12}$ to $\frac{1}{4}$) under the skin, previous to etherizing any patient who is about to undergo a critical operation. The strength is sustained thereby, less ether is required, and the suffering is mitigated. In many instances so little of the anæsthetic is required, under these circumstances, that the operation may be said to have been done under the primary effects of the agent.

It is, of course, important that all possible precautions shall be taken to prevent hæmorrhage, and, in case of its occurrence, that it should be controlled in the speediest and most effectual manner. It is not necessary, in most instances of peril, to apply ligatures to all the bleeding points, as the hæmorrhage from the smaller vessels may be stopped by compress and bandage. Neither is it wise to consume too much time in the toilet of the wound under these circumstances. The object should be to get the patient into a warm bed as soon as is compatible with safety, and many minutiæ of the final dressing may therefore be omitted for the time being. For example, in an excision of the scapula, which was necessarily a long and bloody operation, the principal vessels were tied, the wound was hastily closed, the dressing quickly applied, and the patient, being wrapped in warm blankets, was carried up-stairs feet foremost, and put to bed, where he was allowed to remain undisturbed for three days. At the end of that time he had rallied sufficiently to allow of his being cleaned up, and having his dressings and clothing changed. As it is the little things which tell in these critical cases, they are worthy of notice.

The preservation of animal heat is of the greatest importance, and especial attention should be paid to the matter. Heaters in the shape of hot bricks, or jugs or bottles of hot water, are to be placed about the patient, care being taken that they shall not touch the flesh, and thus possibly be the means of producing an eschar, a not infrequent occurrence. He should be warmly, but not too heavily, covered with blankets, and he should be moved about or disturbed in any way as little as possible, because all these things increase exhaustion, disturb the circulation, and prevent rest. In a desperate case of pyæmic suppuration of the knee-joint, at the Boston City Hospital, an amputation of the thigh was successfully done without removing the patient from his bed. He was not under ether over three minutes, and the shock was only moderate.

A man entered the hospital suffering from a large sarcoma of the knee, of rapid growth. He was in a state of extreme exhaustion. Pulse, 150; temperature, 103°F.; pale, weak, and emaciated. Preparations having been made, he was brought from the ward in his own bed, given a hypodermic injection of morphine (gr. $\frac{1}{6}$), and after inhaling a little ether, he was transferred to the table, still being surrounded by heaters, and covered with blankets and a rubber sheet. The thigh was quickly amputated by the circular method, and as soon as the bone was sawn the ether was removed. Not over three ounces had been consumed, and the patient had not been unconscious more than five minutes. Hardly any shock followed the operation, and in twenty-four hours the temperature was normal. He speedily recovered from the operation.

Another patient, suffering from extensive and long-standing necrosis of the femur, was brought to the lowest state of exhaustion before allowing surgical interference. He finally consented, and under all the precautions mentioned above, the limb was amputated at the hip-joint by making a long external incision, disarticulating the head of the femur, and dividing the soft parts at a single sweep of the knife. The subsequent shock was not serious, and he made a good recovery. Upon the same day

another amputation at the hip was performed upon a boy, the victim of hip disease. The head of the bone had been removed by excision a few weeks previously. The patient was in a most wretched condition, emaciated to the last degree, with high temperature and rapid pulse, suppuration extending in all directions, into the pelvis, through the acetabulum above the pubes, and down the thigh. The operation was performed quickly, and all possible precautions were taken to guard against shock and prostration. For several days he had a high temperature, with sweats, delirium, restlessness, and even vomiting. He finally rallied, gained strength and flesh, and was out-of-doors upon crutches, when symptoms of tubercular meningitis suddenly made their appearance, and he died three months after the amputation.

These cases serve to illustrate the importance of the principles advocated in this paper, and by following them carefully it is firmly believed by the writer that many patients, who are in an apparently hopeless condition, can be carried through a critical operation with safety.

Briefly stated, these principles are as follows: Keep the patient warm. Avoid exposure to cold. Save time, and prevent hæmorrhage to the fullest extent possible. Stimulate and feed by the skin and rectum. Put little or nothing into the stomach until reaction sets in. Give the smallest possible quantity of anæsthetic that will control the major portion of the pain. Disturb the patient as little as possible, and get him into his warm bed as soon as is compatible with a proper performance of the operation. *George W. Gay.*

SHOULDER-JOINT. The articulation between the shoulder-girdle and the humerus. The cavity for the reception of the head of the humerus is called the glenoid fossa, and in animals possessing a separate coracoid bone it is formed by the union of the coracoid and the scapula. In man the coracoid unites with the scapula at an early age, but a trace of the primitive condition is found in fœtal life, for the embryonic coracoid forms a portion of the fossa.

Like the corresponding articulation of the lower extremity, it is a ball-and-socket joint, and in low mammals the two are very similar in other anatomical characters. But as the hip-joint becomes more solid and firm by reason of the necessities of the erect position, so the shoulder-joint becomes freer and more movable when the limb is no longer required to support the body, and less strain is put upon the investing capsule. It is, therefore, one of the loosest joints in the body, depending for its strength less upon the ligaments which unite it and the shapes of the articular surfaces, than upon the muscles which surround it and form a series of active ligaments, so to speak, as their tension may, under ordinary circumstances, be adjusted to the needs of the occasion. Owing to these peculiarities, dislocations occur at the shoulder-joint more frequently than at all other articulations in the body put together, and usually when the muscles are taken off their guard. In reducing the dislocation here it is advisable to remember this peculiarity of the muscles, and to attempt the operation when the patient's attention is attracted elsewhere, or when relaxation has been produced by an anæsthetic.

Outside of the joint proper, with its investing capsule and the muscles immediately in relation with it, there is a secondary investment, consisting of what may be called the acromio-coracoid arch (viz., the acromion process, the coracoid process, and the ligament that stretches between), and the deltoid muscle, which folds down over the shoulder as a dense triangular mass. The deeper structures play against the superficial ones, and large bursal spaces are thus formed, so that there is a secondary imperfect articulation outside of the true one. When we add to these peculiarities the fact that the joint is rendered adaptable for still freer movement by the possibility of shifting the scapula either laterally, or by tilting it upward and downward, it will be seen that we have a mechanism more easily adapted to a great variety of positions, and with a far wider range of motion, than any other joint in the body.

The articular surfaces involved are the large semi-globular head of the humerus (see Fig. 3520), and the comparatively small glenoid fossa of the scapula, deepened slightly by the rim of fibro-cartilage called the glenoid ligament (see Fig. 3521). The area of the cup is about one-third that of the head of the humerus. Examining the latter with great care before the articular cartilage has been removed, it will be seen that the surface involved in the articulation comprises about two-thirds of a sphere, but that the lateral half differs slightly in curvature from the median half, the dividing line being defined above between the coracoid process and the greater tuberosity, below by the scapular head of the triceps. For motions toward the anterior plane of the body there is, therefore, a different set of articular surfaces used from those which relate to the posterior plane. The greatest measurement is in a horizontal direction, indicating the wide extent of the forward and back movement of the arm, and this greatest diameter lies about midway between the upper and lower edges. The greatest vertical diameter lies about in a line with the bicipital groove, and indicates the plane in which the greatest excursion takes place upward and downward. This plane, if produced, cuts the articular surface of the lower end of the humerus obliquely, and usually falls behind the inner condyle. Considerable variation in this occurs in differ-

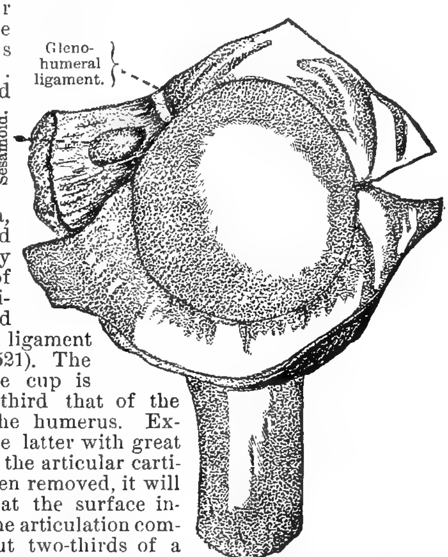

FIG. 3520.—Head of Humerus, with Part of Capsule Attached. (Morris.)

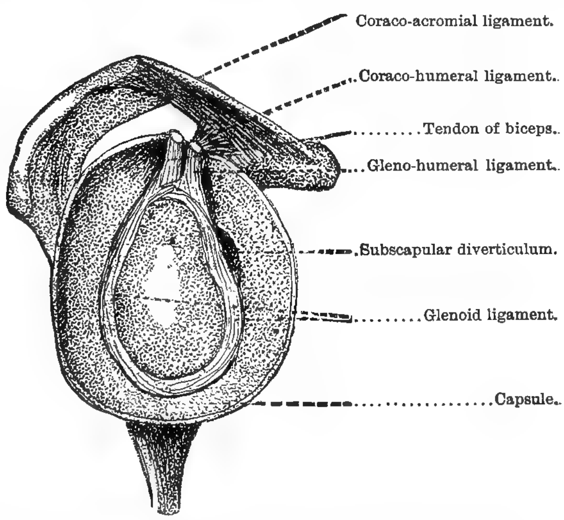

FIG. 3521.—Glenoid Fossa of Scapula, with Part of Capsule Attached.

ent individuals, and it is found that, as we descend to lower races, the angle between the axes of the articular surfaces of the upper and the lower ends of the humerus becomes constantly greater. In the apes this increase becomes still more marked. As movements directly toward the median line are soon checked by contact with the body, there is much more of the articular surface above the horizontal axis of the humeral head than below it.

The head is joined to the shaft by means of a slight constriction marking the attachment of the capsular ligament, called the anatomical neck. A line perpendicular to the central portion of the head represents the axis of this neck. It cuts the axis of the shaft at an angle of about 140°, which may be compared with the angle which the neck of the femur makes with the shaft, viz., 131° in adults. From observations made upon young bones Krause concludes, however, that the anatomical neck is not strictly comparable with the neck of the femur. If we take a humerus of a subject about fifteen years of age, in which the proximal epiphysis has not yet united, and make a horizontal section of it through the greater tuberosity, it will be seen that a strong spur-like projection extends upward and inward from the diaphysis, resembling the similar structure which forms the neck of the femur. This becomes completely encapped by the epiphysial ossification. He regards this as the real neck of the humerus, concealed within the centre of the bone. This may, perhaps, be a vestige of the time when the humerus really possessed a markedly constricted neck.

The cartilage on the head is thickest about the middle, that is to say, at the place where the bone strikes most forcibly when the arms are extended, as in pushing.

The glenoid fossa (Fig. 3521) contrasts markedly with the acetabulum of the hip-joint, being very shallow and much more limited in extent. Instead of having a spherical form it is of an irregularly oval shape, somewhat like a pear, with the large end downward, resting on the strong axillary costa of the scapula, while the upper narrower portion is at the root of the coracoid process. The slight notch on the inner side between these two is a vestige of the original division of the cavity into two parts, one belonging to the coracoid bone, the other to the scapula proper, thus resembling the constitution of the acetabulum. The bony fossa is deepened, as in the hip, by a rim of fibro-cartilage called the glenoid ligament. This is triangular in section, its fibres are concentrically arranged, and it bridges over the slight notch as the transverse ligament does the acetabular notch. Its outline does not exactly fit the head in all positions, but its elasticity allows it to adapt itself to the surface whenever the arm is moved. At the upper part of the glenoid rim the tendon of the biceps muscle of the arm is attached, its fibres passing around and blending with the fibro-cartilage. The tension of the tendon assists in holding the rim firmly against the head, and takes some pressure off the cavity. It has been suggested that the glenoid ligament is merely the remains of a former, somewhat more extensive, insertion of the biceps; that its coracoid head and glenoid head were formerly united in a single muscular sheet which had insertion around the glenoid fossa. No comparative evidence has been adduced for this view, as far as I am aware. The tendon is not so strongly blended but that it can be torn away from its glenoid attachment without detaching the cartilage.

The osteo-cartilaginous cavity thus formed for the humeral head measures only about one inch and a half in its vertical diameter, and an inch horizontally at its widest part. When the scapula is at rest it looks outward, forward and a little downward. It is a little more prominent on the inner side, to counteract the pull of the muscles and the result of blows on the shoulder, which tend to displace it in that direction. The cartilage is thickest at the edges and lower part of the cavity, as it is here that the greatest pressure is received in carrying weights and also in lifting, for the muscles above the joint (biceps, supraspinatus, and infraspinatus) hold the head firmly against this portion. Notwithstanding the sharpness of the edge of the glenoid ligament, imperfect luxations have been noted in which the humerus rested upon it. It is difficult to see how this apparently unstable position could be maintained without there being at the same time a rent in the capsule through which the head extruded, and which thus fixed it.

The capsule of the joint (Fig. 3522) forms a complete

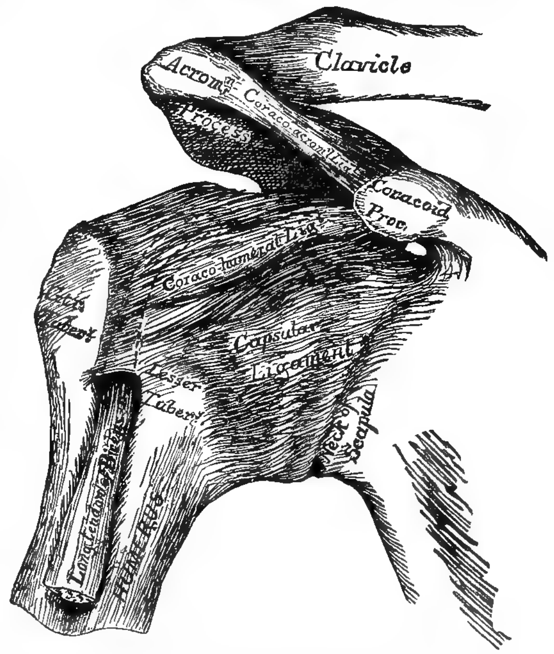

FIG. 3522.—Capsule of Shoulder-joint. (Altered from Heitzmann.)

conical investment attached by its truncated summit to the scapula at the edge of the glenoid fossa. For the greater portion of its extent it is blended with the outer margin of the glenoid ligament. This blending is most complete at the bottom, where it springs immediately from the edge of the ligament; on the sides it is less so, leaving the edge free in the joint-cavity; while above it leaves the ligament and is attached to the base of the coracoid process, affording a free margin for the insertion of the biceps tendon. Upon the humerus it is attached just beyond the articular surface at the base of the tuberosities, except at the bicipital groove, which it bridges over in order to allow the tendon of the biceps to enter the joint-cavity, and below, where it extends for a short distance downward upon the surgical neck. Resection within the capsule is therefore possible, and a pure fracture of the anatomical neck must always be intra-capsular. Some instances of this surgical curiosity are on record, and they almost invariably end unfavorably, as the head appears to be cut off from all nourishment and no union is possible. The capsule is very lax, and would admit a humeral head of twice the size of the actual one. Thus

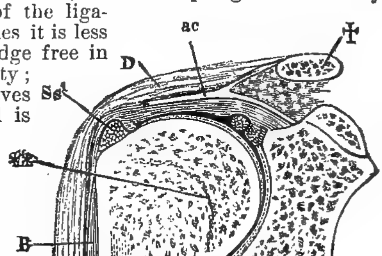

FIG. 3523.—Frontal Sections of the Shoulder-joint while the arm is hanging. (Henle.) †, clavicle; *ac*, acromio-coracoid ligament; *D*, deltoid muscle; *B*, tendon of long head of biceps; *Ss*, subscapularis; *Ss*1, supraspinatus; *Al*, triceps; *Tmj*, teres major; *, posterior circumflex artery; **, trace of epiphysial union.

the arm is never checked in its motions, except at the limits of its course. In the ordinary position, when the arm hangs loose (Fig. 3523), the capsule forms a pocket reaching downward as far as the teres major, and is united there to the periosteum of the upper end of the humerus by loose connective tissue. This pocket may receive any products of effusion or inflammation, and be felt as a fluctuating body in the axilla. When the arm is lifted away from the side (Fig. 3524), it becomes obliterated, and the motion is checked by the tension of the capsule as soon as it has reached a right angle. This is as far as the arm can be lifted without calling in the aid of the scapula. The laxity of the capsule is so great that when effusion occurs into it the bones may be pushed apart to the extent of half an inch, which explains the lengthening of the arm often seen in cases of this kind. When the extension reaches the maximum the elbow is pushed a little backward and the arm rotated inward. If the muscles are all dissected off, the head of the humerus still remains applied to the glenoid fossa, but if the capsule is penetrated, it at once drops considerably. This shows that the articular surfaces are kept in contact by atmospheric pressure, as is the case in the hip-joint. By no other means could the arm have been suspended against a shallow socket with such freedom of motion.

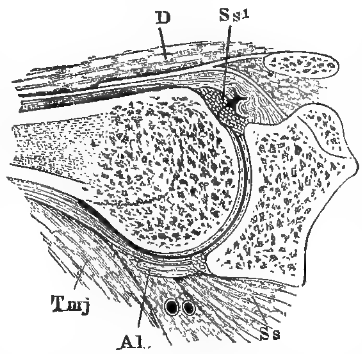

FIG. 3524.—Frontal Section of the Shoulder-joint while the Arm is lifted Horizontally. (Henle.) *D*, deltoid muscle; *Ss*, subscapularis; *Al*, triceps; *Tmj*, teres major.

The capsule is composed of bundles of tissue mostly of the white fibrous variety, but with yellow elastic fibres sparingly intermingled. Some of these run longitudinally, some obliquely, while a deeper set run circularly, parallel to the capsular insertions. A great number of vessels and nerves ramify between these bundles, and there is constantly a considerable quantity of fatty matter, even in lean persons (Sappey).

As there are no great strains put upon it habitually, the capsule does not show the marked differences in thickness which characterize that of the hip-joint. Differences do, however, exist, and are of two kinds, viz., those caused by accessory bands thickening the bundles of the capsule proper, and those caused by the union therewith of the tendons of the muscles which have their insertion near by. Several distinct thickening bands have been described. Among these the coraco-humeral ligament is the most important (see Figs. 3522 and 3525). It arises from the base of the coracoid process immediately below the acromio-coracoid ligament, and passes over the capsule to the greater tuberosity. From its situation it is sometimes called the suspensory ligament of the humerus, and it is indeed likely that the conditions of strain caused by the weight of the arm have occasioned the formation of this band. Sutton, however, considers it a vestige of a former insertion of the pectoralis minor. He finds that in some apes that muscle has an insertion upon the greater tuberosity of the humerus, and concludes that it has been displaced from that to the coracoid process, leaving the coraco-humeral ligament as the atrophied remains of its tendon.

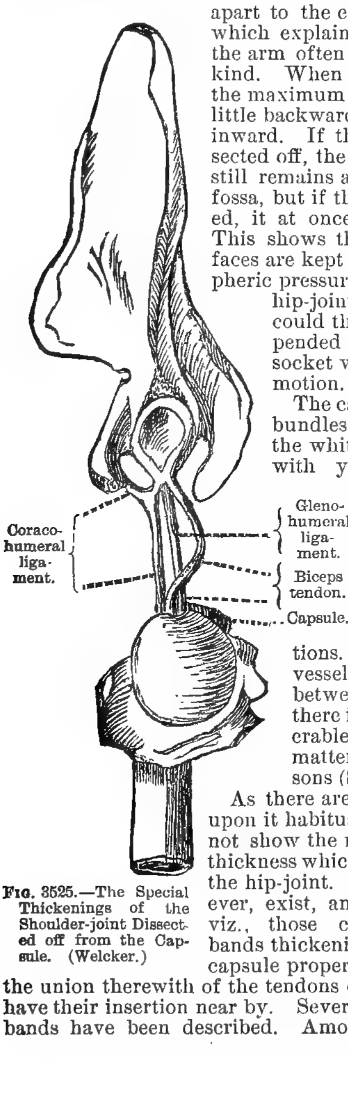

FIG. 3525.—The Special Thickenings of the Shoulder-joint Dissected off from the Capsule. (Welcker.)

Connected with the coraco-humeral ligament is another deeper structure which appears as a fold of synovial membrane, arising from the margin of the glenoid fossa and passing down with that ligament to the humerus. This fold has received various names. It appears first to have been noticed by Schlemm, who called it the *ligamentum glenoideo-brachiale internum* or *innere Schulterband*. Flood called it the gleno-humeral ligament, which is the name generally used by English anatomists. Sappey calls it the coraco-glenoid ligament, tracing it from the coracoid process. Welcker, who has made a careful comparative study of it, describes it as a posterior column of the coraco-humeral ligament, and in this he is followed by most recent German authorities. He considers the two structures as analogous to the ligamentum teres of the hip-joint. His view of their connections when dissected away from the capsule is shown in Fig. 3525. Sutton, who believes that most cord-like ligamentous structures represent the atrophied vestiges of muscles that have formerly been active around the joint, suggests that the gleno-humeral ligament is the relic of a former insertion of the subscapularis muscle. By an examination of many shoulder-joints of lower animals, he finds the ligament constantly present whenever the ligamentum teres is developed in the hip-joint, and traces the whole series back to a muscle which in *Menobranchus* corresponds to the subscapularis of man, and traverses the shoulder-joint very much as the human biceps tendon does. It is generally thought, however, that the structure in question is merely a thickening of the capsule, caused by the play of the biceps tendon against the synovial membrane.

Other accessory bands are described by some authors, viz., an *inner ligament* passing from the inner edge of the glenoid fossa along the lower margin of the subscapularis tendon to the lesser tuberosity, and the *inferior ligament*, which passes from the under edge of the glenoid cavity to the under part of the anatomical neck. These bands appear to be nothing more than the thickenings which naturally take place in the capsule where it is not strengthened by the tendons of muscles. The inner band is usually stretched or torn in subcoracoid dislocations, and the inferior one when the arm is wrenched so as to drive the head through into the axilla, producing the subglenoid dislocation. When this occurs, it may permanently injure the capsule so that whenever the arm is uplifted a dislocation takes place, by the action of the muscles which pull upon the tuberosities.

The tendons of the muscles associated with the joint strengthen it far more efficiently than do any bands of the capsule. They form around the articulation an incomplete hollow cone, with its base at the shoulder-blade and its apex at their humeral insertion, so that the capsule and the muscular investment appear like two interpenetrating cones with their bases in opposite directions. The tendons embrace about three-fourths of the upper surface, the wide tendon of the subscapularis being on the medial side, the teres minor and infraspinatus laterally, and the supraspinatus above. The union of the tendons with the ligaments is not as intimate as at the knee-joint; with care they can usually be dissected off. Beneath the tendons the capsule becomes extremely thin, and under the subscapularis it is deficient, so that the synovial membrane is in immediate contact with the tendon. The subscapularis has usually a small sesamoid

developed in it (Fig. 3520), where it rubs against the lesser tuberosity. Some of the fibres of the long head of the triceps become blended with the lower part of

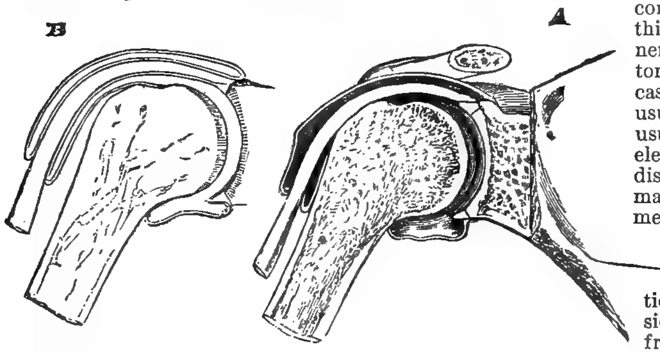

FIG. 3526.—A, Section Showing the Relation of the Long Tendon of the Biceps to the Shoulder-joint. B, is an outline showing the Arrangement of the Synovial Membrane. (Allen Thomson in Quain's Anatomy.)

the capsule, and no doubt tend to draw it downward and prevent it from being nipped when the arm is brought toward the side.

But the most interesting feature of the muscles about

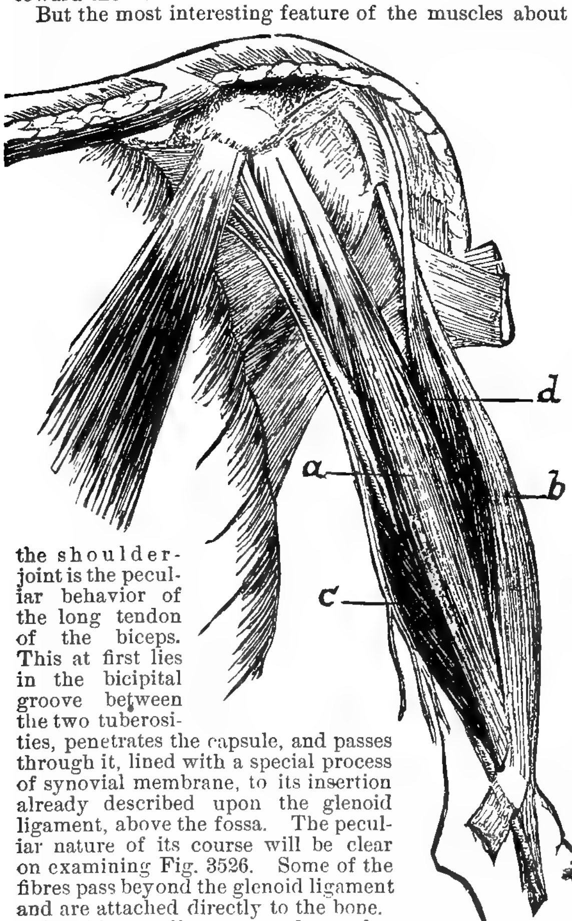

FIG. 3527.—Abnormal Arrangement of the Biceps. *a*, Coracoid head; *b*, glenoid head; *c*, humeral head; *d*, capsular head.

the shoulder-joint is the peculiar behavior of the long tendon of the biceps. This at first lies in the bicipital groove between the two tuberosities, penetrates the capsule, and passes through it, lined with a special process of synovial membrane, to its insertion already described upon the glenoid ligament, above the fossa. The peculiar nature of its course will be clear on examining Fig. 3526. Some of the fibres pass beyond the glenoid ligament and are attached directly to the bone.

By this peculiar course the tendon becomes one of the most efficient strengtheners of the articulation, acting precisely where force is needed, and holding down the bone against the glenoid fossa like a strap, preventing its displacement upward by the action of the deltoid and the muscles inserted into the tuberosities. It grooves the inner tuberosity more than the outer, thus tending to counteract the outward twist of the arm given by the insertion of the muscle upon the tuberosity of the radius (Humphry). Sudden muscular contraction has been known to pull it asunder, and this accident may at once be recognized by a prominent swelling on the front of the arm, caused by the tonic contraction of the muscular belly. In rare cases it has been torn from its seat in the groove, usually by direct violence. The groove can then usually be felt as empty; the humeral head is slightly elevated and rotated inward (White). In cases of dislocation of the humerus the tendon usually remains uninjured, but may be torn from its attachment or dragged from its normal situation. The head of the bone may pass between the two heads of the biceps, which may hold it and offer an obstacle to the reduction of the dislocation. In resection of the head the tendon is considerably in the way, and it is usual to detach it from its groove and hold it to one side. Tillaux holds that in these cases it is quite proper to cut it, if it at all embarrasses the operation, as it is almost certain to slough during the ensuing suppuration.

The varieties which occur in the biceps muscle have given rise to a careful investigation of its mode of origin. One of the most rare of these is shown in Fig. 3527. The biceps here has four heads, one of the supplementary ones arising from the capsule of the joint. Welcker has examined the behavior of the long head of the biceps in many animals, and finds that in some cases it is entirely superficial, separated from the capsule by a bursa. Between this and the usual condition all stages of penetration of the capsule are found. These are shown in Fig. 3529. The tendon first grooves it, then penetrates it, and lies between the ligament proper and the synovial membrane, then buries itself sideways in this, gradually acquiring a fold connecting it with the wall known as the mesotenon; then this is finally lost, the muscle passing freely through the joint invested by its own special sheath of synovial membrane, which becomes continuous with that lining the joint at either end. On investigating the stages of development in the human fœtus, we find a similar series of changes. The mesotenon of the fœtal joint is shown in Fig. 3528. It appears therefore probable that the capsular head shown in Fig. 3527 is merely a detached fascicle, left behind by the long tendon in its gradual penetration of the capsule.

FIG. 3528.—Shoulder-joint of a Fœtus Showing the Mesotenon of the Biceps. (Welcker.)

Some cases of absence of the long head of the biceps have been reported. While most of these are doubtless due to pathological causes, the tendon having been absorbed by inflammatory processes, there are yet some instances of congenital absence, the bicipital groove being empty and nearly obliterated, and there being no trace of a process of the synovial membrane corresponding to an atrophied tendon.

The synovial membrane of the joint is large, but it rarely becomes diseased. Indeed, it is freer from disorders than that of any other of the large joints of the body, owing probably to the general absence of any exciting causes. Two diverticula of the synovial sac are found, as already mentioned, one under the subscapularis, the second running down along the tendon into the bicipital groove. These are respectively called the *bursa scapularis* and *bursa intertubercularis* (see Fig. 3530). The opening of the subscapular bursa varies in size. Humphry states that the head of the humerus has been dislocated into it with but little apparent rupture of the capsule. The place where any effusion into the joint first becomes manifest is anteriorly, in the interspace between the deltoid and pectoralis major.

Immediately outside the capsule are situated a number of bursal sacs which do not usually communicate with the joint, but which alleviate the friction between the muscles immediately surrounding the capsule and

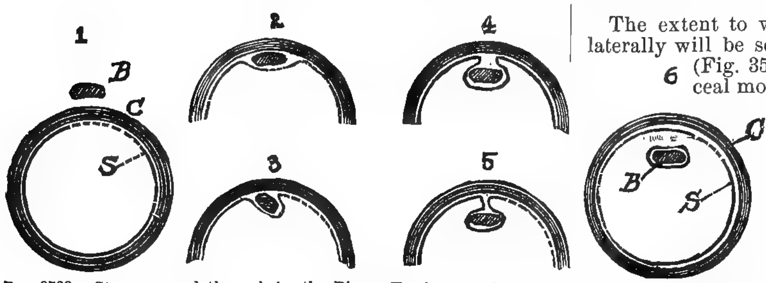

FIG. 3529.—Stages passed through by the Biceps Tendon, as shown by Specimens from Different Individuals. (Welcker.) *B*, Biceps tendon; *C*, capsule; *S*, synovial membrane.

those which lie more superficially. The most important of these is the *bursa subdeltoidea* (Fig. 3530), a large sac, usually double, that lies between the capsule and the structures arising

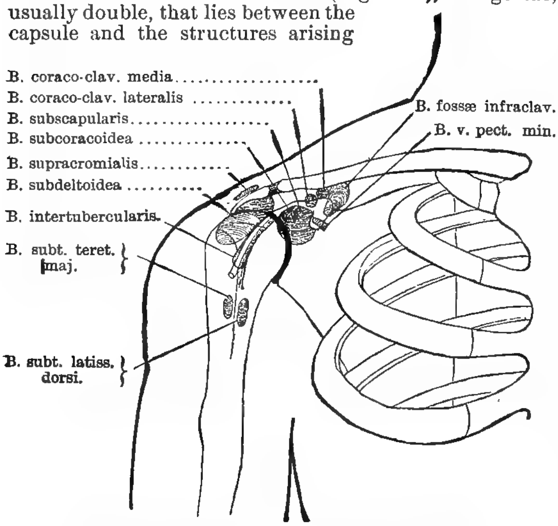

FIG. 3530.—The Principal Bursæ about the Shoulder.

from the acromion process, viz., the coraco-acromial ligament and the deltoid muscle. This may become in-

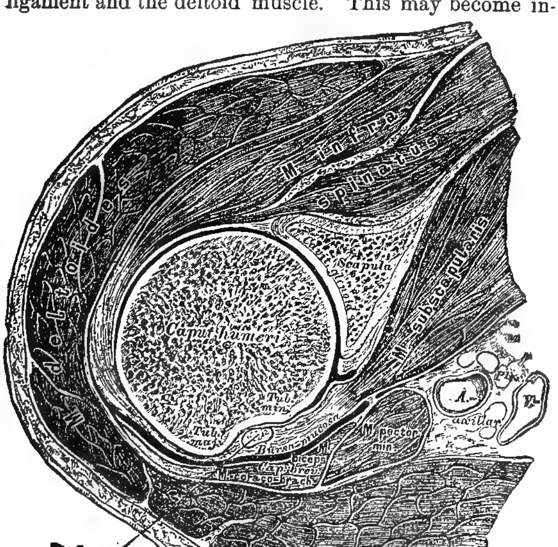

FIG. 3531.—Horizontal Section through the Right Shoulder. (Heitzmann.)

flamed or enlarged, and simulate an affection of the joint.

The extent to which the deltoid caps over the joint laterally will be seen on looking at a horizontal section (Fig. 3531). Its thick and strong fibres conceal most of the features of the joint, but yet the humeral head does make a considerable prominence externally, and whenever it leaves its socket a depression, easily recognized if taken before swelling sets in, can be noted just below the acromion process.

The deltoid is supplied by the circumflex nerve from the brachial plexus, and this also gives the main supply to the joint. The suprascapular and subscapular nerves also send twigs. One of the most frequent complications of a fracture of the surgical neck of the humerus is a paralysis of the deltoid, occasioned by an injury to this nerve where it winds around between the bone and the long head of the triceps. This is a serious difficulty, for the deltoid is the only muscle that can abduct the arm. The nerve must be carefully avoided in all resections of the head.

The arteries supplying the joint are all insignificant branches from the axillary and the subclavian, offering no real obstacle to the surgeon.

The movements possible to the joint consist of angular motion in all directions, the combining of these to form circumduction and rotation. Movement toward the anterior plane of the body is more free than that behind. The coracoid arch limits abduction beyond a right angle, to lift it higher the scapula must be tilted. Rotation is used to assist the pronation and supination of the fore-arm.

Frank Baker.

SIALAGOGUES (also written *Sialogogues*), agents which excite the flow of saliva. Agents producing this effect are naturally divided into two classes, viz., (1) those which act locally and directly, and (2) those which exert their influence upon the salivary glands secondarily, through the medium of the general circulation.

In the first class, termed *masticatories*, may be ranked all agents capable of directly exciting a flow of saliva when placed in the mouth or chewed, excluding, of course, mere alimentary substances. For practical purposes, however, the term is restricted to a limited number of articles, some of which have been employed for medicinal purposes, but most of them are used by the laity for stimulant or narcotic effect. Thus, among people of our own country, tobacco is largely employed as a masticatory, while in South America coca, and in India betel, are used in the same manner. These drugs placed in the mouth and slowly chewed excite a more or less abundant flow of saliva, in which is dissolved the active principles of the plant employed; and the saliva so impregnated being swallowed, or taken up by the absorbents of the mucous membrane of the buccal cavity, produces the effect desired, generally in a slow and continuous manner. But in the case of habitual tobacco-chewers the flow of saliva is, as a rule, excessive, and is commonly ejected from the mouth, the entire narcotic effect being produced through the medium of the absorbents of the buccal cavity.

Now, when we consider the important part played by the saliva in digestion, it appears evident that this excessive flow, nearly all of which is ejected, must be injurious. Still, this is but an incident compared with the narcotic effect of the drug which enters the circulation. And though in some instances the excessive flow of saliva becomes almost a systemic depletion, the more serious results of tobacco-chewing, as compared with tobacco-smoking, are due to the fact that a far greater amount of the drug enters the circulation in the former than in the latter way. This is partly due to the greater concentration of the active principles of the drug in the saliva of the chewer, and partly, also, to the fact that the chewer uses tobacco almost continuously during his waking hours, while the smoker indulges, as a rule, only at intervals.

Among the other masticatories handed down by the text-books from generation to generation are *pyrethrum*, *armoarcia*, and *mezereon*, but their medicinal use in this manner is long since obsolete.

The gum-resins of certain forest-trees, as the sweet-gum (*Liquidambar Styraciflua*), tamarack (*Larix Americana*), and black spruce (*Abies nigra*), are used as masticatories, particularly by women and children, but this habit is an offence against conventionality rather than hygiene. Indeed, gum-chewing, in some instances of feeble digestion, appears to be beneficial, whether by reason of the simple ingestion of saliva—for the gum is practically insoluble in this secretion—or because the individual's mind is diverted from his laboring stomach, it is not important to inquire.

This statement, however, is only applicable to the digestive period, for the pouring of an excessive amount of saliva into an empty stomach is not innocuous.

Turning from masticatories to sialagogues proper—those agents which excite a flow of saliva through the medium of the general circulation—we are struck by the contrast of their diminished number, for the drugs known to possess this property are very few. At the head of the list, until recently, has long stood mercury. Generations of medical men have employed mercury for the express purpose of increasing the salivary secretion, with the idea that in this manner the system of the patient was purified of morbific matter. This practice, begun as a cure for syphilis, rapidly extended until it ultimately became the standard routine treatment for nearly all diseases. Its history is, indeed, one of the curiosities of medical literature, as upon this property of mercury was based a pathological theory which long fettered the medical mind and effectually retarded scientific progress.

As the action of this drug is minutely discussed in another part of this work (see Mercury), it is only necessary here to observe that its use as a sialagogue is practically obsolete. That is to say, profuse salivation by mercury is, at the present day, considered a poisonous rather than a strictly medicinal effect, and it is therefore carefully guarded against. The interest, then, attached to mercury as a sialagogue is little more than historical.

Not so, however, with the next drug to claim our attention, namely, jaborandi. In jaborandi we have an agent which, in addition to a powerful influence upon the sweat-glands, also greatly stimulates those of the salivary apparatus. And this effect is not produced slowly, as is the case with mercury, nor for a great length of time. It follows quickly upon the administration of the drug, and is of short duration. Moreover, the flow of saliva produced by an efficient dose of jaborandi is so abundant as to amount to a positive depletion, often found of essential service, especially in cases of uræmic poisoning. Though the salivary glands are excited to a remarkable degree, this excitement is but transitory; and the inflammation and ulceration so commonly attendant upon mercurial salivation never result from the use of jaborandi. Unfortunately, however, jaborandi is a cardiac depressant, and on this account requires to be used with caution. It is, in fact, the only sialagogue properly entitled to the name, since it is the only agent which can be employed to excite the flow of saliva for remedial purposes. And even as a sialagogue it is much less valuable than as a diaphoretic. (See Jaborandi.)

A few other medicinal agents occasionally produce salivation as one of their effects, but as they are never used for this purpose their consideration may well be omitted.
Laurence Johnson.

SILICATES. The only use at present for the silicates is in surgery, in the preparation of immovable dressings for fractures, etc. For this purpose solutions of both the potassium and the sodium salts (called soluble glass) have been employed, but the latter is far preferable to the former, and should always be selected when possible.

The solution of Silicate of Sodium (*Liquor Sodii Silicatis*) is the only officinal preparation of the silicates. It is "a semitransparent, almost colorless, or yellowish, or pale greenish-yellow, viscid liquid, odorless, having a sharp saline and alkaline taste, and an alkaline reaction. The sp. gr. of the commercial solution is between 1.300 and 1.400. A drop of the solution, when held in a non-luminous flame, imparts to it an intense yellow color. If a portion of the solution, considerably diluted with water, be supersaturated with nitric acid, a gelatinous or pulverulent, white precipitate of silicic hydrate will be produced. A small quantity should not produce any caustic effect when applied to the skin (absence of an excessive amount of alkali)." For an account of the surgical uses of sodium silicate the reader is referred to the article Splints.

Silicate of sodium is said to possess anti-fermentative properties, and has occasionally been employed as an antiseptic by some French surgeons. Marc Sée has reported good results from its external use in chancre, and from urethral injections in gonorrhœa. Dubreuil injected it into the bladder, in a case of vesical paralysis occurring with hypertrophy of the prostate gland in an old man, and found that it prevented ammoniacal decomposition of the urine. The sodium and potassium salts have also been given internally in rheumatism. The medical uses of the salts are, however, obsolete, and as they have been shown to possess toxic properties in experiments upon dogs, it is probably just as well that their therapeutic employment should not be revived.

Hydrated magnesium silicate, the meerschaum from which pipes are made, has been suggested by Garraud as a substitute for bismuth subnitrate, which salt it resembles, in diarrhœa. Good results were reported from its use, but it did not appear to possess any advantages over the bismuth.

SILURIAN SPRING. *Location and Post-office.*—Waukesha, Waukesha County, Wis.

Access.—From Chicago by the Chicago, Milwaukee & St. Paul, or the Chicago & Northwestern Railroads.

Analysis.—Professor W. S. Haines. One gallon contains:

	Grains.
Chloride of sodium	0.1926
Sulphate of sodium	0.2917
Bicarbonate of sodium	0.0301
Carbonate of calcium	9.9277
Carbonate of magnesium	6.8324
Carbonate of iron	0.1285
Phosphate of iron	traces
Phosphate of manganese	traces
Alumina	0.5827
Silica	0.7004
Organic matter	very faint trace
Total solids	18.6861
	Cub. in.
Carbonic acid gas	44.7

Therapeutic Properties.—This water is very similar in composition and effect to the Bethesda. It is mildly alkaline and saline, and, being perfectly free from organic matter, it acts freely as a diuretic and antacid. It is used with success in dyspepsias and kidney and mucous membrane diseases generally. This spring is situated in the southern part of Wisconsin, about twenty miles west of Milwaukee, on the Fox River, in the town of Waukesha. There are a number of good hotels in the village, which has a population of about thirty-five hundred. Within a distance of ten miles are several beautiful lakes, affording good fishing.
G. B. F.

SILVER. I. General Medicinal Properties of Compounds of Silver.—In medicinal dosage the most important effect that follows persistent internal medication with silver is the tendency to a bluish-black discoloration of the skin and mucous membranes. This staining shows first on the mucous membranes, so that by inspection of the inner surfaces of the lips and of the fauces, during a course of medication by silver, and by stoppage of the medicine upon the first beginning of a bluish discoloration of those parts, no serious risk of staining of the skin need be incurred. As a rule, efficient dosage with silver can be maintained for from one to three months before coloration begins. In overdosage silver is a constitutional poison, impairing nutrition generally, and

deranging the nervous system particularly. Therapeutically, impregnation of the system with silver tends to oppose, albeit feebly, the onward march of certain diseases of the nervous system, such as epilepsy and tabes dorsalis. But in the more intractable of these diseases, such as tabes, the influence is so slight as to be of no value—if, indeed, it exist at all—and in epilepsy other remedies are far more potent. The use of silver for constitutional effect is, therefore, in modern practice, seldom resorted to.

Locally, the effects of silver compounds differ with the individual preparations according to their solubility, and will be described in connection with the several compounds themselves.

II. The Medicinally used Compounds of Silver.—These comprise the several salts, *argentic oxide, iodide,* and *nitrate.* The *cyanide* is also officinal in the U. S. Pharmacopœia, but for pharmaceutical purpose only.

Argentic Oxide: Ag_2O. Argentic oxide is officinal in the U. S. Pharmacopœia as *Argenti Oxidum*, Oxide of Silver. It is "a heavy, dark brownish-black powder, liable to reduction by exposure to light, odorless, having a metallic taste, and imparting an alkaline reaction to water, in which it is very slightly soluble. It is insoluble in alcohol" (U. S. Ph.). This oxide readily yields its oxygen in presence of oxidizable matter, and hence should not be triturated with any such material. It dissolves in water of ammonia. From its comparative insolubility this compound has little local effect, but when swallowed, probably through chemical conversion, it is capable of absorption, and exerts the constitutional effects of silver, such as they are. In such operation the oxide is thought to be less prone to discolor the skin than the nitrate, but it is certainly not wholly innocent of this tendency. Upon the stomach and bowels silver oxide has quite a marked potency to allay irritability, tending to quell vomiting, even in such complaints as ulcer and cancer of the stomach, and to control diarrhœa when arising as a reflex of nervous irritation. The principal employment of the medicine is in such disorders of the digestive apparatus. The average dose is about 0.06 Gm. (one grain), best given in powder or capsule. The pill form is bad, because of the deoxidation of the compound by the organic matter of the excipient, which reaction may even be attended by explosion. Gum arabic is recommended as the least objectionable excipient.

Argentic Iodide: AgI. The salt is officinal in the U. S. Pharmacopœia as *Argenti Iodidum*, Iodide of Silver. It is "a heavy, amorphous, light-yellowish powder, unaltered by light if pure, but generally becoming somewhat greenish-yellow, without odor and taste, and insoluble in water, alcohol, diluted acids, or in solution of carbonate of ammonium. Soluble in about 2,500 parts of stronger water of ammonia" (U. S. Ph.). Argentic iodide is, medicinally, substantially a duplicate of the oxide, and may be used for the same purposes and in the same dose.

Argentic Nitrate: $AgNO_3$. This, by far the most important compound of silver, is officinal in the U. S. Pharmacopœia in three conditions, namely, in crystals, in cylindrical sticks moulded by fusion, and in similar sticks in admixture with equal parts of potassic nitrate.

Argenti Nitras, Nitrate of Silver. This title signifies the salt in crystals, which the Pharmacopœia describes thus: "Colorless, transparent, tabular rhombic crystals, becoming gray or grayish-black on exposure to light in presence of organic matter, odorless, having a bitter, caustic and strongly metallic taste and a neutral reaction. Soluble in 0.8 part of water and in 26 parts of alcohol at 15° C. (59° F.), in 0.1 part of boiling water, and in 5 parts of boiling alcohol. When heated to about 200° C. (392° F.), the salt fuses to a faintly yellow liquid, which, on cooling, congeals to a purely white, crystalline mass. At a higher temperature the salt is gradually decomposed, with evolution of nitrous vapors. It should be kept in dark amber-colored vials protected from the light." These crystals constitute the purest form of the nitrate, and are used for internal giving or for the making of solutions.

Argenti Nitras Fusus, Moulded Nitrate of Silver, "Fused Nitrate of Silver," "Lunar Caustic." The crystals are melted by heat, and the fused salt poured into moulds where it sets on cooling. But inasmuch as the pure nitrate is, when fused, inconveniently brittle, the Pharmacopœia provides for a trifling admixture of argentic chloride, which is a tough compound. To this end about four per cent. of hydrochloric acid is added to the melted crystals, whereby a small portion of the nitrate is converted into chloride. Reaction having ceased, the mixed mass is ready for moulding. Lunar caustic is cast in narrow cylindrical sticks, which are hard, brittle, and, when freshly made, white in color. As commonly found, however, they are gray, or even blackish, through chemical reaction with matters present in the atmosphere. "Soluble, with the exception of about five per cent. of chloride of silver, in 0.6 part of water and 25 parts of alcohol at 15° C. (59° F.), in 0.5 part of boiling water, and in 5 parts of boiling alcohol. It is insoluble in ether. Whatever is left undissolved by water is completely soluble in water of ammonia" (U. S. Ph.). Fused nitrate of silver should only be used for its legitimate purpose, that of external application.

Argenti Nitras Dilutus, Diluted Nitrate of Silver. Argentic and potassic nitrates, in equal proportion, are melted together by heat and the fused mass poured into moulds. The product is "a white, hard solid, generally in form of pencils or cones of a finely granular fracture, becoming gray or grayish-black on exposure to light in presence of organic matter, odorless, having a caustic, metallic taste, and a neutral reaction" (U. S. Ph.). The sticks dissolve freely in water and possess the same properties as the undiluted lunar caustic, only in milder degree. They are used only for local application.

Nitrate of silver differs from the oxide and iodide in the essential particular of free solubility, on which property depend the most valuable medicinal virtues of the salt. The most important reactions of the nitrate are that its solutions are precipitated by soluble chlorides to form the very insoluble salt, argentic chloride. This reaction is one of the most delicate in chemistry, and since traces of chlorides are present in almost all natural waters, the use of distilled water is necessary for solutions of nitrate of silver, if a clear, bright solution be desired. Nitrate of silver also reacts on organic matter generally, suffering decomposition, and forming, with the organic substance, compounds insoluble and acquiring a rusty brownish-black color under the action of light. Hence sticks of lunar caustic grow gray and black on the surface by keeping, by reaction with the organic dust of the atmosphere, and solutions of silver nitrate deposit a fine black sediment, and stain textile fabrics and skin. The stain on the skin, if recent, can be fairly well removed by rubbing with a moistened lump of potassic cyanide, and washing—always remembering the very irritant and poisonous character of such cyanide. But if the stain be old, and fixed by exposure to sunlight, the cyanide fails, and the following means may be resorted to: Moisten the stains, drop on them a little tincture of iodine, and then wash in a six per cent. solution of sodic hyposulphite. Or, very efficient, mix in a saucer a few bits of iodine with a little water of ammonia; rub the stains quickly with the resulting preparation, and immediately wash both skin and saucer while they are still wet. This latter precaution is necessary, since the compound of iodine and nitrogen produced by the mixture of chemicals spontaneously explodes upon slight agitation when dry. Other reactions of silver nitrate are its precipitation by sulphuric, hydrosulphuric, phosphoric, hydrochloric, and tartaric acids and their salts; by the alkalies and their carbonates, lime-water and the vegetable astringents, and arsenical and albuminous solutions.

Nitrate of silver is an irritant astringent, with also the peculiar specific effects of silver compounds already detailed, viz., the allaying of gastric irritability, and the induction of certain constitutional control over nervous disease. The local effects are the more important, and are as follows: The salt readily combines with albumin to make an insoluble compound, the albuminate of silver; hence, when in strong solution or in solid stick, its application to the surface of a mucous membrane or of granu-

lation-tissue produces a white streak of cauterization, which, by the insolubility of the compound formed, limits the action of the caustic to the production of such shallow slough. Concentrated applications to the skin speedily blacken the epidermis, and, more slowly, raise a blister. In solutions less than ten per cent. in strength the salt is hardly caustic, but acts only as an irritant astringent. When swallowed, quite small doses act locally like the oxide, while large produce irritant poisoning. Therapeutically, local applications of silver nitrate judiciously made have a marked tendency to promote absorption in such tissues as are capable of undergoing this process ; to induce healing ; to limit and abate the catarrhal process ; to destroy skin-parasites, though not very searchingly ; and to neutralize the virulence of specifically noxious pus.

The medicinal uses of silver nitrate are such as may be deduced from the foregoing. Internally the medicine may be given, for constitutional or local effect, in doses of from 0.015 to 0.03 Gm. (from about one-fourth to one-half grain) in pill or solution. In neither way of giving does the salt probably reach the stomach as nitrate ; for, if in solution, a medicinal dose must almost certainly be decomposed in the swallowing, and, if in pill, be acted on similarly by the necessary organic matter of the excipient. To obviate this effect as far as possible in the case of pills, it is advised that bread-crumb be particularly avoided as an excipient, because of its containing a soluble chloride (common salt) as well as organic matter, and that some vegetable extract, or a dry powder made sticky by a minimum of gum, be selected. In any case the crystallized silver salt should alone be prescribed. Externally, silver nitrate may be used as a caustic, but only where a superficial effect is wanted, as for the destruction of the lining membrane of a cyst. The fused stick is in such cases used, its moistened surface being swept over the surface to be destroyed. More common is the application to promote absorption, as in case of exuberant granulation-tissue or trachoma-bodies ; to determine healing, as in unhealthy ulcers ; or to shorten and abate the course of a catarrh. For such purposes various strengths of the nitrate are used, from application of the pure or diluted sticks of lunar caustic to that of solutions of not more than the one-fifth of one per cent. strength. To determine absorption the stronger applications are necessary, to control catarrhs the weaker; but in all cases care should be taken not to overdo the matter, and, by too strong or too frequent application, to actually interfere through excess of irritation with healing or with resolution. In the case of catarrhs, moreover, the remedy should not be used at all until the second stage of the process is reached, as betokened by the establishment of the catarrhal secretion and abatement of the initial pain or sensitiveness. Then, too, the strength of the application should be adjusted to the different degrees of sensibility of the different mucous membranes ; for while the comparatively insensitive membranes, such as those of the fauces or vagina, may take a five per cent. solution, or even stronger, hardly more than the one-tenth of this strength can be applied without undue irritation to the nasal passages or to the male urethra. When a very brief action is wanted, the application of silver may be immediately followed by one of a solution of common salt, which salt immediately precipitates all excess of nitrate as the insoluble, and therefore inert, compound, silver chloride.

Argentic Cyanide: AgCN. This salt is officinal in the U. S. Pharmacopœia as *Argenti Cyanidum*, Cyanide of Silver. It is a "white powder, permanent in dry air, but gradually turning brown by exposure to light, odorless and tasteless, and insoluble in water and in alcohol. Insoluble in cold, but soluble in boiling, nitric acid, with evolution of hydrocyanic acid ; also soluble in water of ammonia and in solution of hyposulphite of sodium. When strongly heated, the salt fuses, gives off cyanogen gas, and, on ignition, metallic silver is left" (U. S. Ph.). Argentic cyanide is not used in medicine, but only in pharmacy, for the making of diluted hydrocyanic acid.

Edward Curtis.

SILVER, POISONING BY. The most important salt of silver, medico-legally, is the nitrate, which is prepared by dissolving silver in dilute nitric acid. It crystallizes in transparent rhombic plates, and has an exceedingly acrid metallic taste. It is soluble in less than its weight of water at 59° F. (15° C.). Melting-point, 198° C. The melted salt run into moulds forms the officinal *Argenti Nitras Fusus* (lunar caustic). To overcome its brittleness, or to modify its action, the salt is sometimes fused with a certain proportion of silver chloride or potassium nitrate. Nitrate of silver, when pure, is not blackened by exposure to light ; but, when in contact with organic matter, it is decomposed, with formation of a black, insoluble compound. Hence its use in indelible inks. For the same reason living tissues to which the nitrate has been applied soon turn black. Hydrochloric acid or soluble chlorides produce in solutions of this salt a white, curdy precipitate (silver chloride), soon turning violet upon exposure to light, soluble in ammonium hydrate, insoluble in nitric acid. The nitrate is used in indelible inks, in hair-dyes, largely in chemical analysis and in photography, and in medicine, both externally and internally. Poisoning by nitrate of silver may be either acute or chronic.

Acute Poisoning.—This is rare, and is usually accidental, resulting from swallowing pieces of nitrate of silver pencils which have been broken off in the act of cauterizing the throat. Very rarely a solution has been taken accidentally or for suicidal purpose. The disagreeable taste of the salt is likely to frustrate any attempts to make use of it for criminal poisoning.

Symptoms.—Nitrate of silver is a violent irritant and corrosive. Large doses are followed, therefore, by symptoms of gastro-enteritis, namely, severe burning pains in the region of the stomach and intestines, violent vomiting, and diarrhœa. If the ordinary chemical antidote (common salt) has been administered, the vomitus and fæces may be white and curdy, becoming violet or nearly black upon exposure to light. This appearance, as well as the black stains upon those parts of the body with which the salt has come in contact, such as the lips, aid materially in making a diagnosis. The nitrate also acts upon the nervous system, producing loss of consciousness, convulsions, paralysis, and disturbances of respiration.

Fatal Dose—Fatal Period.—These are not determined. Death has followed the ingestion of 1.94 gram (30 grains). Taylor mentions the case of a woman who took 3.24 grams (50 grains) in divided doses, and died in three days. Recovery has taken place in two cases after the ingestion of 31.1 grams (℥ j.). Death has ensued as early as six and nine hours—children in both cases.

Post-mortem Appearances.—These, so far as observed, are similar to those characteristic of the irritant poisons in general, namely, redness and injection of the mucous membranes of the œsophagus, stomach, and intestines. White or grayish patches have been noticed in the stomach and duodenum.

Treatment.—Common salt and milk should be administered freely. Vomiting should then be induced ; for the chloride of silver is soluble in an excess of sodium chloride, and the albuminate is soluble in the digestive fluids. In other respects the treatment should be symptomatic.

Mode of Action.—It is reasonably certain that the nitrate undergoes decomposition as soon as it reaches the stomach. It forms, with hydrochloric acid and soluble chlorides—as sodium chloride—the chloride of silver. This is insoluble in water, but soluble in solution of sodium chloride. With albuminous matters it forms an albuminate, soluble in solution of sodium chloride and in the digestive fluids. It is probable that silver is absorbed in one of these forms, or in some similar form.

Rouget has shown, by experiments on animals, that the soluble salts of silver produce, first, vomiting and diarrhœa, soon followed by muscular weakness, paralysis, disturbances of respiration, and weak clonic convulsions. In cold-blooded animals their administration is quickly followed by severe tetanic convulsions, similar to those

produced by strychnine, then by disturbances of respiration and paralysis. Death is due to asphyxia. Two theories have been proposed in explanation of the asphyxia. One assumes that it is due to congestion of the lungs and to the excessive secretion of mucus in the lungs—such as has been observed in experiments on dogs and cats; the other that it is due to a direct action of the poison on the central nervous system (Charcot and Ball, Rouget, Curci). The results of Rouget's experiments on animals point to the latter as the more probable explanation. For, although finding respiratory symptoms prominent in all cases, only occasionally were any pulmonary lesions found after death. Curci considers the general paralysis a reflex paralysis. According to Falck the temperature sinks 44° to 63.7° F. (6.7° to 17.6° C.) after subcutaneous injection of the nitrate in rabbits.

CHRONIC POISONING—ARGYRIA.—The name argyria has been given to a condition which follows the long-continued use of nitrate of silver, and which is characterized by a gray discoloration of the skin, of greater or less intensity, the color being ordinarily deeper on those parts of the body which are exposed to the light. It is most frequently the result of the long-continued use of medicinal doses of the nitrate taken internally. Two cases are reported which were the result of its application to the throat, extending over some years, as a caustic, small quantities being swallowed and absorbed (Duguet); and a case is reported, the result of the use, for a number of years, of a solution of the nitrate for coloring the beard (Bresgen). Recent observations made on silver-plate workers in Berlin have shown that absorption of silver may follow constant handling, for a long time, of the metal, and that among such workers characteristic-colored patches, round or oval in shape, and varying in size from a millet-seed to a broad bean, are very frequent, occurring principally upon the dorsum of the left hand. The men affected were invariably those who had some ulceration or abrasion of the skin, through which the metal was probably absorbed.

The first symptom of argyria is usually an inflammatory swelling of the gums, with a blue or violet line at the junction of the gums with the teeth. If the administration of the silver compound is continued, there appear later, on various parts of the skin, grayish patches, which gradually increase in size; the whole skin, as well as the visible mucous membranes, finally presenting a grayish or grayish-black discoloration. This discoloration is not, however, limited to the skin and superficial mucous membranes, but may involve the internal organs and mucous membranes. It is more intense on those parts of the skin which have a thin epithelial covering. A local argyria may be produced by the frequent application, over a long period, of nitrate of silver to wounds of the surface of the body or mucous membranes.

The length of time and the amount of silver preparation requisite to produce the discoloration of the skin cannot be definitely stated. A general discoloration of the body is not likely to appear, so far as can be judged from recorded cases, till the lapse of a year or thereabout, or till as much as fifteen to thirty grams ($3\frac{3}{4}$ to $7\frac{1}{2}$ drachms) of the nitrate has been administered. Larger amounts have been taken, however, without producing any discoloration. It would seem that the suspension of the nitrate for a while has no certain effect in postponing the appearance of the discoloration when the administration is again resumed; for a case is reported in which the administration was resumed, after an interruption of six years, and was followed by discoloration in six months. The explanation is probably to be found in the failure of the system to eliminate to any great extent the silver which has once been absorbed. The line on the gums has been observed in two months, during which time 3.9 grams (60 grains) of nitrate of silver had been taken (Guipon).

The general health does not appear to suffer in argyria in man. Bogoslowsky, however, produced argyria in animals, and observed in them loss of appetite, diarrhœa, emaciation, albuminuria, followed by death.

Microscopic examination shows that the discoloration in argyria is due to the presence of minute black granules, probably metallic silver or some compound of silver (according to Krissinsky an organic compound of silver). In the skin they are found under the rete Malpighii in the superficial layers of the corium, in the deep connective tissue, in the sweat and sebaceous glands, in the smooth muscular fibre, and in the media and adventitia of the arteries. The epithelium is free. In the intestines the epithelium is also free from color, while the remaining parts are pigmented. In the internal organs the deposit is most noticeable in the smaller vessels and connective tissue. In the kidneys the glomeruli especially are pigmented. The substance of the brain and spinal cord is free, but in the choroid plexus the deposit is abundant. It is also especially abundant in the cells of the medulla of the bones (Krissinsky), the intima of the aorta and other large vessels, and in the mesenteric glands. Bogoslowsky in his experiments on animals found advanced fatty degeneration of the parenchymatous organs of the body, especially the liver and kidneys; and of the muscles, especially the muscular fibres of the heart.

The discoloration in argyria is permanent. No method of treatment is known by which it can be removed.

Absorption and Elimination of Silver.—Silver is absorbed and may be detected after death in the various organs of the body. The quantity taken into the circulation is probably very minute; the greater part of that taken into the stomach being removed with the fæces. Silver has been detected in the urine, and is probably eliminated chiefly through the kidneys. It is to be inferred from the permanency of the discoloration in argyria that elimination is very slow; that, in fact, in most cases, it is never completed. The pigmentation of the liver has been observed as late as five years after the cessation of a course of treatment with nitrate of silver.

Other Preparations of Silver.—Cyanide of silver and "silver solution," which consists of cyanide of silver dissolved in cyanide of potassium (the proportion of the latter very variable) are the only remaining preparations possessing medico-legal importance. The effects produced by these, so far as observed, do not differ materially from those produced by hydrocyanic acid, and it is probable that their poisonous action is due almost entirely to the acid. Reference is therefore made to the article on Poisoning by Hydrocyanic Acid. Nothing definite is known regarding the poisonous dose of either preparation. Death has occurred in ten minutes after swallowing fifteen cubic centimetres (ʒ iv.) of silver solution.

William B. Hills.

SKELETONS, PREPARATION OF. *General Directions.*—*a.* "If one can choose the specimen, a young adult should be selected. In too young animals the epiphyses are apt to separate easily from the diaphyses, and the symphyses open too easily. On the other hand, old animals sometimes have exostoses, or abnormal growths on their bones, and the sutures and symphyses are liable to be entirely obliterated."

b. If possible, a perfect skeleton of the part or parts under preparation should be before the operator, so that the exact position of delicate bones and processes may be seen, and hence not be lost or broken through inadvertence.

c. Careful notes should be made of the natural curves of the vertebral column, and of the position of the scapula, os hyoides, and in the lower animals of bones unconnected or but loosely connected with the rest of the skeleton. Measurements should be made of the length of the vertebral column and the thickness of the fibro-cartilage between two vertebral centra of each region at least. The thickness of the fibro-cartilage in the pelvic and other symphyses should also be determined, as also the thickness of the muscles separating the scapula from the ribs.

d. Whatever method is employed for the preparation of the bones, it is better to divide the animal, if it is large, into several parts by disarticulating some of the principal joints, as the humero-scapular, the femoro-innominate, the occipito-atlantal, and the other principal joints. The parts will then be more manageable.

e. The whole animal should bear a label, giving the name, date, sex, and, if possible, the age. Each separated part should have a label, giving the above general data, and also the name of the part. This is imperatively necessary with the vertebræ, the ribs, and the phalanges; hence, each must be labelled as it is separated from the rest of the body.

f. Parts like the pelvis and scapulæ, and the limb bones, exclusive of the manus and pes, which cannot be mistaken, may be put together and labelled as for the whole animal. Parts that might be difficult to distinguish should be kept in separate dishes and each properly labelled. The vertebræ might be divided into sets—cervical, thoracic, lumbar, etc.—and then connected by attaching a manilla string to a wire and passing it through the neural canal and tying the ends. The order of the bones cannot then be changed as they separate on the removal of the soft parts.

The ribs of one side, at least, should be removed one by one, and tied in order on a string or put into separate dishes. The phalanges of each hand and foot, commencing with the thumb and great toe, should be tied in order on a manilla string, then they and the other bones of each hand or foot may be very conveniently kept in a small sack made of cheese-cloth. Sesamoid bones would be best preserved in separate sacks or vials, each one having its own label.

In some of the lower animals the so-called splanchnic bones, *i.e.*, bony parts of organs, like the heart in the ox, diaphragmatic bone of the hedgehog, bone of the penis in the cat, raccoon, etc., must be removed from the animal before the cleaning commences, or the organs are removed and thrown away. If these are to form part of the prepared skeleton, it is essential to determine accurately their relative position on the fresh animal as they are removed.

g. Bones of different animals should not be put into the same dish, unless they differ so greatly in size or conformation that confusion would be impossible.

Finally, it is unnecessary to bore holes in the bones in order to allow the interior soft parts to escape or be removed, as is often recommended, for the natural canals in a bone render it somewhat like a sieve or sponge, and give sufficient communication between the interior and exterior.

Artificial and Natural Skeletons, and Methods of Preparation.—When all of the soft parts of the body are removed in any way, most of the bones fall apart, and if they are to be arranged and held in their natural relations, they must be connected artificially by wires, strings, bolts, etc.; hence the name *artificial skeleton*, in contradistinction to a *natural skeleton*, in which the natural ligaments or fibro-cartilages are left to hold the bones in position.

Whether the skeletons are to be natural, artificial, or simply kept as separate bones (so-called disarticulated skeletons), there are four principal methods of removing the soft parts:

1. *Putrefactive Maceration in Water*.—For this, stoneware, porcelain, or glass dishes, or zinc-lined tanks are employed, to avoid discoloration of the bones. The various parts of the animal, prepared as described in the general directions, are placed in separate dishes, and covered completely with clean, preferably soft, water. The dishes should then be placed in a room where the temperature does not fall below 18° to 20° C. (64.4° to 68° F.). If the room is still warmer the maceration will proceed all the more rapidly. The water should be changed frequently at first, *i.e.*, every day or every other day, if possible, for the first ten days or two weeks, then occasionally until the maceration is as complete as desired. By macerating in a warm room, and changing the water as directed above, discoloration of the bones and the formation of *adipocire* are almost always avoided. According to Morel and Duval, experience has shown that the placing of bodies in running water is not so good a method of maceration as that described above; there is, also, far greater danger of losing some of the bones.

During maceration the bones should be examined occasionally, and, if a natural skeleton is desired, the bones must be removed as soon as the muscles have decayed. If the bones are to be entirely freed from soft parts the maceration should be allowed to continue till these have completely decayed, or until they may be readily removed by a brush or a dull but smooth-edged knife. When sufficiently freed from their adherent soft parts the bones are rinsed with water and placed on clean paper or wood, to dry, each bone or set of bones being always accompanied by the proper label. The vertebræ, ribs, etc., may remain tied on a string, or they may be numbered. The bones of the hand and foot, and other small bones, are very conveniently kept in small cloth sacks.

It requires from two weeks to several months for complete maceration of a skeleton. The bones of small animals, and the young of the larger ones, macerate much more rapidly than those of large adult animals. Dissecting-room bodies that have been preserved by antiseptic injections macerate with great slowness. Frequent changes in the water, especially at the beginning, are necessary in order to wash away the preservative, which prevents the action of the putrefactive bacteria. It may be necessary to boil the bones of such subjects to remove most of the soft parts, using the macerating method only to finish the cleaning process.

2. *Boiling in Water alone, or in Water to which has been added some Chemical Substance*.—The animal is prepared and all the precautions taken as described under the general directions, then the bones are soaked a day or more in cold water, to dissolve out the coloring matter of the blood. They are then boiled in water, changing the water once or twice, until the soft parts are so far softened that they may be completely removed if an artificial skeleton is desired, or all removed but the ligaments and the fibro-cartilage, if a natural skeleton is to be prepared. Bones boiled in plain water are liable to be "greased," as it is called, that is, the melted fat penetrates the bones and makes them appear as if they had been soaked in oil. To avoid this, and also to hasten the disintegration of the soft parts, some saponifying substance is often added during the last half of the boiling. The following has proved quite satisfactory: After soaking the bones in cold water, and then boiling in plain water, about half as long as described above, they are boiled in the following mixture, diluted with an equal volume of water: Best soap, 75 grams; nitrate of potash, 12 grams; strong water of ammonia, 150 c.c; water, 2,000 c.c.

After the bones are cleaned by the boiling process they are rinsed and spread out to dry, as described for the macerated bones.

Boiling and the use of the saponifying substance have the advantage of being far less disagreeable than the macerating process. It is also much more rapid. For small animals, in which the bones are very dense, this method is entirely unobjectionable; but for man and the larger animals, generally, the ligaments, periosteum, etc., are so tough and thick that the boiling must be continued so long to soften them that the organic base of the bones is partly gelatinized and dissolved out, thus leaving the bones too brittle.

Preparation of Skulls.—The skull should be separated from the body, and if only the skull is to be preserved it is well to keep with it the atlas and axis. The eyes, skin, and most of the muscles are removed; the brain is broken up with a stick or metal instrument, and washed out with a syringe or strong stream from the tap; the larynx and os hyoides are removed together from the rest of the skull, and a natural skeleton made, leaving the larynx in its natural relations with the os hyoides. It is unsafe to macerate or boil the os hyoides and larynx, and a natural skeleton should be made by scraping (see below) the fresh specimen, or after preservation in twenty-five to thirty per cent. alcohol.

The skull may be boiled or macerated. Maceration is preferable for all but the smaller skulls. It is well to macerate the smaller skulls, even after they are cleaned so far as possible by boiling, in order to remove the soft parts covering the turbinated bones. To prevent the teeth from falling out it is well to disarticulate the man-

dible (inferior maxilla) and place the skull and the mandible, with the teeth uppermost, in the macerating dish; then they are held in place by gravity. The cleaning must be done with great care, to avoid breaking delicate processes and injuring delicate bones. Pieces of wood of various sizes and shapes are excellent for removing the softened muscles. etc.

Cements for Bones and Teeth.—The pelvis and mandible often separate at their symphyses, and the teeth may become loose and be in danger of falling out. This is especially liable to occur with macerated skulls. To unite separated or broken bones one may use glue, proceeding as for gluing wood; or the white-zinc cement used by histologists for sealing microscopical preparations may be used. If weight or traction is to be brought to bear on the connected parts they must be wired also. For fastening teeth in their sockets either of the above cements may be used, or plaster-of-Paris for large animals, or silicate of soda or potassa (liquid glass) mixed to a paste with powdered chalk. This hardens quickly, therefore it, as well as the plaster-of-Paris, must be used soon after preparation. The silicate cement and the glue are softened by water, and the white zinc is softened by the benzine used in degreasing. (See below.)

As soon as a macerated skull is rinsed, the teeth that are loose should be taken out one by one, the socket partly filled with one of the cements and then the tooth replanted. In this way the teeth may be kept in their proper places, and as the skull dries the teeth will be firmly fixed. Although the teeth of a boiled skull may be loose while it is moist, the gelatinized dental periosteum will usually fasten them very firmly as the skull dries. The teeth may, if necessary, be cemented as directed for macerated skulls.*

3. *Cutting and Scraping the Soft Parts from the Bones of Fresh, Dried, or Preserved Specimens.*—Fresh, dried, or preserved specimens may have the skeleton cleaned by simply cutting and scraping away the soft parts. It is necessary to work with great care, otherwise delicate processes and thin bones will be injured in removing the tough connective tissue. When the bones are cleaned as well as possible they are allowed to dry, when they may be degreased and bleached as described below.

The safest way to prepare the sternum, with its costal cartilages, the os hyoides, in connection with the larynx, is to prepare them fresh as just described, or, after preservation, in thirty to forty per cent. alcohol, if they cannot be freshly prepared. Cutting and scraping the flesh from the bones of minute animals, either in the fresh condition or after preservation in alcohol, is probably the only safe method. It is an especially valuable method for the preparation of natural skeletons of small and medium-sized animals, and of parts, as the sternum, of larger animals.

4. *Allowing Insects (Ants, Dermestes, Wasps), Tadpoles, or Sea-animals, to Eat away the Soft Parts of Fresh Specimens.*—It is desirable to remove the skin and most of the soft parts as for maceration or boiling; then, if dermestes are to be utilized, the partly cleaned skeleton is left in a damp room. The dermestes will find them, and the larvæ of these beetles will eat away the soft parts. If the aid of ants is to be sought, the partially cleaned bones are put in a box, with several holes in it, and placed near an ant-hill, and sugar sprinkled along the ground and on the bones. The ants will clean the bones more satisfactorily than the dermestes. It usually takes about a week for them to clean a cat's arm. Part of a fresh animal may be hung by a wasps' nest; they are said to clean it quickly and well. If tadpoles or sea-animals are to be utilized, the fresh specimen should be sunk in water in which the proper animals are known to be present. These methods are unsatisfactory. Only small animals or small parts of large animals will be cleaned by wasps or ants, and the dermestes only aid decomposition in the air, and the bones are very dirty and offensive after their action. In utilizing water-animals there is great risk of losing small bones. As a general remark it may be stated that a really good skeleton, perfect in all its parts, can be obtained only by a great amount of care, knowledge, and skill.

Preparation of the Bones of Young Animals.—Great care is necessary in this, on account of the readiness with which the epiphyses separate and the bones of the skull fall apart. The maceration or boiling should proceed only about as far as in preparing natural skeletons, the rest of the cleaning being done by careful scraping and cutting. As the boiling process is so rapid, it is perhaps safest, as the specimen is then constantly under the eye of the preparator.

Disarticulating Skulls.—A young or barely mature animal should be chosen, since the cranial sutures are liable to be partly or wholly obliterated in adults and the old. The skull may be cleaned by maceration or boiling. If the boiling process is used, boil the skull half an hour longer than for one not to be disarticulated. While still moist, the bones may be separated by steady traction and careful prying and wedging. This may be done with great readiness if half-grown animals are used. Skulls that have dried are usually more easily disarticulated after being soaked in cold or warm water until the remnant of connective tissue between the sutures has become softened. For a human skull to be disarticulated, that of a person from fifteen to eighteen years is best. It can be best cleaned by very complete maceration; then, while it is still moist, or after it has been remoistened, the bones are separated by traction, by wedging and prying, as described above. It is best to commence with the bones of the face, so that the larger and firmer bones may serve as a kind of handle, and also as a support. The disarticulation of skulls, except those of young animals, is very tedious, and requires a great deal of time and skill.

Degreasing Bones.—Except in rare cases neither does all the fat decompose in maceration, nor is it all saponified in the boiling process, hence it is necessary to use some solvent of fat to remove what remains. This solvent should not injure the bones, and it should be cheap. Benzine answers these requirements. After the bones have been cleaned in any of the ways described above, and thoroughly dried, they are placed in large glass jars or other vessels that can be tightly closed, and covered with benzine. If the bones are very greasy, it may be necessary to change the benzine once or twice. The time required for the degreasing depends on the size of the bones and the amount of grease in them. Two weeks is usually sufficiently long for a human skeleton.

Natural skeletons may be degreased by the benzine, but they must not be left too long in it, for it makes the ligaments, especially of boiled skeletons, too fragile.

Bleaching Bones.—If care be taken in changing the water during the first few days of maceration so as to remove all the blood, also if the blood be soaked out before boiling, the bones usually require no bleaching.*

If for any reason the bones are not sufficiently white they may be bleached after being well degreased: (*a*) By exposure to the sun, rain, and dew. This requires considerable time and a protected place. (*b*) The bones may be soaked in a weak solution of chloride of lime—chloride of lime, 2½ grams; water, 100 cc.—Labarraque's solution or eau de Javelle, 1 part to 4 or 5 of water. Chlorine is the bleaching agent in all of these, and the hydrochloric acid formed in the chemical reactions remains in the liquid and injures the bones, hence the necessity of a weak solution and a short exposure (4 to 12 hours). After the bones have become sufficiently bleached,

* "So far as concerns the general aspect of the skull, the incisors may be interchanged, and missing teeth may be replaced by teeth from other skulls. It is to be feared that such substitutions are sometimes made with skulls prepared for sale. Unless the changes are carefully specified such skulls have no real scientific value as regards the teeth." The same may be said of skeletons in general, in which several are put into the same macerating or boiling tank, and then the completely separated bones selected out and put together, or incomplete skeletons are completed by borrowing bones from another animal of the same or an allied species.

* If one has the specimen to be skeletonized in a fresh condition, it usually repays the trouble to wash out the blood by injecting a large amount of water into the blood-vessels. The arch of the aorta might be injected until the water runs uncolored from the veins. A constant-pressure apparatus is very convenient for this.

they are washed and dried. It is often advantageous to give the bones several short immersions, allowing them to dry in each interim, rather than one long immersion. Great care is necessary in bleaching natural skeletons with any of the chlorine compounds. (c) Degreased bones are quickly bleached by peroxide of hydrogen ($H_2 O_2$.). A so-called twelve to fifteen volume per cent. solution, diluted with an equal volume of water, and rendered neutral or slightly alkaline by the addition of ammonia or carbonate of soda, etc., will bleach a human skeleton in a few days. The bones must be put into a jar, and then covered with the peroxide solution, and tightly closed to prevent the escape of the oxygen. It is well to remove the bones and allow them to partly dry once or twice, to hasten the bleaching. The stock solution of peroxide should be kept in a cool place, and tightly corked, to prevent deterioration. Peroxide is the best bleaching agent for bones, as no injurious product is formed during the bleaching process. It is, however, expensive.

Final Arrangement of Skeletons.—If the skeleton is to be a disarticulated one, that is, if the bones are to remain separate, it is desirable to have each skeleton in one box, having the smaller bones in sacks or small boxes. The articulation or joining of the bones to make an artificial skeleton is a purely mechanical process, although it requires skill and experience. It can best be learned by working with an experienced workman. Rule of thumb should, however, be checked by careful observation of the natural attitude of the body and its curves, also the actual position of such movable parts as the scapula in the various positions in which it is desirable to mount skeletons. This can be done only on the living model.

A good general rule to follow in articulating a skeleton is to bore all necessary holes before attempting to put the bones of a part together. In this way strain on the partly mounted skeleton, and the necessity of boring holes in inconvenient positions, will be avoided. It is desirable to have diagrams of the various parts, showing the exact number and position of all wires and bolts. For study, and also for guidance in mounting, a hand and foot, with the bones held in apposition with spiral springs, instead of the wires ordinarily used, are very convenient, as the bones can be sufficiently separated to bring the articulating surfaces into view.

For natural skeletons the various parts should be arranged as desired while the skeleton is moist. If the parts are held in position by strings, pins, etc., they will dry and remain in the desired position. It is a great advantage to have a natural skeleton somewhat flexible. This may be attained by soaking the skeleton before it has been dried, or after remoistening it, in *Wickersheimer's preservative,** for three to ten days before it is arranged and dried. It is an excellent plan for small and young animals to have the hyoid, sternum, and tail prepared as flexible natural skeletons ; it is also desirable in many cases to have the hand and foot (manus and pes) of one side prepared as a flexible natural skeleton, although the rest of the skeleton is artificial.

The statements and directions in the present article are based upon personal experience in the Anatomical Department of Cornell University, upon the manuscript notes of Dr. Theobald Smith, and upon the works and papers named below.

* This solution is prepared as follows: Arsenious acid, 16 grams ; sodium chloride, 80 grams ; potassium sulphate, 200 grams ; potassium nitrate, 25 grams ; potassium carbonate, 20 grams, are dissolved in 10 litres of boiling water. After cooling, the solution is filtered, and to it is added 4 litres of glycerin and 750 c.c. of ninety-five per cent. alcohol. For the purposes of preparing flexible natural skeletons the alcohol is unnecessary.

SKIN, ATROPHY OF THE. Synonym: Atrophia cutis propria. Atrophy of the skin may occur as a sequence of certain well-defined cutaneous diseases which produce ulceration or absorption of tissue, such as syphilis, lupus, or favus. It is also observed to follow and depend upon certain injuries of nerve-trunks, forming the glossy skin of Paget and Mitchell. But neither of these two conditions is a true idiopathic atrophy, and they will, therefore, not be considered in the present article.

Four forms or conditions of primary or idiopathic atrophy of the skin may be noticed, viz., atrophia cutis generalis, senilis, linearis, and maculosa.

1. *Atrophia Cutis Generalis.* — General or extensive atrophy of the skin is very seldom met with, although it is recognized by authors, and instances of it are occasionally reported. Many of these cases, however, belong more properly to xeroderma, morphœa, and scleroderma. In those cases of unilateral atrophy of the face in which the skin appears drawn down and atrophied, the lesion is deeper and involves the subcutaneous tissues, muscles, and occasionally even the bone. These cases, therefore, should rather be excluded here, as they are due to deep nerve influence—possibly, as has been suggested, to permanent irritation of the cervical sympathetic.

2. *Atrophia Cutis Senilis.*—Senile atrophy of the skin is to be looked upon as a physiological rather than a pathological condition, although the changes which take place with advancing years are such as predispose to certain diseases, notably pruritus senilis, and epithelioma. The skin of elderly persons loses its elasticity, the surface becomes dry and wrinkled, and the hue changes from the well-known flesh-color to more nearly the appearance of parchment, with a tendency to the formation of pigment points and to slight desquamation. The anatomical alterations upon which these changes depend consist in an atrophy of all the component parts of the skin and subcutaneous tissue, expressed in a thinned epidermis, flattened papillæ, shrunken corium, and atrophied hair-follicles, either with or without fine lanugo hairs ; the sebaceous glands have lost their activity, and are often found filled with dried epidermal masses. Another condition or form of atrophy is also described, in which the tissues undergo degeneration into a more or less homogeneous mass, styled hyaloid or waxy degeneration, or they may become granular and pigmented.

3. *Atrophia Cutis Linearis.*—Synonyms: Striæ atrophicæ ; Atrophic lines. These consist in lines or streaks in the skin, of various dimensions, of an inch or more in length by half an inch in width ; they are seen to be sharply defined in the healthy skin, slightly depressed, have a whitish or bluish-gray color, and give to the touch a sensation of being perceptibly thinned. When pinched up the surface presents fine wrinkles, very different from those in the adjacent skin. The most common and well-recognized form of this alteration is seen on the abdomen and breasts of women who have borne children, where the surface is more or less thickly covered with these striations (lineæ albicantes). They occur, however, in many other conditions and situations as well, and may appear wherever the skin has been subjected to somewhat rapid stretching, as on parts which have been anasarcous ; also where there has been sudden increase and diminution in flesh ; they are seen principally on the thighs and buttocks. The streaks are usually more or less parallel to one another, and commonly parallel to the long axis of the body. Microscopically these patches show atrophy of the textures of the skin, thinned epidermis, an almost entire absence of papillæ, and the connective tissue and elastic fibres of the corium are gathered into very thin bundles, with a few slender blood-vessels between them.

4. *Atrophia Cutis Maculosa.*—Synonyms: Maculæ atro-

phicæ: Atrophic spots. This most curious condition is quite rare, but is occasionally met with in very marked form. It consists in well-defined spots, from an eighth to half an inch or more in their longest diameter, generally roundish or oval, slightly depressed, whitish, smooth, and glistening, and suggestive of a very supple scar. Often but few will be seen, but occasionally several dozen may be observed scattered over various regions of the body. It is stated that these patches first manifest themselves as erythematous spots, and it is suggested that the condition is closely allied to morphœa, although there is none of the lardaceous deposit preceding the atrophy, such as is seen in the latter disease. No cause for the affection has been discovered.

The conditions here described are not such as generally call for treatment, and little or nothing can be done to affect them favorably. Local faradization and stimulants externally may arrest the increase of the linear and macular varieties. *L. Duncan Bulkley.*

SKIN DISEASES, CLASSIFICATION OF. The oldest forms of dermatological classification were based upon the seat of the affection, *e.g.*, diseases of the scalp and diseases of the rest of the surface. Later, skin diseases were divided into the local or idiopathic, and the constitutional, general, or symptomatic. "Unfortunately, not only may the same cutaneous affection be produced by the most different causes, but the most varied diseases of the skin may also be caused by one and the same morbid agent. And it is not possible in every instance to draw, from the form and appearance of a dermatosis, any certain inference as to its origin from a local or general cause" (Hebra).

Erasmus Wilson and others adopted an anatomico-physiological system, starting from the opinion that it is possible to ascribe distinct names and characters to the affections of the different tissues which make up the skin; that is to say, of the epidermis, of the rete, of the papillæ, of the corium, and of the follicles, the vessels, the nerves, etc. But the integument is an organ of which the component tissues are very rarely separately affected by disease, so that it is very often impossible to say which strata are more, and which less, involved. Systems of this sort have been found so peculiarly unpractical that they have never found many adherents.

The most popular classifications of skin disease in the past have been those which have for their basis the external form of the disease. The most important of these classifications was that of Willan, which included all cutaneous affections under the several heads of: 1, Pimples; 2, scales; 3, rashes; 4, vesicles; 5, pustules; 6, tubercles; 7, spots. At first sight this arrangement seems almost fascinating in its simplicity. But a single character is not enough for the determination of a disease, especially when thus torn from its connection with the other symptoms with which it is associated, and when all other appearances presenting themselves in the course of the case are left unnoted. Perhaps no other one thing, unless it be the eccentric and singular nomenclature devised by one or two great writers, has so hindered the study of diseases of the skin as this apparently simple classification.

The system, however, which for many years, and until quite recently, has dominated the German and American schools of dermatology, is that of Hebra. Less imposing perhaps than others which pretended greatly to scientific accuracy and logicalness, or which assumed the airs of a "natural system," Hebra's system has been found practically useful, and it is only of late years, with the great advance made in the clinical and pathological study of diseases of the skin, that this system has begun to prove cramping and insufficient. As modified slightly by the American Dermatological Association, and still used by it as the official framework for its valuable annual statistics of dermatology, this classification is as follows: Class 1, *Disorders of the glands;* class 2, *inflammations;* class 3, *hæmorrhages;* class 4, *hypertrophies;* class 5, *atrophies;* class 6, *new growths;* class 7, *neuroses;* class 8, *parasitic affections.*

In 1881 the late Professor Auspitz, of Vienna, put forth a system of classification more suitable to our present knowledge and needs than any one previously in use. As it cannot be clearly comprehended without the entire series of subdivisions, the whole scheme, excepting only the names of the specific affections, is given below:

FIRST CLASS.

Simple Inflammatory Processes of the Skin (Dermatitides Simplices).

A. Superficial Inflammations of the Skin.

(Dermatitides Catarrhales, Catarrhs of the Skin.)

I. Family: *Superficial Catarrhs of the Skin.*

1. Mere hyperæmia prevailing.
2. Sero-purulent exudation prevailing.

II. Family: *Erosive Catarrhs of the Skin (Stigmatoses).*

1. Due to animal parasites:
   Parasitic stigmatoses.
   (a) Entomoses.
   (b) Acarinoses.
2. Due to wounds of other kinds:
   Traumatic stigmatoses.

III. Family: *Follicular Catarrhs of the Skin (Perifolliculoses).*

1. Only around the apertures of the follicles.
2. Also around the excretory ducts of the follicle and the follicle itself.
   (a) Without simultaneous disease of the hair-sheaths and hairs.
   (b) With simultaneous disease of the hair-sheaths and hairs.

IV. Family: *Stasis Catarrhs of the Skin.*

1. With the termination of the formation of epidermis.
2. With the termination of cicatrization.

B. Deep-seated Inflammations of the Skin.

(Dermatitides Phlegmonosæ, Phlegmons of the Skin.)

I. Family: *Diffuse Phlegmons of the Skin.*

1. Due to burning.
2. Due to freezing.
3. Without external wounding.

II. Family: *Circumscribed Phlegmons of the Skin.*

III. Family: *Stasis Phlegmons of the Skin.*

SECOND CLASS.

Angioneurotic Dermatoses.

Dermatoses with the character of an extended disturbance of the tonicity of the vessels, together with more or less marked inflammatory congestion on the surface of the skin.

I. Family: *Infectious Angioneuroses of the Skin (Acute Exanthemata, Eruptive Fevers).*

1. With prevailing catarrhal character.
2. With prevailing phlegmonous (diphtheritic) character of inflammation of the skin.

II. Family: *Toxic Angiomata of the Skin (Medicinal Exanthemata).*

1. With prevailing inflammatory congestion.
2. With prevailing spasm of the vessels of the skin.
3. With obstruction of the vessels and termination in necrosis.

III. Family: *Essential (Idiopathic, Diathetic) Angioneuroses of the Skin.*

1. With prevailing inflammatory congestion.
2. With prevailing spasm of the vessels of the skin.
3. With dilatation of the vessels, and new growth of vessels.

THIRD CLASS.

Neuritic Dermatoses.

Due to diseases of the sensory (and also trophic ?) nerve elements.

I. Family : *Neuritic Dermatoses with Determinate Course.*

II. Family : *Neuritic Dermatoses with Indeterminate Course.*

1. With prevailing inflammatory congestion (neuritic inflammatory processes in the skin).
2. With prevailing spasm of the vessels of the skin (neuritic œdema of the skin).
3. With prevailing atrophy of the skin (neuritic atrophies of the skin).
4. With actual necrosis of the skin (neuritic necrosis of the skin).

FOURTH CLASS.

Stasis Dermatoses.

Dermatoses with the character of passive circulatory disturbance and injurious vaso-lymphatic absorption.

A. With Incomplete Stasis.

I. Family : *Hyperæmic and Anæmic Stases.*

II. Family : *Transudation Stases.*

1. The transudation remains in fluid form.
2. The transudation leads to induration and hypertrophy of the connective tissue of the skin.
3. The transudation leads to atrophy of the connective tissue of the skin.

B. With Complete Stasis.

Only Family : *Necrotic Stasis.*

FIFTH CLASS.

Hæmorrhagic Dermatoses.

Dermatoses resulting from increased passage of the red blood-corpuscles through the walls of the cutaneous vessels, without inflammatory congestion or local stasis in the latter.

I. Family : *Traumatic Hæmorrhages.*

II. Family : *Essential Hæmorrhages (i.e., Independent of External Irritation).*

1. With the existence of slight general disturbance.
2. With predominant general disturbance.

SIXTH CLASS.

Functional anomalies of the nerves of the skin without trophic changes of the skin.

A. Sensory Neuroses of the Skin.

I. Family : *Tactile Neuroses.*

II. Family : *Neuroses of Cutaneous General Sensation* (Dermatalgia).

1. The neurosis occurs in the form of pain.
2. The neurosis occurs in the form of itching.

B. Simple Motor Neuroses of the Skin.

Only Family : *Dermatospasmus.*

SEVENTH CLASS.

Anomalies of growth of the epidermis and its appendages.

A. Anomalies of the Epidermis and Secretion (Keratonoses).

FIRST ORDER.—Keratoses in a Narrower Sense.

I. Family : *Hyperkeratoses.*

1. Diffuse.
2. Around the follicle.
3. In areas, but independent of the follicles.

II. Family : *Parakeratoses.*

1. Diffuse.
2. Follicular.

III. Family : *Keratolysès.*

SECOND ORDER.—Trichoses.

I. Family : *Hypertrichoses.*

II. Family : *Paratrichoses.*

III. Family : *Atrichoses.*

1. Diffuse.
2. In areas.

THIRD ORDER.—Onychoses.

I. Family : *Hyperonychoses.*

II. Family : *Paronychoses.*

III. Family : *Onycholyses.*

FOURTH ORDER.—Steatoses.

I. Family : *Hypersteatoses.*

II. Family : *Parasteatoses.*

III. Family : *Asteatoses.*

FIFTH ORDER.—Idroses.

I. Family : *Hyperidroses.*

II. Family : *Paridroses.*

III. Family : *Anidroses.*

B. Anomalies of Pigment Formation in the Skin (Chromatoses).

I. Family : *Hyperchromatoses.*

1. Congenital.
2. Acquired.

II. Family : *Parachromatoses.*

III. Family : *Achromatoses.*

1. Congenital.
2. Acquired.

C. Anomalies of the Prickle-cell Layer of the Epidermis (Akanthoses).

I. Family : *Hyperakanthoses.*

1. Proliferation of the prickle-cell layer on the surface of the skin (warty akanthomata).
2. Proliferation of glandular ducts (cutaneous adenoma).

II. Family : *Parakanthoses.*

1. With distinct cornification of the newly-formed cells.
2. Without cornification of the newly-formed cells.

III. Family : *Akantholyses.*

EIGHTH CLASS.

Chorioblastoses.

Anomalies of growth of the corium and of the subcutaneous connective tissue.

A. Excessive Development of the Connective-tissue Layer.

Only Family : *Hyperdesmoses.*

B. Paratypical Growth of the Connective-tissue Layer of the Skin (Paradesmoses).

I. Family : *Granulomas of the Skin.*

II. Family : *Desmomas of the Skin.*

C. Atrophy of the Connective-tissue Layer, or Congenital Deficient Development of the Same.

Single Family : *Adesmoses.*

1. Universal and diffuse.
2. Partial.

NINTH CLASS.

Dermatomycoses.

Fungous diseases of the skin and its appendages.

I. Family : *Mycosis Scutulata.*

II. Family : *Mycosis Circinata.*

III. Family : *Mycosis Pustulosa.*

IV. Family : *Mycosis Furfuracea.*

Auspitz's method in the construction of his classes has been to regard, first the sum total of the processes upon which the skin diseases depend, and then, selecting from these processes those which are most essential and fundamental, to group the affections accordingly. The result has been an etiological division, rather as a necessary consequence of the method than from any original design on the author's part. The most essential pathological processes prove also to be those which stand in a proximate causative relation to the cutaneous affections. The method adopted by Hebra differed from this in that the skin affections were classified according to certain previously observed rules of general pathology. Auspitz's method reaches much further, and seeks to carry the inquiry to what may be termed the prime motives of diseases (Bronson).

By Auspitz's classification the objects classified are not so much the skin affections themselves as the general morbid conditions which tend to the production of skin disease.

Objection has been made to this classification on the score of its want of adaptability to dermatological study. But although not so simple as former systems, its mastery will give a command of the general subject which can be gained in no other way.

Within the last year or two Bronson has, in two able papers, criticised Auspitz's system, and has proposed some modifications which have yet to be acted upon by dermatologists. Reference is made below to these papers.

Arthur Van Harlingen.

SKIN-GRAFTING (*Greffe épidermique*, Fr.; *Hautüberpflanzung*, Germ.). By this term is meant the application of minute pieces of the outer layers of healthy skin to a granulating surface for the purpose of hastening its cicatrization.

The principle of this method is that, if a piece of living epidermis be transferred to a proper soil it will grow there, and serving as a focus of cicatrization, will unite with other similar points, or with the cicatrizing edges of an ulcer, and thus close it more rapidly and with less subsequent contraction than if it be left to heal from the edges alone. Experience has further taught that this also stimulates the cicatrization at the edges to greater activity.

This little operation received its present general adoption as a surgical procedure in 1869, from Reverdin,[1] an interne in La Charité Hospital, in Paris, and was by him reported to the Société de Chirurgie on December 8th of that year. His report excited great interest, and MM. Guyon, Gosselin, A. Guérin, Duplay, and Marc Sée offered him facilities for further trials, and others in France and other countries, notably Poncet,[2] of Lyons, and Pollock,[3] of London, practised the operation. This was soon found so simple and useful that it immediately became recognized and practised throughout the professional world.

The operation is to be performed by first washing the surface of the ulcer with warm antiseptic solution (mercuric bichloride 1 to 3,000, or carbolic acid two and one-half per cent.), and the surface from which the "grafts" are to be taken with one of double that strength. A minute piece of skin from the cleansed surface is then seized with a pair of fine forceps, lifted up, and snipped off with a pair of fine scissors curved on the flat. For this purpose a pair of single-toothed forceps a little stronger than the ordinary iridectomy forceps, and the usual iridectomy scissors, are the most convenient and quickest to work with. M. Reverdin used a needle to lift the epidermis with and shaved the graft off with a thin, sharp scalpel. A combined forceps and scissors, working together by a single motion, has been invented and is figured in most articles on this subject; but I have found it not nearly so satisfactory as the less expensive and always obtainable separate forceps and scissors. The piece removed should be about the size of the head of an ordinary pin; if larger, it may be made smaller by placing it upon the thumb nail, previously disinfected, and cutting it into two or four pieces according to its size. Only the epidermic layer of the skin is to be taken; the cut surface should not bleed, but should show the blood-vessels underneath. The rete Malpighii is the layer sought for application to the granulations. The little piece is immediately placed upon the granulating surface in the position removed, *i.e.*, cut surface downward, pressed gently into it, with just sufficient firmness to allow it to adhere, care being taken not to cause the granulations to bleed.

The grafts are best applied along the edge of the ulcer, from one-fourth to one-half an inch distant from it, and at equal distances from each other. If the ulcer be not too large they may be arranged in a series of parallel rows across it; or, if the outline be very irregular, a bridge may be thrown across a bay from cape to cape. The arrangement is immaterial, but they should not be applied at a distance from already formed skin, though I have exceptionally found them to "take" when in a group by themselves quite remote from the edge.

After the grafts have been inserted a piece of thin gutta percha protective, previously placed in an antiseptic solution for twenty minutes, is laid over the grafts, extending beyond them over the ulcer if it is large, and beyond the edges upon the skin. This is covered again by a layer of absorbent or borated cotton, and the whole is secured in place by a roller of sublimated gauze bandage. The part should be kept as motionless as possible, so as not to disturb the surface, and the dressing should not be removed for about three days, when the coverings down to the protective should be taken off to see if there be any considerable amount of pus secreted. If the edges of the cotton beyond the protective are soaked with pus, or if pus has dried upon the dressing to any considerable degree, it is all to be carefully washed with an antiseptic solution. A little stream of the solution from an irrigator is best, but the surface must not be wiped with anything, and if it all looks clean underneath the protective, fresh dressings above this are to be reapplied and allowed to remain for three days more. If, however, there be considerable pus, either under the protective or on the cotton, the former must be very carefully lifted off, and a stream of the antiseptic solution allowed to run over the ulcer to wash the pus away. If the grafts are not washed away with the pus a fresh clean piece of protective is to be applied, and the other dressings added as before. This process is to be repeated at intervals of about three days or oftener, depending on the amount of pus found on the dressings, until the "grafts" are seen to have fairly "taken," as will be shown by the appearance on their edges of an extremely thin, smooth, delicate, pellucid, pink line of cicatrization, which indicates the growth of the epidermis over the granulation (Fig. 3532). The protective may then be omitted, and a simple dressing substituted, vaseline or other bland, unirritating salve applied on a piece of absorbent cotton or other substance, according to choice.

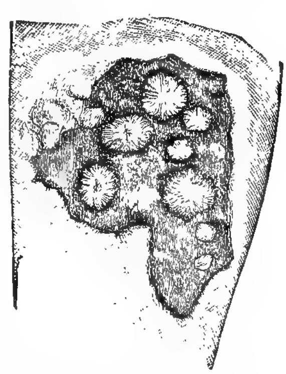

FIG. 3532.—Skin-grafts Growing.

The grafts should be taken from a thin skin, *i.e.*, where the external layers of epidermis are not superabundant or hard—the inside of the thighs, the flexure of the elbow, or the walls of the chest below the axilla—and where there are but few hairs or glands.

The operation itself, therefore, is quite simple; the essential point is the selection of the time when the granulations are in the proper condition to receive the grafts; it is on this more than on any other one point that the success of the treatment depends. They must be suppurating slightly, indicating activity in the blood-supply, but not profusely, or the grafts will be washed away before they have formed adhesions. They should be florid and fresh-looking, soft and succulent, but not flabby nor exuberant, not glazed over nor œdematous and overhanging the edges; nor must the ulcer be excavated or the granulations be hard, bright red, and irritable-looking. They must be in the condition most favorable for cicatrization at the edges, and the surgeon may derive some aid from the circumstance of peripheral cicatrization in determining the proper time to apply the grafts; but he should also be able to judge independently of this by the granulations themselves. The skill of the surgeon consists in bringing the granulations to the proper condition, and in recognizing this when he sees it, rather than in the technique of the trivial operation.

As soon as one set has formed attachments and begun to grow, another set inside of this may be inserted, and again another inside of this, until the ulcer is closed. It depends on the size of the ulcer as to whether it may be entirely covered with the grafts or not; and it is well, if the first set show that the granulations are in a favorable condition to nourish the grafts, to seize the opportunity, and at once cover over a larger surface with them. The advantage of applying the grafts around the edges is that they will form adhesions with the skin of the edges, and thus become connected with the rest of the cutaneous circulation and have a better prospect of living; the supposition being that the island formed by the growth of the graft will not extend indefinitely. The limit of this extension has been placed at an area of about the size of an English sixpence, but I have seen one over the cranium, where the scalp had been torn off, that was much larger than this, and quite unattached at its edges.

After the grafts have been applied for a few days, it will be noticed that they have become quite white and apparently lifeless, and a stream of water running over them will wash off the superficial layers, leading one to think that the graft has separated from its bed, and has not "taken;" careful observation, however, will show that the deeper layers are still attached, the external layers of the epidermis only having separated; while a spot, larger or smaller, pinkish in color and smooth on its surface, remains attached. It is from this that the remainder of the epithelial covering grows.

Scrapings of the epidermis and shavings of corns are said to have been successfully[4] used for grafts, but this plan has not found general approval, as it is too uncertain. Grafts of this kind would naturally have less vitality, be less capable of proliferation, and have less reproductive power than the younger cells of the rete Malpighii.

Do the grafts grow by a reproduction of their own elements? Do the epithelial cells multiply by a duplication of their nuclei? Or do the grafts, *i.e.*, the epithelial cells, act simply as stimulants to the granulations, *i.e.*, connective-tissue cells underneath, causing them to take on an epithelial growth? These questions have been actively discussed by various investigators and pathologists. It was thought that the question was settled when the experiment was made of engrafting the epidermis of a negro upon an ulcer on a white person,[5] the result being that a series of pigmented islands were formed, which gradually coalesced with the surrounding skin, leaving a black cicatrix. The observations, however, have not been uniform, for in other cases the grafts have not been pigmented, and the results were therefore negative. The counter-experiment of white grafts upon a negro is not so valuable, as it is well known that an ordinary, non-grafted cicatrix of an ulcer on a negro is sometimes white, or perceptibly less pigmented. If we may argue by analogy from the development and growth of the tissues from the germinative-layers of the embryo, we certainly are not justified, in the absence of positive observation of the steps of the transformation, in regarding a transformation of connective tissue as ever taking place here.

The newly-formed, like other cicatricial skin, remains thinner than the surrounding integument for some time, and is more liable to break down if subjected to any considerable irritation, or if the patient be attacked by an exhausting disease; but it gradually becomes thicker by the consolidation of the deeper with the superficial layers of the granulations, forming respectively the epidermis or cuticular layer, and the corium or connective-tissue layer. It serves the purpose of normal skin in protecting the parts below, and, except for the absence of all the glandular elements, hair-bulbs, sweat-glands, and sebaceous follicles, it is true skin.

It does not seem to be necessary that the subject from whom the grafts are taken should be living at the time they are removed. Dr. J. H. Girdner,[6] in 1877, used grafts removed six hours after death, taking a large piece from the inside of the thigh of a young man dead from hæmorrhage. This large piece was cut into minute grafts and inserted upon a large ulcer on the arm and back of a boy, ten years of age, who had been burned by lightning some months previously, and the grafts took well. The limit of vitality of the piece of skin after it has been removed is of great practical interest, and has been the subject of much experimentation. Dr. E. P. Brewer,[7] of Norwich, Conn., found that thirty-six hours was the limit of vitality, out of eight trials in which he removed pieces of skin from amputated limbs, and, without any especial care in their preservation, afterward cut grafts from these pieces and applied them in the usual way.

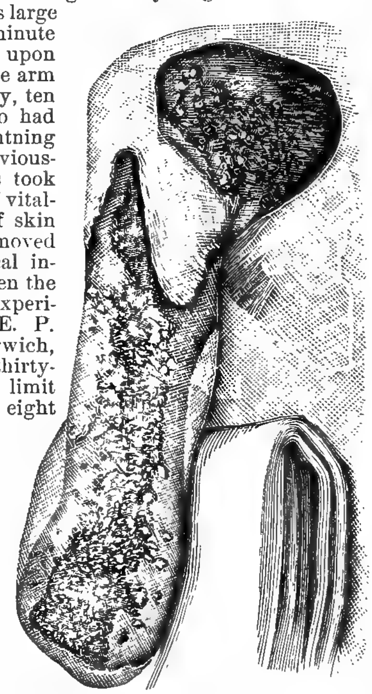

FIG. 3533.—Dr. Girdner's Case of Grafts Taken from Dead Subject.

Georges Martin[8] experimented with grafts kept at different temperatures, and found they preserved their vitality in inverse ratio to the degree of heat, though the longest period that he was able to keep a graft and have it live and take was ninety-six hours, the graft being kept at a temperature just above 0° Centigrade (32° F.). There was a slight difference in favor of "confined" as distinguished from "free" air in M. Martin's experiments.

Grafts have been taken from the skin of animals (zoö-grafting), and have taken root on ulcers on the human subject. The preparation and selection of the skin is similar to that in the case of the human subject. The part is to be shaved, washed, and the grafts taken from the deeper layers. It goes without saying, from what we know of the growth of the skin as already described, that there can be no expectation of a reproduction of hair or other adnexa. Liétevant[9] proposes a nomenclature for the different varieties as follows: Auto-epidermic, when taken from the same person, hetero-epidermic, when from another person, and zoö-epidermic, when the skin of an animal is used.

Of course, great care must be taken, in transferring grafts from one person to another (hetero-epidermic), that the one from whom the grafts are taken be free from any constitutional disease. The danger that syphilis might

thus be communicated, led some surgeons, in the early days of the procedure, to regard the hetero-epidermic method as unjustifiable; but the experience of thousands of operations has shown that by careful investigation such an unfortunate complication may be avoided. On the other hand, Deubel reports a case in the *Gazette médicale de Paris*, No. 35, 1881, in which syphilis was communicated to a father by grafts taken from his son, who was, unknown to the surgeon, the subject of this disease.

In the year following the publication of the account of M. Reverdin's operation, Dr. Frank H. Hamilton[10] claimed precedence for the principle of skin-grafting by referring to an operation which he had performed in 1854, having previously, in 1847, suggested a similar operation to another patient, which was declined. The account of the operation was published in that year (1854). If anyone will, however, take the trouble to read the original description of Dr. Hamilton's operation, it cannot be otherwise than evident that it was simply a plastic operation, a transplantation of the whole skin, after a new method, it is true, but certainly not the grafting of a minute particle of epidermis upon a granulating surface. He[11] calls his operation elkoplasty, or ulcers treated by anaplasty. It was performed for the cure of a large ulcer of the right leg. It consisted in preparing a flap of integument, seven by four inches, from the opposite (left) leg, "extending in depth through the cutaneous and cellulo-adipose textures, until the fascia was in sight," and dissecting it from below, but leaving it attached "by a broad and thick base." This flap he prevented from uniting with the surface from which it was "lifted," by a dressing inserted between them, and *two weeks afterward*, after granulations had formed upon the cut surface, he prepared the ulcer on the right leg for the reception of the flap "by dissecting out the granulations and part of the cicatrix . . . forming a deep bed" into which he inserted the flap after "removing the granulations" from its under surface. The legs were then fastened together, and two weeks after this, or four weeks after the commencement of the operation, "the base of the flap was separated from the left leg, the flap having united through most of its edges and under surface."

This is the application of the principles of the Italian, or Taliacotian, operation to an ulcer which had been converted as far as possible into a fresh wound, not a grafting upon a granulating surface. It is true that Dr. Hamilton found, in the progress of the healing, that the margins of the flap grew into, or extended over, the remaining intact granulations, promoting the cicatrization of the rest of the ulcer; and so far his fourth proposition is the recognition of a before unexpressed principle in the growth of the skin; but practically, he simply made another and fresher margin to the ulcer, and quite failed to appreciate the extent to which the principle of Reverdin's epidermic grafts could be applied. Assuming, for illustration, the absurdity that a surgical procedure may be patentable, it is quite doubtful, if Reverdin had patented his method, whether Hamilton would have been able to claim an infringement; or, if, on the other hand, Hamilton had patented his process, whether any court would have granted him an injunction against Reverdin for infringement.

Presenting a much closer resemblance to Dr. Hamilton's operation than Reverdin's, is the method devised in 1880 by Dr. E. Fischer,[12] of Strasburg, of grafting large strips of skin upon ulcers, both ulcer and skin-flap having been rendered bloodless by the application of an Esmarch elastic bandage previous to the operation. Dr. Fischer first tried rendering the grafts ischæmic, and found that not only was this plan followed by unusual success, but that he could also transfer much larger grafts than had heretofore been possible. Prompted by this, he conceived the idea of rendering the ulcer itself bloodless before making the transference, and he reports the success as even greater; for he found that ulcers of the leg treated in this way might be completely covered with pieces of skin of almost any size, and that they immediately healed without any "secretion," the dissolution and decomposition of the external layers of the epidermis of the grafts did not take place, the wound (ulcer) remained dry. The method was, after considerable experimentation, finally practised as follows: Premising that there be a healthy, recently amputated limb from which to take the strips of skin, the limb to be treated is rendered bloodless by Esmarch's method, care being taken in the application not to wound the granulations of the ulcer, which should be protected by a piece of cloth (Dr. Fischer says silk). The limb from which the strips are taken is to be first carefully scrubbed with soap and warm water, the hair being shaved off, and it is also to be rendered bloodless by the application of a rubber bandage. It is then washed in an antiseptic solution (1 to 1,000 of mercuric bichloride), after which the skin is cut off in strips of from two and a half to three centimetres in breadth, and as long as the ulcer requires. The strips are taken off very close, *i.e.*, free from subcutaneous tissue, the under surface being as smooth and flat as possible. As the strips are applied the surface of the ulcer should be cleaned off with an antiseptic solution from an irrigator, but not wiped, lest the granulations be caused to bleed. The application need not be so extremely accurate, as it is expected that after uniting with the granulations the skin will grow from the edges into and over the remaining granulations, in the same manner as occurs in the case of the smaller grafts, and in this way fill up or cover over the remaining granulation surface. This is in accordance with the principle enunciated by Hamilton in his fourth proposition, *i.e.*: "If smaller than the chasm which it is intended to fill, the graft will grow or project from itself new skin to supply the deficiency." A rubber protective is to be applied over the strips, secured in place by adhesive plaster, and then absorbent cotton and a gauze bandage are applied over all.

This, it is evident, is much more nearly like Dr. Hamilton's procedure than it is like Reverdin's, or than Reverdin's is like Hamilton's. The methods of both the French and the German surgeon differ from Hamilton's in that the grafts are applied to a granulating surface, and have all their connections severed before being applied to the open surface. They have a very close resemblance to the method of skin-transportation, to be described in the next article.

SKIN, TRANSPORTATION OF. *Dermanaplastie*, Esmarch.[1] This is a method of performing plastic surgery, in which a piece of the whole thickness of the skin is entirely removed from one part and transferred to another distant part to fill up a gap.

The term is used to distinguish it from any other form of plastic surgery or transplantation in which a continuity of the flap with the adjoining integument is preserved by a pedicle, of whatever shape or size it may be. The method is a happy development of Reverdin's skin-grafting, associated with, and made possible only by following out the principles of, antiseptic surgery. Gruening[2] proposes to distinguish this as the British method, in con-

tradistinction to the hitherto well-known Italian and Indian methods; and inasmuch as its birth-place is the same as that of Listerism, to which it owes so much of its success, the suggestion is quite pertinent. The author, Dr. J. R. Wolfe,[3] of Glasgow, acknowledges his indebtedness to Reverdin for the idea of transporting small pieces of cuticle to distant parts, but he is entitled to the credit of originality in transporting large pieces to entirely fill up freshly-made wounds, with the intention to get immediate union at all points of contact, but especially underneath. He does not seek to plant a piece in favorable soil and have it increase in size, but to have it grow upon, to simply adhere to, the surrounding and underlying tissue.

The operation is most frequently performed for the correction of deformities caused by the contraction of cicatrices from burns, in which there is no opportunity to perform one of the ordinary plastic operations. The most frequent seat of these operations has been about the face, where the contractions have so drawn upon the skin surrounding one or the other orifices, that the integrity of the contained organ (as the eye) is threatened, or the usefulness of the part itself (as the mouth) becomes impaired, and when the difficulty of getting a piece of healthy skin from the immediate neighborhood, by sliding or transplantation, is great. Dr. Wolfe's first cases were for the relief of ectropion of both eyelids of one eye. There is, of course, no other limit to its applicability in other situations than that all the conditions of success be attainable. These are: 1, Perfect asepsis of both wound and flap; 2, perfect coaptation at all parts, underneath and around the edges; 3, undisturbed rest afterward until union has taken place. How much the size of the flap removed has to do with the success is still the subject of experiment, as is also the question whether there are other points than those above mentioned. In an operation so new as this it is impossible to anticipate all the obstacles that may arise.

The antiseptic precautions to be taken pertain to both wound and flap, to the hands of the surgeon, of his assistants, and of the nurses, to the dressings, the instruments and sponges—in short, to everything used about the operation.

There are now-a-days so many ways of achieving asepsis that it may be superfluous to describe any at great length, and it would be presumptuous to make claim to any one particular method as infallible. My practice is to have both the part to be operated upon and the part from which the flap is to be taken scrubbed first with soap and water, and then, for twenty-four hours before the operation, washed every three or four hours with a solution of mercuric bichloride, 1 to 1000. At the time of operating I usually wash the parts with a saturated solution of iodoform in ether, 1 part to 8, or the solution recommended by De Ruyter,[4] of 1 part of iodoform, 2 parts of ether, and 8 parts of alcohol. The instruments should be laid for half an hour before the operation in a two per cent. solution of carbolic acid; solutions of mercuric bichloride, 1 to 1000 and 1 to 3000, should be at hand for irrigating, and also hot water to add to these solutions as they may be needed in the course of the operation.

Assuming that the operation is for the relief of a cicatricial contraction, an incision is to be made through the skin in the most suitable direction to relieve the deformity, and carried through the subcutaneous connective tissue. It may be necessary to remove a piece of the cicatricial skin, if it be very much thickened and distorted, but it is a good rule to take nothing away that will be likely to live. All contracting bands of the subcutaneous tissue, as well as of the true skin, are to be divided freely, or, if thick and likely to interfere with rapid union, they should be dissected out. In certain places, as in the axilla or neck, care must be taken that this dissection does not involve large vessels or nerves which may have been dragged into the cicatricial bands. This is by no means a theoretical source of danger, for uncontrollable hæmorrhage has occurred from the axillary or jugular veins having been ruptured or cut. Loose pieces of fat or connective tissue are to be removed, and all bleeding points secured; hot water will usually control capillary hæmorrhage, but if a vessel requires ligation it should be tied with aseptic catgut rather than twisted, as a subsequent hæmorrhage is fatal to success.

When the preparation of the wound is thus completed a pattern of cloth is cut of *exactly* the size of the wound; the surface of the latter is then to be carefully irrigated, and covered with a cloth or sponge, wrung out in the warm antiseptic solution, and extending well beyond the circumference. The cloth pattern is then placed upon the skin to be removed to form the flap, and its outline accurately marked out upon the skin, allowing one-third in *every* direction for shrinkage after removal. It is necessary to maintain this proportion in *every* direction; for instance, if the piece is one and one-half by three inches, twice as much must be allowed in the length as in the breadth, and the piece marked out must, therefore, be two by four inches. The incision is to be made perpendicularly through the skin, and the edges all around the flap are to be dissected up from the underlying connective tissue, as little of the latter as possible being removed with the flap. Then, while the main part of the flap is still attached, it is much the best plan to make, according to a verbal suggestion made to me by Dr. E. Gruening, a row of punctures, or small incisions, all around the circumference, for the subsequent introduction of the sutures. For this purpose I have had made a little punch, on the plan of an ordinary shoemaker's punch, which makes incisions about two millimetres in length. These are made perpendicularly to the edge, about eight millimetres apart, all around the circumference, and as they are simply incisions there is no loss of tissue to be repaired, and they gape when the needle is introduced, but close up around the thread as soon as it is drawn taut, leaving no space which requires to be filled up by granulations. The accompanying cut (Fig. 3534) gives a better idea of the instrument than a description. It is made perfectly smooth, with an unlocking hinge, so that it can be taken apart and cleaned, and can be readily kept aseptic. I much prefer the use of the continuous catgut (aseptic) suture, as facilitating a closer union than any other. If the surgeon, however, prefers interrupted sutures, whether silk or catgut, they should now be inserted, with a separate needle for every suture, and after introduction through the flap, *from without inward*, they must be allowed to remain threaded.

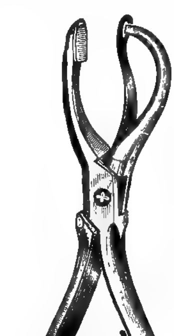

FIG. 3534.

The next step is the entire separation of the flap, which should be done expeditiously and smoothly by means of a very sharp knife, long sweeps being made with it as close to the true corium as possible, leaving no fat or shreds of connective tissue attached. In all manipulations about the flap avoid seizing it with forceps, using the fingers in preference when possible; but if forceps must be used, let them be the single mouse-toothed forceps, which make but one bite or puncture, and not the ordinary dissecting forceps, which crush a considerable amount of tissue included in their grasp. Having removed the flap, place it quickly on the palm of the hand of an assistant, or on a warm cloth dampened with the antiseptic solution, with the epidermis downward and, smoothing it out, with a pair of sharp scissors curved on the flat, trim off all shreds of fat or loose connective tissue which may remain attached to it. This is an extremely important procedure, for the internal surface of the flap should be as smooth and free from every scrap or loose shred of tissue, which may by any possible chance become necrotic and serve as a focus of suppuration, as it is possible to

Skin Transportation.

get it.[5] This trimming is a matter requiring a little patience, owing to the elastic connective tissue of the skin causing it to curl or roll up at the edges. While lying thus with the raw surface upward, the flap should be kept irrigated with the warm antiseptic solution, and as soon as the preparation is completed it is to be turned over upon the wound, previously prepared and free from blood, and fitted accurately to it. The flap must not "pucker" at the edges, neither must it under any circumstances be put upon the stretch by the sutures; it must simply fill up accurately the whole wound. Unless there are angles or other points to determine quickly and accurately the proper adjustment, it is well, as soon as the flap is marked out, to indicate a couple of points upon it, either with ink or indelible pencil, or by means of a thread drawn through it, to correspond with like points on the skin in the vicinity of the wound, in order that no time may be lost, and that the flap be not subjected to unnecessary manipulation in fitting. As soon as it is fitted, it should be pressed down by a soft and warm sponge or cloth, to exclude all air from beneath it, and this pressure must be kept up firmly but gently during the introduction of the sutures, which must now be inserted all around it, without any sliding or other movement of the flap upon its bed. To this end the assistant must keep up the pressure with the soft sponge, uncovering only just enough of the edge to allow the introduction of the needle (curved). The advantage of the incisions previously punched in the flap will now be appreciated, for without them the insertion of the sharpest needles would inevitably drag upon the flap, loosening and disturbing its contact with the parts below, and just so far interfering with the prompt union of the two fresh surfaces. The only reliable alternative is to have as many needles threaded as there are sutures to be introduced, and, as stated above, to insert them beforehand in the flap, so that the subsequent tying of each one may take but little time and make no dragging. The objection to this plan is, that the flap cannot be trimmed at its edges without interfering with the stitches already inserted, and as these should not be more than six millimetres apart, in a flap of any size the number of needles required would be considerable, and threads and needles would almost certainly become so entangled in the necessary manipulations that valuable time would be consumed. I therefore prefer, as stated above, to use a continuous catgut suture, which may be inserted very rapidly, and in which the overlap keeps the edges together better. It is better to insert the needle through the incision in the flap first (from without inward), and carry it then through the sound attached skin from within outward, as this disturbs the flap less; the operator can also see better where to insert the point of the needle than if he approaches the little incision from below. The part is now to receive its final irrigation, and the permanent dressing is to be applied. The particular form of antiseptic dressing employed to prevent suppuration is to be determined by the principles of general surgery. There is of course a wide field for the judgment of the individual operator. In places remote from the eye or mouth, Billroth's "sticky" iodoform gauze (consisting of 10 parts by weight of resin, 6 parts of castor-oil, 16 parts of alcohol, and 5 parts of iodoform, which are used to impregnate 25 parts of gauze) may be placed over the surface, a compress of absorbent or some medicated cotton applied evenly over this, and the whole smoothly yet firmly bandaged over with antiseptic gauze to the exclusion of the air.

The part is now to be left as quiet as possible for five or six days or more—nothing can be done to promote union after the proper dressing is applied. Nature must now be depended upon to do the rest. In obedience to former surgical traditions, I at first applied artificial dry heat to the outside of the dressings, but have lately discontinued it, and with as good results. It is cumbersome in application and adds materially to the subsequent care. The normal temperature of the body will keep the flap warm by contact under the protection of the cotton dressing, so that beyond this I am disposed to regard additional heat as detrimental, in stimulating putrefactive changes.

The method of dressing described, or some other permanent antiseptic procedure, is, according to my experience, greatly superior to any other, but it would be presumptuous, in view of the good results obtained by other surgeons, to say absolutely that it is the best. Wadsworth,[6] Matthewson and Pilcher,[7] and Howe,[8] all used with success some form of transparent covering directly over the wound, viz., court-plaster, gold-beater's skin, or collodion, with pressure from cotton over it. Fryer [9] dispensed with everything but his gold-beater's skin. Dr. Bull [10] had the singular experience in all his cases of having points of suppuration at his sutures only. He used "carbolized silk." All these cases just cited and most of the others were upon the eyelids, and it may be that the greater vascularity of the skin there gives a better chance for the flap to unite; my experience, which has been upon the hands, neck, and scalp, has gradually led me to the adoption of the permanent antiseptic dressing, against which there can certainly be no theoretical objection.

Care must be taken not to apply a dressing that will cause an absorption of the fluids of the flap and its subsequent destruction. While the epidermis is intact the dressing above described, of iodoform gauze and absorbent cotton, answers well, but *when the epidermis peels off early*, as it may do in the course of a week, the dressing had better be modified by the interposition of a piece of india-rubber protective, or other impervious material, between the flap and the absorbent cotton or gauze. If this be not done the flap will become mummified as in dry gangrene, turning black, and becoming as hard as tanned sole leather. I found this in one case, to my great disappointment. The protective may be applied directly against the flap, or, as I think better, between the sticky iodoform gauze and the absorbent cotton, extending well beyond the edges of the gauze.

When the flap of skin is prepared for insertion in the wound, and afterward, it is of course quite bloodless, and the contrast with the surrounding skin is very marked, so much so as often to excite a fear, in one who is not familiar with the appearance, that it may indeed be dead and incapable of being again included in the circulation in its new situation. This appearance continues, indeed, long after adhesion with the parts beneath has taken place, and of course after the re-establishment of the circulation. The outer layers of the epidermis usually become detached in more or less considerable flakes at different periods of from one to four weeks, giving rise again to the fear that the flap is sloughing away; but an attempt to move it from its bed will show that union has taken place.

My experience has been that union takes effect more readily and sooner beneath than at the edges; that the latter do not become firmly united with the main skin, indeed, until after the flap has become quite firmly attached, and whenever a portion only of the flap sloughs it is some part of the edge rather than the centre. Whole flaps may be lost by faulty preparation or after-treatment, but the central portion more frequently unites than the edge, showing that the supply of nourishment is derived from the bed of the wound rather than from the cutaneous circulation. In a flap $4\frac{1}{2} \times 2\frac{3}{4}$ inches, which I inserted into the skin of the neck just below the chin, for cicatricial contraction following a burn, the only loss sustained was at one end, which had been subjected to too much manipulation in the fitting; the central portion preserved its vitality, being nourished of course only from beneath.

The experiences of the pioneers in this branch of surgery, Wolfe, Wadsworth, and others, have proved that a pedicle really plays but a subordinate rôle in the nourishment of a skin flap; that the main source of supply is from the underlying exposed connective tissue. It would seem that this method of *transportation* of large pieces of skin is capable of wider application than it has heretofore received at the hands of surgeons, the modern methods of treatment being much better adapted to obtaining union by first intention.

SKULL, JOINTS OF THE. The skull, as the encloser and protector of the brain, is necessarily a closed shell, affording exit and entrance only to such structures as are absolutely essential. Were it not that in fœtal life it is subject to a very rapid increase in size—which increase does not cease entirely until the age of puberty is reached—it is probable that the necessities of the economy would have long ago obliterated the joints between the bones. We know, in fact, that this must have occurred to a very considerable extent, for as we descend in the animal scale the joints of the skull become more and more numerous, reaching in the osseous fishes a maximum far exceeding the number in man. The same phenomenon occurs in the fœtus. Many of the bones which present a perfect union in the adult are found to be separate in the fœtus and in early childhood, and the sutures which represent this early separation may persist as abnormal conditions. The frontal bone is ossified from two separate halves; the occipital bone from at least five portions; the temporal from four (at an early stage from seven); while the sphenoid may claim to be formed from at least ten distinct ossific integers.

Again, as we advance in age there is a tendency for the sutures to become obliterated. Quite early the occipital and the sphenoid join; indeed, it is so unusual to find an adult skull in which they are separate, that some authors have described them together as a spheno-occipital bone. The parietal bones unite early, and it is not very uncommon to find old skulls in which nearly all the

(From Bruns.)

sutures have disappeared, and the cranium has become, what is doubtless more effective from the protective point of view, a bony case almost without joints.

To this general statement one exception should be made. The mandible or lower jaw articulates by a joint that throughout life remains freely movable. Representing as it does one of the branchial arches, this freedom is assured from the first. The hyoid bone is not, for the purposes of this article, considered as a bone of the skull, although from a morphological point of view it would be quite proper to so class it; for it is developed in one

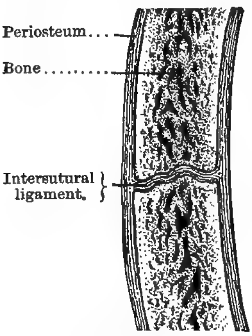

FIG. 3536.—Suture.

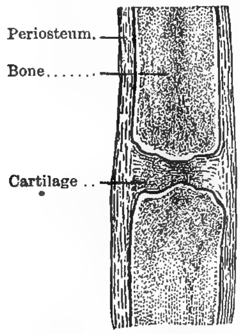

FIG. 3537.—Synchondrosis.

FIGS. 3536 and 3537.—Synarthrodial Joints.

of the branchial bars which appear to be the visceral arches of the same segments which form the cranium.

The joints of the skull are then, with but one exception, immovable. These immovable joints are usually classed together as sutures, but they do not all satisfy exactly the technical definition of that joint, the union between the occipital and the sphenoid at the base of the skull being rather a synchondrosis or union by cartilage (see article Arthrology and Figs. 3536 and 3537).

The sutures form two distinct groups, one antero-posterior, another transverse, in direction. These again are subdivided. In the median line the entire vault is originally separated by the sagittal or inter-parietal suture which connects the two parietal bones, continued downward in early life through the frontal bone as the metopic or frontal suture, and still farther downward as the separation between the nasal and superior maxillary bones in front and the palate behind. The perpendicular plate of the ethnoid, the vomer, and the sphenoid, also show traces of a bilateral separation at an early stage.

Laterally, also, there is a system which runs in a general antero-posterior direction, formed by the frontal bone joining successively the nasal, maxillary, lachrymal, ethmoid, sphenoid, and malar bones in front, forming what is sometimes called the transverse suture; by the parietal joining the great wing of the sphenoid, the squamous and mastoid portions of the temporal. This may be continued back and form a union with the same suture of the opposite side by a suture cutting off the upper part of the occipital bone, thus forming an interparietal bone (see Fig. 3538). This anomaly occurs so frequently in Peruvian skulls that the supernumerary bone is sometimes called the inca bone (os Incæ, of Tschudy and Ribero).

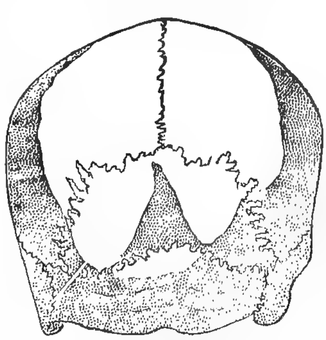

FIG. 3538.—The Interparietal Bone, as Shown in a Peruvian Skull.

The best marked transverse set is constituted by the coronal suture between the frontal and parietal bones, continued downward by the temporo-sphenoidal and occipito-sphenoidal. This usually suffers a slight interruption in man, the wing of the sphenoid pushing back so as to articulate with the antero-inferior angle of the parietal. In the orang the continuity is not interrupted, the temporal articulating regularly with the frontal, and this is the case in about five per cent. of human skulls. (Somewhat more than this in African skulls, judging from an experience of some years in dissecting-rooms, where such subjects abound. See Figs. 3539 and 3540.) The lambdoid suture, between the occipital and the parietal bones continued downward to the base of the skull, as the

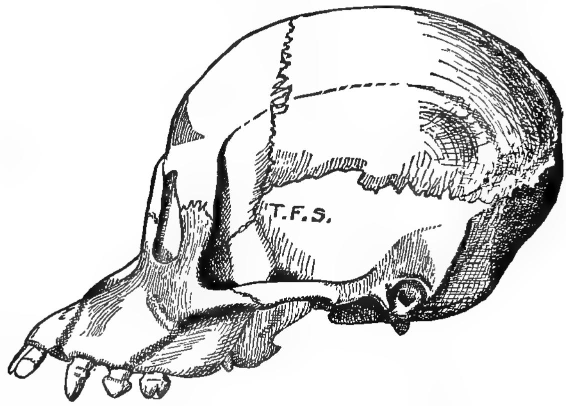

FIG. 3539.—Orang's Skull, Showing Temporo-frontal Suture.

occipito-temporal is also transverse. In the face the indications of transverse sutures (indicating visceral arches?) are more obscure. The palato-maxillary and palato-sphenoid are the principal ones belonging to this class.

The primoidal skull, it should be remembered, is to be considered as a membranous capsule with a cartilaginous base. This capsule is continuous and without joints, and the bones appear as secondary modifications. The increase of size of the capsule is not due to any increase of bone, but to the interstitial growth of the membrane in which the bone is formed. This membrane re-

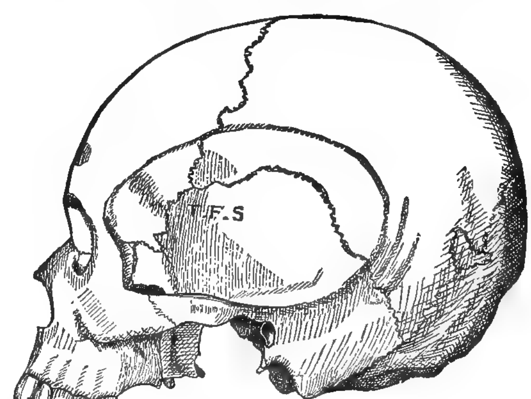

FIG. 3540.—The Same Suture from a Skull in the Author's Possession.

mains, spanning the surface between the bones as long as their growth is insufficient to encase the entire brain.

The growth of the several bones by their edges varies considerably according to their thickness, the thicker bones growing faster. Welcker estimates the growth from birth to adult life as follows:

Frontal bone	along coronal suture		18–22 mm.
Parietal	" "		17–19 "
"	"	sagittal suture	25–33 "
"	"	squamous suture	4 "
"	"	mastoid "	24–27 "

Growth is arrested by the pressure of one edge against another, and, should there be an unusual growth of bone

at any time during childhood or fœtal life, this pressure may be so great as to cause an early obliteration of the suture. This occasions a deformation of the skull which varies according to the sutures affected. In Figs. 3541

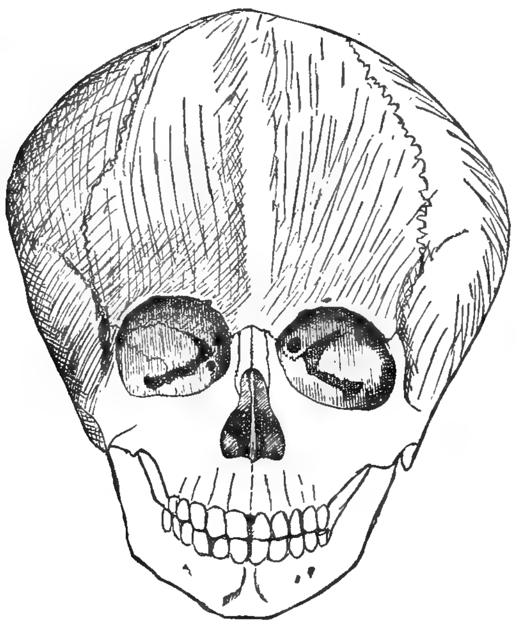

Fig. 3541.—Trigonocephalic Skull. Front View. (After Welcker.)

and 3542 there is a premature union of the medio-frontal or metopic suture. The skull thus deformed is known as trigonocephalic. The suture usually begins to close during the first year after birth and from above downward. It is very common to find traces of it in adult

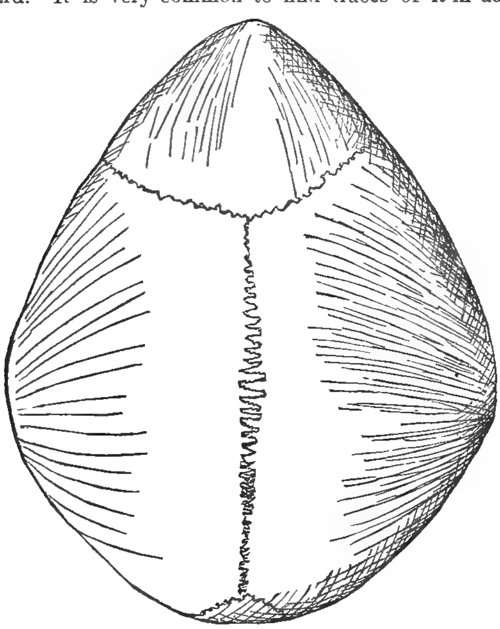

Fig. 3542.—The Same. Top View. (After Welcker.)

skulls. In the trigonocephalic skull it appears to commence to ossify at either end.

By a premature union of the sagittal suture a keel-shaped form of skull is produced, termed scaphocephalic. Examples of this are seen in Figs. 3543 and 3544; and these are by no means uncommon.

There are several types of scaphocephaly depending upon the portion of the parietal bones which first become united. It would appear that, wherever the union may be, it tends to form a constricting band which pushes the brain out forward and laterally. In this way are doubtless produced many of the deformities and asym-

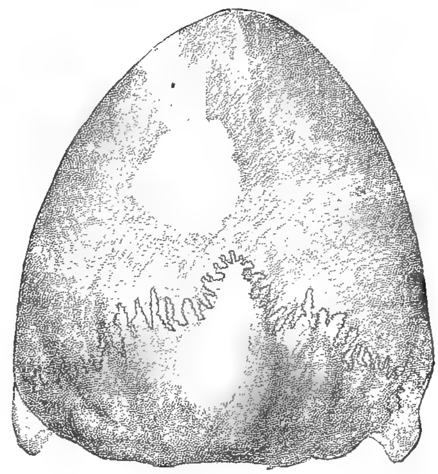

Fig. 3543.—Scaphocephalic Skull, from Behind. (Welcker.)

metries, which are known to be much more common than is generally supposed. An inspection of the outlines which are usually kept by hatters for the blocking of hats, affords convincing proof that irregularities in the contour of the head are frequent. One of the most common is the so-called annular type, shown in Fig. 3545.

This consists of a circular depression situated just be-

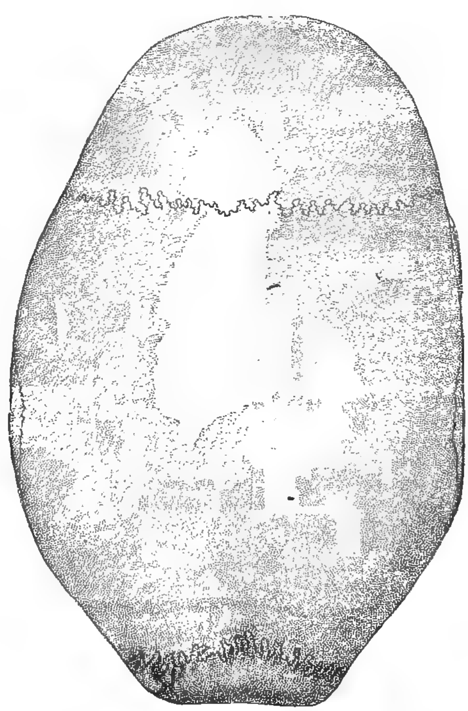

Fig. 3544.—Scaphocephalic Skull, from Above. (Welcker.)

hind the coronal suture, and indicating that the sagittal suture first united at that point instead of further back, near the parietal foramina, as in normal cases.

Another type of deformity is found by the premature

union of the coronal suture together with obliteration of the sagittal. The skull is then turned acrocephalic (see Fig. 3546), as it appears high and pointed. It is well known that the skull of Sir Walter Scott was of this class, as

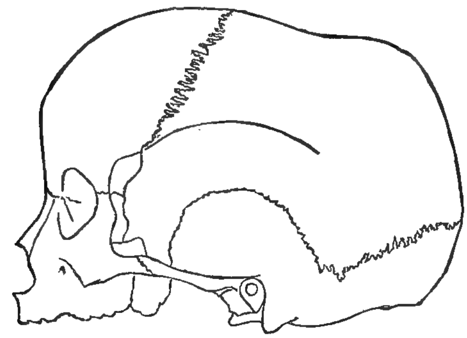

FIG. 3545.—Annular Scaphocephalic Skull. (Topinard.)

may be seen by looking at his portraits. This leads to an interesting series of considerations as to whether these premature unions affect in any way the intellectual faculties. It is clear that in many cases there is no positive

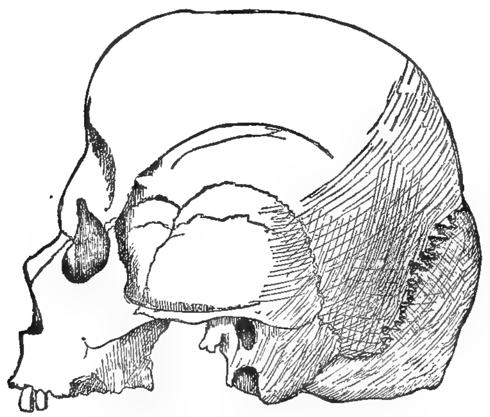

FIG. 3546.—Acrocephalic Skull. (Topinard.)

defect observable, but yet it must be confessed that the evidence on this point, gathered by taking cases of exceptional men, is not conclusive. Statistics gathered from insane asylums show that there are a greater proportion of such deformities found there than in the population in general, and Lombroso holds that there is a much larger proportion also among the criminal classes.

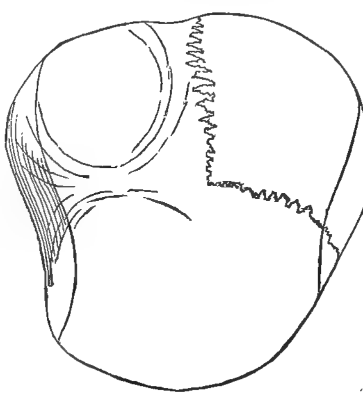

FIG. 3547.—Plagiocephalic Skull. (Topinard.)

In case the obliteration affects only a portion of the sutures involved, there is sometimes produced a twisted appearance in the skull. Fig. 3547 shows an instance of this, which is known as the reniform or plagiocephalic skull.

It has been alleged that the deformities here described are more frequent in the inferior races. Topinard doubts if this is the case, and considering the fact that they are probably not to be considered as phylogenetic characters, but variations depending upon ante-natal conditions or accidental impressions, it seems unlikely that any ethnologic value can be attached to them.

As an opposite condition to early obliteration, undue persistence of fœtal sutures may also occur. This is almost always the case in cases of chronic hydrocephalus. The medio-frontal suture is the most frequently persistent, but the transverse occipital is also found (see Fig. 3538); and occasionally the petro-squamosal portion of the temporal bone and the squamous portion may continue open. Fissures, indicating situations where ossification has been imperfect, may remain and simulate fractures.

A very considerable difference occurs in sutures as regards their character. Some are perfectly simple, like those by which the vomer unites with the two superior maxillary bones; others exceedingly irregular, fitting into each other by jagged margins, sometimes saw-like, tooth-like, wavy, intricately involved with sinuous outlines, like the edges of leaves. This last is especially noticeable in the sagittal and the lambdoid sutures. The coronal suture is usually quite simple above and below, but full of intricate turns at the place where it covers the temporal line. The winding pattern which involves the outer table of the skull is not repeated by the inner table. This has a pattern of its own, and even the diploë between the two has its own peculiar form of joining, which is different from both inner and outer tables. This

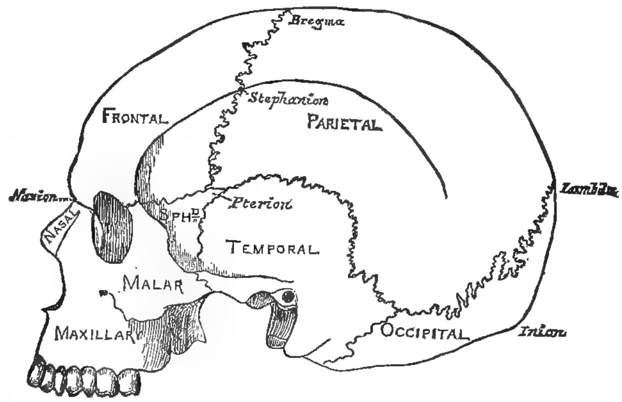

FIG. 3548.—Diagram showing the Principal Craniometric Points on the Lateral Surface of the Skull.

variety in the junction of the different parts lends great stability to the union of the bones, and it is rare that any of the common expedients for separating the sutures, like filling a skull with dried beans and then allowing them to swell in tepid water, does not break the bones apart instead of separating the sutures.

The sutures are extensively used as landmarks from which craniometrical measures are taken. Broca, who may almost be said to be the father of modern craniology, invented a series of terms for the most useful points, and these are now generally used in works which treat of the measurements of the skull. A number of these points are shown in Fig. 3548. They are also useful as topographical data for determining the situation of the convolutions and sulci of the brain in relation to the skull. These relations are somewhat imperfectly shown in Fig. 3535. The upper end of the fissure of Rolando, of the brain, lies nearly two inches behind the bregma (Fig. 3548), or about one inch more than half-way back from the nasion to the inion. The lower end of the fissure of Sylvius is at the pterion, a little over an inch directly behind the external angular process of the frontal bone. The precentral sulcus lies just behind the coronal suture, and parallel to it. The inferior frontal runs forward from it, about on a level with the stephanion. The parieto-occipital fissure is just in front of the lambda.

Fig. 3535 also shows the relation of the superficial arteries, viz., the temporal at 1, with its branches, transverse facial (4), antero-temporal (5), and middle tem-

poral (6), the posterior auricular (7), and the occipital (8). The usual points of ligation are shown by stars.

Frank Baker.

SKULL, PERFORATING TUMORS OF THE. This term is applied to tumors which originate in the cranial bones, and which, during their growth, destroy the entire thickness of the bony wall; it is also applied to extra- and intra-cranial tumors which cause perforation by pressure, atrophy, or invasion of the bone by the neoplasm. With but very few exceptions this group is composed of sarcomatous tumors of the coverings of the skull, the cranial bones, or the dura mater, which, from a pathological and clinical aspect, present certain peculiarities that entitle them to separate consideration.

1. Perforating Sarcoma of the Skull, of Extra-Cranial Origin.—An extra-cranial sarcoma has its starting-point in the skin, in the galea, or in the periosteum. When it develops in the skin primarily, it is frequently found engrafted upon a pigmented mole, or a wart. Tumors of this kind, as a rule, belong to the variety of spindle-celled sarcoma which manifests a marked tendency to infiltration of the subjacent tissues. They penetrate the galea, the periosteum, and the cranial vault. After reaching the dense, fibrous structure of the dura mater, their central extension usually becomes limited, but their growth extends over the surface of the dura mater, between this membrane and the cranial vault. I have seen two patients, both men of middle age, suffering from perforating tumor of the skull of such origin, and which pursued this course. In one of the cases the tumor started as a nodule in the scalp, painless and movable, which had begun, without any apparent cause, twelve years before the patient came under my observation. In the meantime seven operations had been performed. Every successive operation became more difficult, requiring the removal of more tissue. In the last two operations small portions of the skull were removed, and in the last it was ascertained that the entire thickness of the skull had been destroyed by the tumor. When the patient came under my care a pulsating tumor, covered by a dense cicatrix, somewhat oval in shape, and about two inches in diameter, was found to occupy the vault of the skull near the median line, about an inch posterior to the junction of the parietal bones with the frontal. Firm pressure diminished the size of the tumor, but as soon as compression was removed the swelling resumed its former dimensions. The size of the tumor also increased on coughing, or when the head was placed in the dependent position. After each of the previous operations the wound had healed kindly, but within a few months the disease recurred, invariably in the cicatrix. Pulsation could be distinctly felt by the palpating finger over the entire surface of the tumor. On auscultation a slight bruit could be heard, synchronous with the heart's action. The margins of the tumor overlapped the bony defect to such an extent that the opening in the cranium could not be felt. The operation was performed under strict antiseptic precautions. Ether was administered as an anæsthetic. The tumor was circumscribed by a circular incision about an inch from its margins, which divided all the tissues down to the bone. On reflecting the soft parts toward the tumor, a circular opening in the bone was found, about an inch in diameter, with irregular, ragged margins, bevelled at the expense of the external table, and filled by a projection of the neoplasm. The chisel was now resorted to for the purpose of enlarging the perforation, in order to ascertain the condition of the dura mater underneath. On reaching this membrane it was found that the tumor had infiltrated its outer surface and had extended underneath the bone, so that the whole tumor presented the appearance of a cuff-button, the constricted portion corresponding to the part occupying the perforation in the bone (Fig. 3549).* The chiselling was continued until apparently healthy dura mater was reached. The shaving off of the tumor from the dura mater was attended by alarming hæmorrhage, which was followed by a speedy collapse of the patient. I have since thought that the collapse, which was sudden and profound, and which nearly proved fatal, might have been due, in part at least, to the introduction of air into some of the large venous channels which had been opened. The upper portion of the body was lowered to favor blood-supply to the brain, and the hæmorrhage was finally controlled by ligation, compression, and the free use of the actual cautery. This operation was performed about ten years ago, before the time of heroic brain surgery, hence no part of the dura mater was removed. It was hoped that the portions of the tumor contained in the dura mater had been thoroughly destroyed by the vigorous use of the cautery. The patient rallied from the operation, and, a few weeks later, the wound being nearly closed, he left the hospital. I learned subsequently that the disease again recurred in the cicatrix two months after closure of the wound, and that the patient died a year later, having manifested for several weeks prior to death well-marked cerebral symptoms. In the other case the disease started in the scalp, at the junction of the left temporal with the frontal bone. It pursued the same relentless course, proving fatal five years after its commencement. During this time four or five operations were performed by several of the best surgeons in the country.

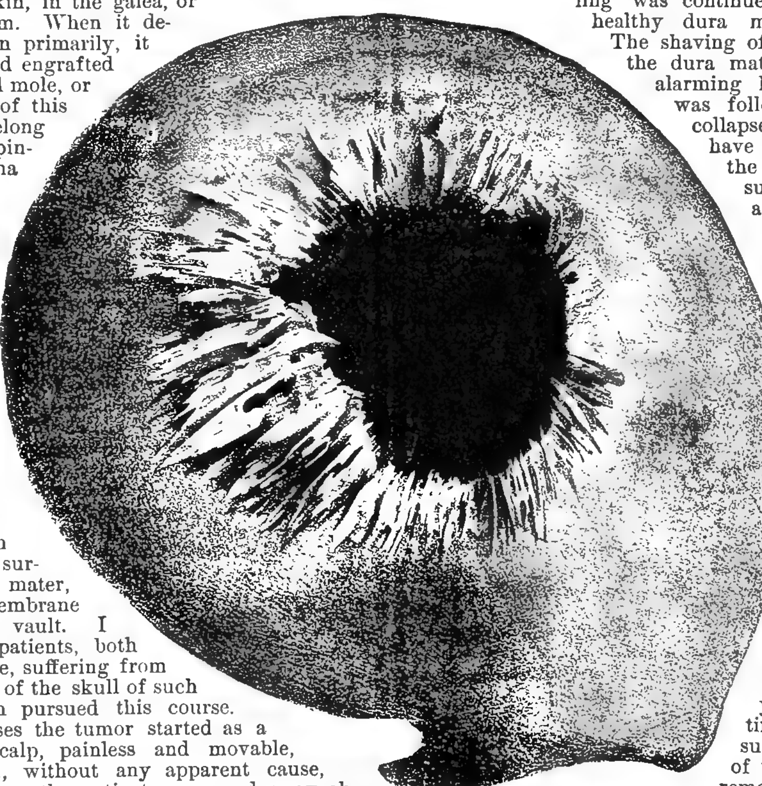

Fig. 3549.—Perforation in the Bone, showing the Osseous Framework of the Base of the Tumor.

One of the most prominent features of an extra-cranial sarcoma is its liability to return, even after what appears a most thorough operation. The recurrence is always local, in the cicatrix. Every successive operation be-

* This and the following illustrations in the present article are taken from Von Bruns' Chirurgischer Atlas.

comes more difficult and serious as the disease penetrates deeper and deeper, following the blood-vessels into the bone, and causing a circular perforation. After it has reached the interior of the skull it spreads diffusely over the outer surface of the dura mater, and at the same time penetrates the meshes of this membrane. When the disease originates in the galea or the periosteum it pursues a more rapid course, as the vessels of the diploë are reached earlier, a circumstance which favors early penetration and perforation.

Pulsation is not a positive diagnostic evidence that perforation has taken place, as a vascular pericranial sarcoma, like any other very vascular sarcoma, may pulsate independently of cerebral pulsation; but in the latter event the pulsations are synchronous with the arterial pulse, and the respiratory pulsations, which are present in a perforating tumor which pulsates, are always absent. A number of such cases are reported by Bruns. A periosteal sarcoma is almost always the seat of formation of new bone, which appears in spurs, traversing the tumor in all directions, imparting to it a degree of firmness proportionate to the amount of bone formed. Figs. 3550 and 3551.

2. Perforating Sarcoma of the Skull of Diploëic Origin.—A sarcoma starting in the diploë of any of the cranial bones is a true osteo-sarcoma, or, more properly speaking, a medullary sarcoma. A medullary sarcoma

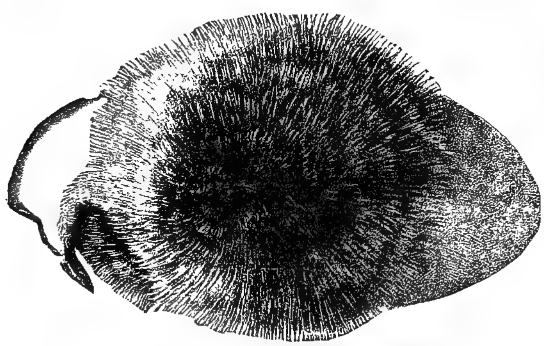

Fig. 3550.—Osteogenic Sarcoma; external surface.

first destroys the structures in its immediate vicinity, the trabeculæ of the diploë, before it affects either of the tables of the bone. When the compact layers are reached the tumor will advance in the direction which offers the least resistance, which is usually toward the external surface of the skull, as the outer table yields more readily to pressure than the inner. The bone expands, and the location of the tumor at this time is indicated externally underneath the scalp by a slight elevation of the smooth external surface of the cranium. The swelling by expansion is of short duration, as the disease infiltrates the compact portion of the bone along the course of the blood-vessels and soon causes a loss of continuity, the defect being covered at this stage by a number of fragments of the external table held together by the neoplasm. At this stage of the disease a crackling sensation is often elicited by the palpating finger. As soon as the tumor has perforated the periosteum extensive and rapid infiltration of the superimposed soft parts takes place. This occasions such a stretching of the overlying skin that ulceration from pressure, atrophy, or some accidental external cause speedily ensues, an event which is followed by protrusion of a fungous, bleeding mass, the fungus hæmatodes of the older authors. While peripheral destruction is going on the disease also travels in a central direction by following the blood-vessels, thus reaching the dura mater and completing the perforation. Only in exceptional cases is the dura mater perforated by the neoplasm. The brain symptoms are usually due to compression caused by the bulging of the tumor toward the cranial cavity, pushing the dura mater before it. In rare cases the disease appears multiple, or becomes so by regional diffusion. Regional infection of the lymphatic glands of the neck has never been observed, but systemic dissemination by metastasis frequently takes place, and death may finally be due to this cause.

Histologically the medullary sarcoma of the cranial bones belongs to the round-celled, giant-celled, or net-celled variety of sarcoma, and very often it appears as a mixed tumor containing two or more kinds of cells. The tumor of the skull described by Kocher as a myxo-sarcoma did not only present pulsation, but on auscultation a distinct and loud bruit could be heard. Heineke, in his article on "Sarcoma der Schädelknochen," describes a case of medullary sarcoma of the skull that came under his observation. The patient was a man, forty-one years of age, who, after having suffered a short time from headache, noticed a small elevation over the occipital region on the right side. This swelling increased quite rapidly in size, so that six months later it had attained quite large dimensions. At this time a swelling formed on the same side over the temporal region, which also increased rapidly in size. The pain in the occipital region ceased at this time, and shifted to the swelling in the temporal region. The general health was not impaired. Seven months later the tumors had attained the size shown in the illustration.

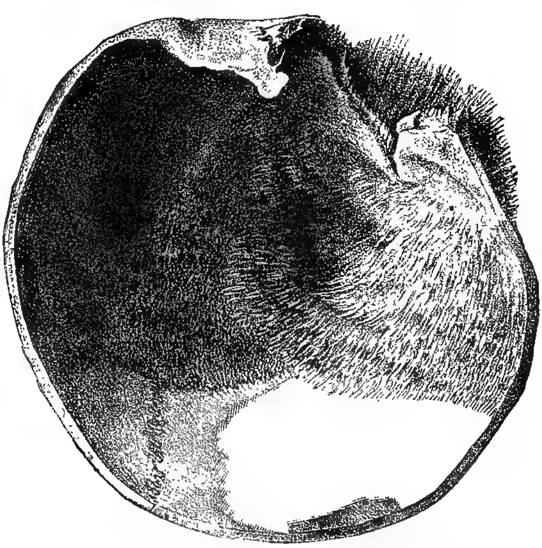

Fig. 3551.—Osteogenic Sarcoma; internal surface.

Both tumors were quite soft to the touch, immovable, but not adherent to the skin. The anterior portion of the ninth rib, on the right side, was also the seat of a tumor the size of an apple. During the operation for the removal of the first tumor it was found that it was surrounded by a distinct capsule. The hæmorrhage occasioned by the incisions necessary for exposing the tumor was alarming. When the margin of the tumor was reached it was found to extend into the bone, and no further attempts were made to remove it. The hæmorrhage was arrested and the wound closed. The patient remained in a comatose condition and died three days later. The post-mortem examination showed that the tumor had its origin in the interior of the occipital bone and contained a framework of bone. The tumor had encroached upon the cranial cavity by pushing the dura mater before it. The internal location of the tumor was marked by a depression of the brain several lines in depth. Microscopically it was composed of an alveolar network of spindle-shaped cells, the spaces of which were filled by large nucleated, round, and polygonal cells. The alveoli contained also numerous blood-vessels, the walls of some of which appeared to be composed of the tumor cells. Where the tumor was attached the dura mater was infiltrated by numerous nodules of the same character as the primary growth. The spurs of bone in the tumor penetrated into, but not through, the dura mater. The tu-

mors in the right temporal bone and the ninth rib were of the same character and structure. Numerous small metastatic deposits were also found in the lung.

But little is known in regard to the etiology of sarcoma of the cranial bones. It is said that it has been observed to follow an injury of the skull, but when we consider how frequently the skull is the seat of traumatic injuries, and how seldom this affection is met with, it is difficult to trace a direct etiological relationship between the alleged cause and effect. Like sarcoma in any other locality, the primary starting-point must be from an embryonal matrix of connective tissue, and a trauma may occasionally, but not always, act as an exciting cause in stimulating the matrix to tissue proliferation by diminishing the physiological resistance of the adjacent tissues. The affection has been most frequently met with in young people, and in those of middle age. The diagnosis is not difficult if the tumor is examined at a time before perforation of the superimposed soft tissues has taken place, as its deep location and its immobility leave no doubt as to its connection with the subjacent bone, while its rapid growth distinguishes it from any benign tumor of the cranial vault. Before the continuity of the surface of the bone has been destroyed by the tumor it might be mistaken for an exostosis, but its growth is more rapid and in a short time the external table of the bone gives way. A periosteal sarcoma in the beginning is softer than a medullary sarcoma, as the latter is covered by the compact layer of the outer table of the bone before perforation outward has taken place. If the tumor has attained a considerable size, it is often impossible to differentiate between a sarcoma of the extra-cranial tissues, of the medulla, or of the dura mater. If, by palpation or by exploratory puncture, it is possible to prove the existence of a framework of bone in the tumor, it is positive evidence that the primary growth started in the periosteum or in the diploë.

The prognosis of a medullary sarcoma is more grave than is that of an extra-cranial sarcoma, as perforation toward the cranial cavity takes place earlier, an occurrence in the history of the tumor which initiates a new source of danger by directly compromising the functions of the brain. While life may be prolonged from five to ten years in cases of extra-cranial sarcomata, death follows a medullary sarcoma of the diploë within a year, or, at best, within two or three years, from extension of the disease to the dura mater, unless the tumor is attacked early and vigorously by operative measures.

3. Perforating Sarcoma of the Skull starting from Dura Mater.—Sarcoma of the dura mater, the *fungus duræ matris* of the older authors, is the most frequent form of perforating tumors of the skull. It occurs as a primary or secondary formation. As a secondary tumor it arises by extension of a sarcoma of the skull, or of the remaining envelopes of the brain, to the dura mater, or by metastasis when a sarcoma exists in any other part of the body. Not infrequently metastatic sarcoma of the dura mater occurs as a multiple formation, and, as the disease, by farther dissemination from the primary tumor, affects at the same time other important organs, a fatal termination takes place before perforation of the skull can occur. Extension of the disease from a primary sarcoma of the arachnoid or pia mater to the dura mater seldom, if ever, leads to perforation of the skull, as the encroachment of the tumor in the direction offering the least resistance produces such extensive and serious lesions within the skull as to result in death before perforation can occur. A primary sarcoma of the dura mater may also extend in a central direction, and produce a fatal result without any perforation taking place. In a number of such cases it has been observed that not only no attenuation of the cranial vault takes place, but the overlying bone becomes thickened by osteophytes which develop upon its inner surface. The cases, however, that present the greatest practical interest to the surgeon are those in which early extension takes place to the skull, resulting in perforation by pressure-atrophy, or by direct infiltration and destruction of the superimposed bone. In such cases the perforation becomes positive proof of the existence of a suspected endo-cranial neoplasm. In the beginning a sarcoma of the dura mater appears as a round nodule, which by pressure upon the adjacent bone causes pressure-atrophy, but perforation is always preceded by a direct extension of the disease to the bone. Analogy and examination of recent specimens tend to prove that infiltration takes place along the course of pre-existing and new blood-vessels. When the neoplasm has reached the diploë, diffusion readily takes place along the numerous venous channels which normally exist in this structure. The defect in the bone presents irregular, oblique margins, the obliquity being caused by the more extensive destruction of the internal than of the external table of the skull (Fig. 3553). As soon as perfo-

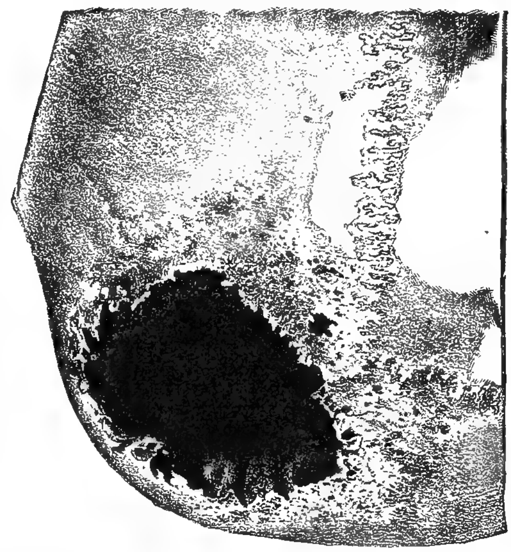

Fig. 3552.—Perforation in the Bone from a Tumor without Osseous Framework.

ration has taken place, the tumor can be felt externally, under the scalp, as a small, elastic, and often fluctuating swelling, which by pressure can be made to disappear completely. At this stage of the disease the defect in the skull can be readily ascertained by making deep pressure with the tip of the index finger, which by indenting the scalp can be insinuated into the opening. Soon after perforation has taken place the tumor extends in a peripheral direction between the cranium and the scalp, thus overlapping the margins of the opening, an occurrence which interferes with further digital palpation of the perforation in the skull. As soon as the tumor has become extra-cranial, it grows with great rapidity and encroaches upon the superimposed soft coverings of the skull, becoming adherent to the tense scalp. Perforation of the scalp usually follows superficial ulceration caused by tension, due to pressure, and by the resulting defective nutrition of the skin. When the skin has given way the tumor appears as a fungous, bleeding mass, which after exposure to the infective influences contained in the surrounding atmosphere, soon breaks down and disintegrates, a rapid loss of substance taking place. The necrobiotic and necrotic changes in the tissues of the tumor, occurring in consequence of infection with pus microbes, is often followed by sepsis which hastens the fatal termination. Until this occurrence has taken place, the patient may have had a healthy appearance, but he now presents a sallow complexion, a rapid, feeble pulse, and a rise of temperature indicative of the existence of a septic condition. The base of the tumor appears attached only to the external superficial layers of the dura mater, or it infiltrates the entire thickness of this membrane. In the former instance, it is easily separated from the dura, in the latter its removal is only possible by excising with the tumor the entire thickness of the dura mater. Sar-

comatous tumors of the dura mater, located at the base of the skull are, as a rule, more liable to encroach upon the contents of the skull, while perforation is a frequent occurrence if they originate in that portion of this membrane which lines the vault of the cranium. Perforating tumors at the base of the skull often appear externally through the frontal sinus, nose, pharynx, or external ear. While sarcomata of the dura mater have often been found in connection with a sarcoma in some distant part of the body as secondary or metastatic formations, it is a well-known fact that a primary sarcoma is seldom the cause of more than a localized dissemination. Volkmann was the first one who claimed that primary malignant tumors of the dura mater were not carcinomatous in their structure and behavior, but that they belonged clinically and histologically to the class of sarcomatous tumors.

A sarcoma of the dura mater always appears as a circumscribed tumor, surrounded by a distinct capsule, while a carcinoma, wherever found, is recognized readily by the absence of any distinct macroscopical boundary-line between the tumor and the adjacent tissues. Microscopical examinations of these tumors have shown that

FIG. 3553.—Perforation of the Skull from within Outward, as seen in Cases of Sarcoma of the Dura Mater.

they are generally composed of spindle-shaped cells, and more rarely contain giant-cells or myxomatous tissue. This affection is found most frequently in young adults, but is not limited to this period of life as it has been met with in young children and persons of advanced age. Among the early symptoms may be mentioned headache, vomiting, and vertigo, manifestations which point to the existence of meningeal irritation. If the tumor is situated at the base of the brain, sight and hearing may be affected. When perforation has taken place, the cerebral pulsations can always be felt over the tumor, a symptom which disappears as soon as its external portion is large enough to overlap the opening in the skull. Arterial pulsation may remain for a longer time, and when present is due to the arterial impulse of the vessels in the tumor. The external tumor may attain the size of a child's head, and always presents a smooth surface and a semisolid consistence. Pseudo-fluctuation is often present, and may lead to a mistake in diagnosis and treatment. If the growth of the tumor encroaches upon the brain as well as the external surface, the signs of cerebral involvement become more prominent, and may include well-marked focal symptoms, such as we observe from pressure due to any other endo-cranial cause. After ulceration has taken place the extreme vascularity of the protruding mass often gives rise to repeated and profuse hæmorrhages, which rapidly undermine the patient's strength, and which also favor local infective processes at the site of ulceration.

The prognosis of a sarcoma of the dura mater is always grave. Without surgical interference the affection leads inevitably to a fatal termination within one or two years. The surgical treatment has so far been unsatisfactory, either because a correct diagnosis was not made early enough, or because the disease had advanced beyond the reach of the surgeon's knife at the time the operation was performed. Before it was deemed safe and expedient to remove a corresponding piece of the dura mater with the tumor the operation necessarily proved a failure, as the neoplasm always invades more or less of this membrane, and hence portions of the tumor were left as starting-points for subsequent return *in loco*. We have also reason to believe that many of the operations proved fruitless on account of imperfect exposure of the endo-cranial

FIG. 3554.—Multiple Perforations from without Inward, in a Case of Periosteal Sarcoma.

portion of the tumor by not removing a sufficiently wide margin of the overlying bone. Before the antiseptic treatment of wounds came into use the removal of an endo-cranial tumor was always an extremely hazardous procedure, as it was necessarily attended by many grave dangers incident to traumatic infection, more particularly septic thrombo-phlebitis and lepto-meningitis. The immediate cause of death in cases that are allowed to run a natural course is either cerebral pressure from extensive growth of the endo-cranial part of the tumor, or, after the extra-cranial portion has broken through the skin, exhaustion from recurring hæmorrhage, or septic infection from the exposure of the tissues of the tumor to the deleterious influences of pathogenic germs brought in contact with the abraded, ulcerated surface.

The medical treatment of sarcoma of the dura mater is merely palliative, and consists in the administration of such remedies as are calculated to meet the most urgent symptoms. In the operative treatment of a sarcoma of

the dura mater, whether perforating or otherwise, it is essential to remove the entire thickness of the dura with the base of the tumor, a step in the operation which is only possible after removal of the bony covering to the same extent by chiselling. In all operations upon the brain or its envelopes the strictest antiseptic precautions must be observed, so as to protect the patients against septic infection. The entire scalp should be shaved, washed with warm water and potash soap, and thoroughly disinfected with a 1 to 1,000 solution of corrosive sublimate. If the tumor has not perforated the entire thickness of the skull, the incisions through the soft parts are to be made in the same manner as for any other endo-cranial operation. If perforation has taken place, a circular incision should be made, at least an inch from the margin of the tumor down to the bone. After arresting the hæmorrhage from the incision through the soft parts, the tissues are separated from the bone, as far as the seat of perforation, by an elevator, and then with chisel and Luer's forceps the bone is removed all around until the endo-cranial portion of the tumor is freely exposed. After arresting the hæmorrhage from the bone, which is apt to be quite profuse, by pressure and plugging of large vessels by a minute aseptic tampon, the surgeon is ready to remove the attachment of the tumor by excising the dura mater, being careful to carry his incisions from half an inch to an inch beyond the visible borders of the tumor. If the tumor is situated in close proximity to the superior longitudinal sinus, or if it lies directly over it, it becomes necessary to resort to prophylactic measures for the purpose of preventing entrance of air, or a serious loss of blood on cutting through this large vessel. Volkmann lost a patient on the table from air-embolism, while he was removing a sarcoma of the dura mater, having severed the superior longitudinal sinus in the dissection. The patient was a woman, sixty-three years of age, who was affected with a perforating sarcoma of the dura mater. The tumor was noticed about two years before the operation, and was located in the region of the posterior extremity of the sagittal suture, and for a long time gave rise to no inconvenience. For the last six months it had caused intense headache. On one occasion a physician, believing that it was an atheroma, attempted its removal, but as the first incision gave rise to copious hæmorrhage he desisted from any further attempts, and the wound healed kindly. When the patient was admitted, under Volkmann's care, into the Klinik at Halle, the tumor presented a lobulated appearance, being composed of three parts, each about the size of a plum, and was located over the posterior extremity of the sagittal suture. To the touch the tumor was soft and elastic, and imparted to the finger a feeling of distinct pulsation. Gradual compression reduced its size one-half, but when the pressure was removed it resumed its former dimensions. On auscultation a blowing sound was heard, synchronous with the radial pulse. By pressing the end of the index finger deeply between the lobes of the tumor a bony defect in the skull was readily detected. The conclusion was reached that the tumor had sprung from the dura mater, and that perforation of the skull had been caused by the prolonged pressure, leading to interstitial absorption of the cranial vault. During the patient's stay in the hospital the tumor increased very rapidly in size. As no brain symptoms were present it was assumed that the substance of the brain was intact. In view of a speedily fatal issue, which of necessity would take place without operative interference, Volkmann decided to remove the tumor. The operation was performed on April 2, 1875. Under strict antiseptic precautions the tumor was exposed by a crucial incision, the flaps with the periosteum being reflected to the margins of the opening in the skull. The aperture in the bone measured five and one-half by four and one-half centimetres in diameter. With a Luer's cutting forceps the opening was enlarged to seven by eight centimetres. The tumor, when exposed, was nearly as large as a fist, and firmly adherent to the dura mater. The dura mater was carefully divided around the margins of the tumor, which had now been liberated from all its attachments, except the falx cerebri. It was now drawn forward through the opening in the skull, and the falx cerebri was divided, the incisions being made from before backward. This step of the operation was attended by alarming hæmorrhage. As the blood was being sponged away to expose the field of operation, a peculiar and characteristic lapping sound was heard, which indicated to all present that air had entered the longitudinal sinus. At the same time the assistant, who was giving the chloroform, remarked, "she is dying." The wound was immediately compressed with a large carbolized sponge. The patient was in collapse, her breathing was interrupted and stertorous. After a short pause it was determined to complete the operation, but as soon as the tumor was again drawn forward and its attachment at the junction of the longitudinal with the transverse sinus was divided, air again entered, accompanied by the same characteristic sound. The tumor was separated rapidly from its remaining attachments, and a Lister dressing was applied in such a manner as to make compression sufficient for the double purpose of arresting

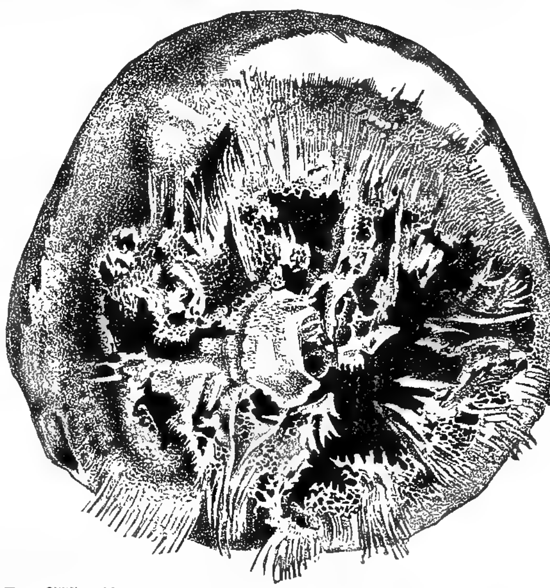

Fig. 3555.—Almost complete Destruction of the Occipital Bone from a Perforating Tumor of the Base of the Skull.

hæmorrhage and preventing further ingress of air. At this time the patient was pulseless, with dilated pupils, and cold and blue extremities. Auto-transfusion, by constricting the arms and legs with elastic bandages, had the effect of momentarily stimulating the heart, but respiration became more irregular and interrupted, and after a few brief moments the patient expired. At the post-mortem examination, which was held on the following day, the right side of the heart was opened under water, and air-bubbles escaped, showing conclusively that air had entered through the longitudinal sinus. The left side of the heart contained no air. Air was also found in the pulmonary artery and in the subpleural vessels. The left side of the brain had suffered more from compression by the tumor than the right. The defect in the dura mater corresponded to the opening in the skull. An additional source of hæmorrhage was detected at the posterior margin of the defect in the cranium, where the opening of a vein in the substance of the bone, five millimetres in diameter, could be seen. Under the microscope the tumor showed small spindle-shaped cells, with a very vascular intercellular substance.

In my experiments on air embolism I determined the fact that entrance of air through a wound in the superior longitudinal sinus can take place only when the head is elevated, as in this position intravenous pressure is diminished, and as, from the unyielding nature of the ves-

sel walls, collapse cannot take place, the essential conditions for the admission of air are thus created. As long as the head is in a dependent position a wound in the longitudinal sinus gives rise to profuse hæmorrhage, but air-embolism cannot occur, as the lumen of the vessel is constantly filled by an uninterrupted column of venous blood. In the same series of experiments I also proved the feasibility and practicability of ligation of the superior longitudinal sinus as a prophylactic measure against air-embolism and hæmorrhage in operations which implicate this vessel, a practice which Kuester had adopted previously in extirpating an endo-cranial sarcoma. It is not only advisable, but positively indicated, to resort to ligation of the superior longitudinal sinus in all cases of ex-

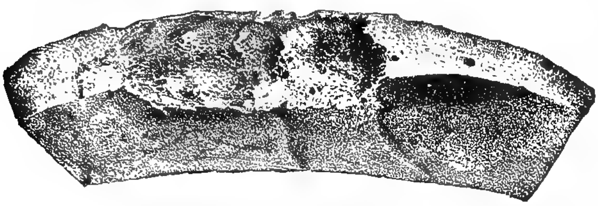

FIG. 3556.—Sarcoma of the Diploë; Tumor encroaching upon both Surfaces of the Skull.

tirpation of sarcomatous tumors of the dura mater whenever it becomes necessary to traverse this vessel by the incision, thus guarding effectually against the two great risks attending such a procedure—air-embolism and profuse hæmorrhage. With a sharply-curved needle two catgut ligatures are passed beneath the sinus, about half an inch apart, and, after tying the ligatures, the vessel is divided between them, and the excision of the dura mater with the tumor is completed. It remains to be shown whether the practice of Macewen, of replanting fragments of bone, after trephining, could not be followed in these cases. This procedure, if it should prove successful, would repair the extensive bony defect that follows the ordinary methods of operating. After arresting all hæmorrhage and closing the external wound as nearly as possible, by suturing, it becomes necessary to apply a thick compress of an antiseptic hygroscopic dressing material, which should always be retained by a few turns of a plaster-of-Paris bandage, so as to prevent all possibility of exposing the wound to secondary infection. If no urgent indications present themselves the primary dressing should be allowed to remain for one or two weeks, after which time there will be but little liability to the occurrence of secondary infection, as the portion of the wound not closed by primary union will be found covered by a layer of granulation tissue, which furnishes the best protection against infection.

SLEEP, DISORDERS OF. Sleep is a condition in which consciousness is normally lost, and in which the whole body, but particularly the brain, enjoys functional rest, while constructive and nutritive activity goes on. The most conspicuous phenomenon of sleep is the subsidence of the higher cerebral functions; yet other organs, notably the muscular system, also take part in the resting process. The statement of Foster, that sleep is the diastole of the brain, is therefore only partially true. Persons who lie quietly in bed all night without cerebral sleep get some muscular sleep and a measure of refreshment. For the essence of the state is functional rest and nutritive repair, similar to that which occurs in the cells of the pancreas or salivary glands in the intervals of their activity. We may even rationally assume that in sleep the brain-cells during repose are building up complex molecules, just as the salivary and other glands build up their mother-ferments or zymogen.

The brain, during this period of rest, is slightly anæmic, the deficiency in blood being a part of, but not the cause of, the phenomenon. The remote cause of sleep is inherent in the nervous tissue itself, which follows the great rhythmical law common to all living tissue, of rise and fall in its irritability. It is probable that the immediate cause of drowsiness is the exhaustion of the irritability of the cortical cells and the benumbing of them by the circulation of waste products in the blood. While sleep involves so large a part of the economy, it is true that it is the highest organized tissue, that of the cortex of the brain, which is most affected in this state.

Many facts in the history of the pathology of the brain point to the existence of a sleep centre, which, being especially acted upon, tends to inhibit the consciousness and draw the mind into a somnolent state.

As sleep is only a function, and a passive or a negative one at that, it follows that we cannot speak of its diseases, but only of its disorders, and that these really form but a part of the diseases of the brain, or of general diseases. It is a matter of convenience, however, to discuss some of these separately.

Custom has established the use of certain terms for the various disorders of sleep, and such terms must be for the most part adhered to. It will be proper, however, for the sake of completeness, to arrange the various disturbances we are to discuss in accordance with the modern methods of studying the pathological changes of bodily functions. We propose, therefore, the following classification, which indicates the various depressions, exaltations, and perversions of the function of sleep.

I. State of Normal Sleep. *Hypnosis.*	Somnus.
II. States of Absence of Sleep. *Ahypnosis.*	Insomnia. Egregorsis. Vigilance.
III. States of Imperfect or Partial Sleep. *Hypohypnosis.*	Dreams, sleep-drunkenness or somnolentia, night-terrors, nightmare.
IV. States of Perverted or Artificial Sleep. *Parahypnosis.*	Somnambulism, sleep-walking, hypnotism, mesmerism, trance, somnium.
V. States of Excessive or Frequent Drowsiness and Sleep. *Hyperhypnosis.*	Morbid drowsiness or somnolence, paroxysmal sleep, epileptic sleeping attacks, trance sleep, carus, cataphora, lethargy, sleeping-sickness of Africa.

I. NORMAL SLEEP varies much in accordance with age, sex, the individual, and, to a slight extent, with occupation, race, and climate. The infant sleeps fourteen or sixteen hours out of the twenty-four, the adult needs about eight hours, while the aged live healthfully with but six. Women need half an hour or an hour more than men. A few persons, generally men, need nine, ten, or even twelve hours of sleep daily; others require only six. Brain-workers, as a class, take less sleep than laborers. Sleep is sounder and longer in cold climates and among northern races.

II. AHYPNOSIS.—*Insomnia* is a term given to conditions in which persons simply suffer from insufficient and restless sleep, or from entire absence of sleep for a long time. Such conditions result from a great variety of causes. It is my purpose to discuss only those forms in which the trouble is functional or nutritional, leaving out of consideration the symptomatic insomnia of organic brain disease, and that occurring as the result of painful diseases.

Ahypnosis, entire absence of the capacity to sleep, occurs most often and typically at the onset or in the course of insanity. It is here a prominent and most distressing symptom. The length of time during which a person

can live without any sleep is about the same as that during which he can go without food, viz., three weeks. There are, doubtless, instances in which this period has been exceeded, but authenticated cases are certainly rare. Many hysterical, neurasthenic, or incipiently insane individuals will assert that they have not slept for weeks, but careful examination shows that they have at least been in a drowsy, somnolent condition, which is, in a measure, physiologically equivalent to sleep.

The cases in which persons can only get a troubled rest of a few hours are much more numerous. The young and the old, less often than middle-aged, suffer from this form of insomnia. It is a disorder of the third, fourth, and fifth decades of life. Women are less liable to suffer from it than men, and the laboring classes less than those engaged in business or professional pursuits.

A frequent symptom of neurasthenia is an imperfect, and especially an unresting, sleep. In these neurasthenic cases there is a loss of vaso-motor tone. Ordinarily, as mental activity subsides and sensory excitations are shut out, the inhibitory vaso-motor centre asserts control and slightly exsanguinates the cortex of the brain; but in these insomnic states such action does not occur, the blood continues to flood the tissues concerned in the conscious workings of the mind, and sleep cannot be induced. In gout and in the so-called latent gout, or lithæmia, insomnia is a frequent symptom. One of the few nervous symptoms of secondary syphilis is insomnia. Insomnia may develop as a bad nervous habit, in persons who are neglectful of themselves. It occurs sometimes as a hereditary neurosis. I am personally acquainted with a family in which, for four generations, one or more of the members have suffered from chronic insomnia throughout life.

In anæmia and chlorosis there is often insomnia at night, combined with somnolence during the daytime. Disease of the heart and arteries may lead to insomnia, and under this head come the cases which occur in Bright's disease with tense arteries and anæmic brains.

Disorders of the stomach lead to disturbed sleep oftener than complete insomnia, and the liver, when inactive, causes somnolence rather than the contrary. The poison of malaria, and the toxic agents of fever, must be added to the list of causes of imperfect sleep.

It will be seen from a review of the foregoing that the causes of chronic functional insomnia may be classed under the following heads:

1. Neurasthenic and vaso-motor, including hereditary and habit insomnia.
2. Vascular and cardiac, including heart-disease, arterial fibrosis, and general anæmia.
3. Auto-toxic or diathetic, including lithæmia, gout, and uræmia.
4. Toxic, including syphilis, lead, malaria, tobacco, and various drugs, such as coffee, tea, and coca.

In many cases there exists a combination of these causes.

The forms and degrees of insomnia vary greatly. In children it is accompanied usually with much mental and physical disturbance. The patient is restless, excited, talkative, or querulous and irritable. The insomnic child is more ill than the insomnic adult. In neurasthenic insomnia there is a tumult of thoughts which prevent sleep, or sleep is superficial, unresting, and interrupted by dreams. In many cases of insanity insomnia is characterized by great motor restlessness. In old people insomnia is generally of the quiet kind.

Treatment of Insomnia.—As insomnia in all its phases is often a symptom of some general disorder, treatment of a curative kind must be directed to this. Anæmia, lithæmia, uræmia, malaria, and the other toxic influences must be removed by remedies adapted to these conditions. But besides constitutional treatment there is a symptomatic treatment which will be discussed here.

The older physicians, in treating insomnia, used to depend largely on hyoscyamus, camphor, opium, and the fetid drugs, such as assafœtida, musk, and valerian. Hyoscyamus is still used. It is to be given in large doses, such as five or ten grains of the extract, or even more, and from ten to twenty drops of the fluid extract. The hydrobromate of hyoscine, in doses of gr. $\frac{1}{150}$ to gr. $\frac{1}{100}$ or more, is one of the best forms. Crystalline hyoscyamine does not have so much of the narcotic principle; and amorphous hyoscyamine, which is much like hyoscine, is said to be variable in composition. Hyoscine is indicated in the insomnia of the insane, especially in forms accompanied with motor activity. Chloral hydrate still holds its own as one of the surest of hypnotics. The dangers involved in its use have been somewhat exaggerated, though they are sufficiently real. Doses of gr. x. and gr. xv. are often quite large enough, but in alcoholic insomnia it may be given in twice the above amounts, guarded with carbonate of ammonia. The taste is best disguised by raw whiskey, ice, or a licorice elixir. Not a few persons find that chloral has bad effects. The patient awakes with a dull, heavy sensation in the head, slight headache, or gastric disturbance.

The various bromides are efficient and safe hypnotics if properly used. The immediate effect of them is simply sedative, and sleep is not produced unless very large doses are given. Some persons are even kept awake by average doses (gr. xv.–xx.). In insomnia, therefore, bromides are best prescribed in doses of gr. xv. three times a day. By the second evening sleep is generally secured. The bromide habit is rarely formed, and is in itself not so seriously injurious as the chloral or opium habit. The drug in some cases can be taken in moderate doses for years without doing much harm. Still, in most persons it produces a disagreeable hebetude, anorexia, foul breath, and acne, so that its continual use may prevent the attempts at restorative treatment which are being made. The bromides alone are hardly strong enough hypnotics for alcoholic insomnia, or the insomnia of insanity. I have found them to fail in the insomnia of the aged. While there seems to be advantage to the stomach in varying and combining the bromides, there is no essential difference in their action. The bromide of sodium is the most palatable, the bromide of nickel the least so. Hydrobromic acid causes less acne and hebetude, but it involves the taking large amounts of a strong mineral acid. The bromides are sometimes advantageously combined with ergot (ʒ j. dose) or conium (♏x.–xx. of fluid extract). Paraldehyde ranks close to chloral in its value as a hypnotic. In some persons it disturbs the stomach, but not in all, and it may be used as a hypnotic for months without its power being impaired. It is a disagreeable drug, and there is nothing, so far as I know, that palliates its offensiveness. I prefer, however, to prescribe it in ʒ j. doses, poured upon a teaspoonful of powdered sugar. Doses of ʒ ss. are sufficient to cause sleep in many cases, and collapse may be caused by ʒ ij. given to weak patients. Urethan, in doses of a scruple or more, is a mild and agreeable hypnotic, but not so certain as paraldehyde, and it is at present date very expensive. Amylene hydrate is a hypnotic of similar properties to paraldehyde, but less disagreeable. It is given in doses of about one drachm.

Hypnone, so called, has found no favor as a sleep-producer. Much the same may be said of the various active principles derived from cannabis indica. Lupulin in large doses, gr. x. to gr. xx., is said to be a good hypnotic. Among the antispasmodics are several drugs which occasionally answer well in the insomnia due to nervous irritability. A drachm of the fluid extract of valerian, or of spirits of lavender, for example, may be prescribed. In some forms of insomnia—perhaps best in those due to fever, or pain, or some rheumatic or gouty trouble—antipyrin in twenty-grain doses acts well. It is known that in many cases of mild types of insomnia a dose of whiskey, brandy, or beer will put the patient to sleep. Besides drugs, there are many hygienic or mechanical measures to which the physician may successfully resort—listening to monotonous noises, reading dull or heavy books, counting, or keeping before the fancy some blank or wearying picture—

> "A flock of sheep that leisurely pass by,
> One after one: the sound of rain and bees
> Murmuring; the fall of rivers, winds and seas,
> Smooth fields, white sheets of water, and pure skies."

The mechanical remedies have nearly all for their purpose the withdrawal of the blood from the brain to the skin and abdominal viscera. Hot foot-baths, or warm general baths, cold douches down the spine, beating the limbs with rubber hammers, brisk exercise, a light meal, massage, all are at times efficient hypnotics. Persons who suffer from insomnia should sleep in cold rooms, the head should not be too high nor very low, and in most cases they are better without late suppers, even though these be light. Mental work should be laid aside several hours before retiring, and the evening devoted to quiet conversation and reading, or amusements that do not actively excite the nerves. Many persons live in good health though they sleep in the day and stay awake at night. Journalists and editors, whose work obliges them to go to bed in the early morning, often continue for years without impairment of physical vigor. Yet despite this, it is true that the best time for sleep is at night, and that the old maxim, "early to bed," is a sound one. The human system requires a certain amount of sleep, and should have it. The industrious and ambitious often try to train themselves to shorter hours, but, though they may succeed for a time, nature will not be cheated out of her due, and health suffers in the end. It is a widespread custom in some countries to take a short nap in the daytime, and the custom is a good one. America has not adopted it, but might do so with benefit to the health of her brain-working class. Many from childhood up do not get a sufficient amount of sleep.

III. Disorders of the Hypohypnotic State.—These are: *dreams, sleep-drunkenness* or *somnolentia, night-terrors, nightmare.* Sleep is said to reach its deepest stage in from one to two hours after it begins. There is then after this a gradual lessening of the depth of sleep. Probably there are great variations in this rule, for many persons seem in soundest slumber several hours after falling asleep. But, at any rate, there are lighter stages of sleep at its inception and toward its end. These are the favorite times for dreams, and at this period also there develop the peculiar phenomena of sleep-drunkenness.

Dreams.—When sleep is perfect and profound, dreams afterward remembered do not occur. Dreaming is, therefore, a morbid symptom, although often of trivial significance, especially if it occurs at about the time of natural waking, when slumber is, in its physiological course, passing into the lighter stages. In sleep, no matter how light, the action of the regulating centre which directs thought, controls emotion, and exhibits itself in volition, is suspended; the psychical mechanism, if excited to action at all, works without purpose, like a rudderless ship at sea. Ideas and emotions succeed each other by the laws of association, but are not properly correlated, and judgment and logical reasoning are gone. As a rule, dreams are made up of somewhat ordinary ideas and fancies incoherently associated, and shifting too rapidly to call up much feeling. When from some point in the body painful sensory excitations do excite disagreeable images, emotions of a most violent kind may be felt.

Dreams, when painful, depressing, or unusually vivid in character, are called morbid, and Hammond speaks of symptomatic morbid dreams and essential morbid dreams, or nightmare. But while there are, doubtless, cases of nightmare in which the trouble is a pure neurosis, or vice in nervous structure and nutrition, yet, as a rule, the characteristic symptoms of nightmare are excited by some agent which is recognizable. It is, therefore, also symptomatic.

In the earlier stages of civilization, among primitive people, dreams were comparatively rare. When they did come with vividness they were regarded with importance, and often were considered visitations of spirits. Civilized man dreams more, but he has learned to treat his fancies with corresponding indifference. The attempts of scientific men to formulate laws regarding them have been productive of small results. Some diseases, however, produce, as a rule, dreams of a more or less peculiar kind. Thus heart disease is accompanied with dreams of impending death. Previous to attacks of cerebral hæmorrhage, patients have dreamed of experiencing some frightful calamity, or of being cut in two. Dr. Thos. More Madden states that intermittent fever is often announced by persistent dreams of a terrifying character. Hammond ("Treatise on Insanity") has collected a large number of what he terms prodromic dreams, all going to show that, before recognizable signs of disease are present, morbid dreams of various kinds may occur. Albers, quoted by Feuchtersleben, has given a complete summary of his views regarding the significance of dreams. Among his dicta are these: "Frightful dreams are signs of cerebral congestion. Dreams about fire are, in women, a sign of impending hæmorrhage. Dreams about blood and red objects are signs of inflammatory conditions. Dreams of distorted forms are frequently a sign of abdominal obstructions and diseases of the liver." Lyman asserts with truth that in certain somnolent states the brain becomes extraordinarily sensitive to external impressions, hearing in particular being greatly intensified. He asserts that at one time he always was awakened nights several minutes before his bell rang. When thus awakened he could at first hear nothing, but felt perfectly sure that the bell would ring shortly. Dr. Lyman would explain some of the cases of alleged thought transferrence on this theory of somnolent exaltation; but here we are treading in regions of the undemonstrated.

Nightmare.—That nightmare is a disorder incident to the hypohypnotic state, or that of incomplete sleep, is, I believe, strictly true; for though the cause of nightmare may act upon the patient while sleeping soundly, it must first bring him into the somnolential state before he experiences his sufferings.

Nightmare is one of those minor ills that are nearly always symptomatic of an irritation in some part of the body. The usual causes of it are some digestive disturbance (repletion) and cardiac disease. Persons of a nervous temperament are more subject to it; and there are individuals whom it makes suffer all their lives. The popular belief that sleeping on the back favors it, is, in general, a correct one. When nightmare occurs in cardiac disease a certain position, semi-recumbent or on the right side, must be maintained, or the painful fancies awaken the patient.

Healthy people can get sound sleep whether lying upon the back, the side, or the stomach. But light sleepers, and those with sensitive abdominal viscera, generally find that the position on the right side is the most comfortable, and less provocative of unpleasant dreams. Prolonged mental or physical strain, excitement, and worry predispose to nightmare. Farinaceous foods, excessive use of strong liquors, coffee, and tobacco, all have a similar tendency.

Nightmare occurs also in anæmia and malaria, and it may, in fine, be excited by painful sensations in any part of the body. It sometimes occurs about the menstrual period in women. Its most common feature is a sense of suffocation or impending death.

Pavor nocturnus, or night-terrors, is a sleep disorder peculiar to children. It is allied to nightmare on the one hand, and sleep-drunkenness on the other. It differs from the former condition in that the child continues to suffer from the distressing fancies for some time after he is awake. Night-terrors occur usually one or two hours after sleep has begun. The child wakes up screaming with fright, and perhaps runs about the room or seeks its parents for protection against some imagined harm.

The disorder occurs in weakly, anæmic, nervous, or rheumatic children. It is due sometimes to lithæmia, or, as the older writers put it, rheumatism or gout of the brain. Digestive disturbances, worms, dentition, hereditary syphilis, mental strain, fright, and excitement are placed among the causes. It sometimes appears to be a paroxysmal neurosis allied to epilepsy. The disorder is usually harmless, and the prognosis favorable.

Somnolentia, sleep-drunkenness, *Schlafentrunk*, is a condition of incomplete sleep in which a part of the faculties are abnormally excited, while the others are buried in repose. It is a kind of acted nightmare. The person affected is incoherent, excited, and often violent. He experiences the delusion of some impending

danger, and while under it acts of violence have been committed. The condition is one of medico-legal importance, therefore, and has been discussed by writers on that science (Wharton and Stillé). Minor degrees of it are often noticed in children, and in adults who are roused from a very profound sleep. It at times becomes a habit, and a most annoying or dangerous one. The disorder, in its severe form, is fortunately a very rare one. Some of the classical cases are the following:

A sentry, on being suddenly awakened from sleep by an officer, made a violent attack upon him with a sword, and would have killed him but for the interference of others.

A laborer who had been sound asleep was awakened by his wife. He sprang up and dealt her a fatal blow.

A woman dreamed that her little boy told her the house was on fire. She jumped up and threw him out of the window.

Although sleep-drunkenness is a phenomenon of imperfect sleep, and belongs to the states of hypohypnosis, yet it seems often to occur in those who sleep very profoundly, and is, therefore, somewhat different etiologically from the states of dreaming and nightmare.

The treatment of morbid dreams, nightmare, and pavor nocturnus must be directed to a removal of the causes. Tonics, cardiac stimulants, laxatives, anti-rheumatics, attention to diet, are called for according to the condition of the patient. Change in surroundings is often necessary. Among symptomatic remedies the bromides are the best, except in lithæmia, when alkalies and salicylates may prove more serviceable. In somnolentia the patient should be prevented from getting into too profound a sleep. He may be awakened once or twice during the night, or take a nap in the daytime. The head in sleeping should be raised high, and the body not too heavily covered.

IV. PARAHYPNOSIS. — *Somnambulism, Sleep-walking, Somnium, Hypnotism, Trance, Mesmerism.*

Somnambulism.—Some authors have regarded somnambulism as an incomplete sleep (Symonds, Hartmann, and others). Dr. Chambers thinks it is a condition of unusually profound sleep. It appears to me to be a condition peculiar to itself, and not to be classified under the heads of incomplete or too profound slumber. Hence I adopt the term for it of parahypnosis.

Somnambulism is a condition similar to hypnotism or the mesmeric state. In it volition is abolished, and the mind acts automatically under the dominance of some single idea. Sight, hearing, and nearly all the avenues of sense are closed. The sleep-walker avoids obstacles and performs ordinary acts automatically, like an absent-minded man, which in reality he is. All those mechanisms which have been trained by constant repetition to act automatically, like that which preserves equilibrium, are preserved, and their powers may even be heightened, so that the somnambulist may walk along roofs or on dangerous roads, and thread intricate passages without harm. The automatism of the somnambulist may continue for hours, until a journey has been performed or a task completed. He may carry out with success intricate mathematical calculations, write a letter, or work upon a picture, but he only follows along the lines established by constant iteration in his waking moments. He can originate nothing new. He is roused from his state with difficulty, and when out of it he remembers nothing of what has occurred.

Somnambulism usually arises, according to Chambers, from overeating. Sleeping with the head too low is another cause. Violent emotions, according to the author referred to, act only indirectly by disturbing digestion. The habit being once established, however, attacks occur without apparent cause. The disorder occurs oftenest in young people about the age of puberty, and it then attacks the sexes alike. Later in life women are more often affected. The disease is fostered sometimes at school by the attentions of the school-mates. In most cases a condition of morbid nervous sensitiveness underlies it. The patients are neurotic. Hereditary somnambulism has been observed. Its attacks have alternated with those of catalepsy. They are likely, after a time, to become periodical, occurring every week, fortnight, or month.

The somnambulic state may come upon a person in the daytime. It is then regarded as spontaneous trance, or hypnotism. It is not the case, however, that persons who are easily hypnotized are usually somnambulists, though the reverse may be true.

Somnambulism is a term that should include not only sleep-walking, but sleep-talking, and Chambers even considers that spermatorrhœa and nocturnal enuresis are disorders allied to it. In this, however, it seems to me he is mistaken.

The treatment of somnambulism is very much like that for sleep-drunkenness. The patient's surroundings must be investigated, and unfavorable influences, such as may occur at school or from injudicious nurses, be removed. He should be prevented from sleeping too soundly, the head should be raised, the clothing light, the diet regulated. Remedies like iron, quinine, phosphorus, and cod-liver oil may be given. When the patient is discovered in the somnambulistic state, he should not be awakened, or at least not until he is safely back in bed.

Hypnotism, Trance, Mesmerism.—This is a state in which phenomena allied to those of perturbed sleep are exhibited.

Definition: Hypnotism is a morbid mental state characterized by (1) perversion or suspension of consciousness; (2) abeyance of volition; (3) automatic response to commands or external sense impressions; and (4) intense concentration of the nervous force in some particular direction.

Susceptibility and Causes.—Hypnotic states are generally produced artificially by causing the patient to concentrate the attention on an object, while certain muscles, generally the eye muscles, are kept on a strain.

Young persons, the hysterical, those of sensitive nervous organization, of deficient education, and weak will-power are most subject to the state. About one in every ten or fifteen adults is susceptible to the condition. It can be produced in the lower animals. Those who have been mesmerized once are more easily affected afterward, and may even pass into the state involuntarily. Indeed, by cultivation almost anyone can train himself to enter it at will.

Symptoms.—The person who has been hypnotized at first sits or lies quietly in the position he had assumed during the manipulations of the operator. No notable physiological changes occur, as, for example, in the pulse, respiration, temperature, pupils, skin, etc. Some increase in the cerebral blood-supply, however, is said to be present. The patient will now respond automatically to any outside command, or will be dominated by any idea which is suggested to him. He will talk, or walk, or run, or gesticulate, assume expressions of fright, anger, or joy, entirely in accordance with the command given. Apart from these commands he is entirely dead to the outside world. He hears, sees, smells, tastes, and feels nothing. He can be burned, cut, or injured without showing any signs of feeling. At a suggestion he may be made cataleptic, somnambulic, or paralytic. This state is termed *somnambulistic trance.* If left to himself, he gradually sinks into a deep sleep, from which he can with difficulty be roused. After a time, rarely more than one or two hours, he awakes as from ordinary slumber. This latter state is called trance-coma, or *lethargic hypnotism.* The attempts of some French writers to divide hypnotic phenomena into three forms, the somnambulic, cataleptic, and lethargic, are hardly successful. Sensitive subjects can be thrown at once into lethargy, catalepsy, or somnambulic states, at the command of the operator.

The phenomena of hypnotism depend upon the wonderful sensitiveness and quickness of the subject in responding involuntarily, with all his nervous energy, to outside suggestion. Dishonest persons may learn the latter trick and thus simulate the hypnotic state. Travelling mesmerizers utilize such persons largely, hence no confidence can be placed in the phenomena exhibited by them.

The best method of inducing hypnotism is to hold for

five to ten minutes some bright object at a distance of six to eight inches from the eyes, and a little above the horizontal plane of vision.

Hypnotic states may be self-induced, by rigorously fixing the attention upon some object. The ecstatic states of the saints, and the nirvana of the Buddhists, are forms of hypnotism; so also are the trance states into which some clairvoyants and spiritualistic preachers place themselves; this same curious phenomenon is at the bottom of the so-called "mind-healing" science, and it enters into rational therapeutics and orthodox religion. The capacity of the human mind for hypnotism or semi-hypnotic states is, therefore, a most curious and important fact.

After a time, as already stated, subjects who have been hypnotized learn to pass into the state much more easily; even a word of command being sufficient.

The practice of hypnotizing persons is injurious to them, tending to exhaust the nervous force, and weaken the will. It should be done only with the greatest care. Its utility in therapeutics I greatly doubt. It may relieve symptoms in the hysterical for a time, but it cannot be of permanent benefit, and is likely to lead to actual harm. The popularization of mind-cures, Christian science, etc., accomplishes its results at the expense of mental demoralization, and faith-healing institutes are more pernicious elements in society than gin-mills.

Patients naturally come out of the mesmeric state through the channel of deep sleep or lethargy. Ordinarily they are dehypnotized by word of command, or by a pass of the hand, or any such impression which the patient expects to be used for the purpose.

Hypnotized persons have been observed to have a diminution in the spinal reflexes, and a muscular hyperexcitability. They sometimes show a most extraordinary exaltation of visual, auditory, or other special sense. The statements of Luys and other French observers, that they are sometimes susceptible to the action of medicines at a distance, enclosed in sealed vials, can hardly be credited. The alleged phenomena must be explained at present on the theory of unconscious suggestion.

Something may be properly said here regarding the physiology of the hypnotic state.

Physiology.—1. There exists in each of us what the philosopher Locke well described as a "power to begin or forbear, continue or end the several actions of our minds and motions of our bodies, barely by a thought or preference of the mind." This power is called the Will. It is not thought by modern psychologists, or even by all of the older schools, to be a separate and distinct force enthroned within us. Exactly what it is, however, is a question that we need not enter upon now. We do know that every man can check, regulate, or set in action, such muscular movements, or such trains of thought as he wishes. One can understand that if this power were taken from us, it would materially limit our physical and mental being. We should be very much like machines, acting only, or chiefly, under certain stimuli applied from without. Our actions would then be essentially reflex in character. The reflexes would differ much in complexity, however, and they may be roughly divided into three classes:

(*a*) The first embraces the simple reflex actions, which are processes belonging pre-eminently to the spinal cord and medulla.

(*b*) The second class embraces higher centres and more complex activities. Human beings all possess more or less of certain dexterities, such as riding, walking, the playing on musical instruments, etc. There are a few of these, such as suckling, which are possessed even at the time of birth. But the most are acquired by practice. Whatever their kind, the individual goes through the various complicated movements pertaining to them, for the most part unconsciously. Thus, a person can walk, or dance, or play, and be entirely unconscious of expending any voluntary effort. We characterize these acquired and these inborn dexterities as automatic; and such, indeed, they are, using the term automatic in perhaps a rather loose sense. They are machine-like in character. Once being started they go on as a clock does when it is wound up. And we suppose that the particular place where this machinery is located is in the lower ganglia and hinder part of the brain. The cells and connecting fibres in these ganglia have become arranged into definite groups, each corresponding with and governing certain classes of muscular movements. All that is needed to set or keep these groups at work is the proper stimulus or successive stimuli; they then go on discharging efferent impulses, and producing the definite motor results.

We have an example of this in the inception and continuance of an ordinary walk, or in playing a well-known piece of music. It is a case like that of setting a machine going by the turning of a key. The brain's co-ordinating mechanism is generally set in motion at first by conscious impulses from the higher brain-centres, themselves roused by the visual sense. But after a time it may also be stimulated by afferent impulses that do not rise to consciousness. When the impulses go to and fro without exciting consciousness, we suppose that they do not pass up to the cortex at all, and that only the lower ganglia are active. The reflexes are genuine, but more complicated than those of the spinal cord. We may class them as reflexes of the second order, or of the middle projection system.

(*c*) There is still a third and higher system of reflexes. Thus, a person sees an object which excites in him emotions of fear, or hears a suggestion which excites an idea, and which in turn excites the desire to cry out. In the former case we trace the afferent impulse along the optic nerves to the part of the brain concerned in sensation and ideation, and that process of linking the two which is called perception. From these higher centres efferent impulses start down to the facial or other muscles, and the expression of fear is seen upon the countenance.

In the second case the process is a similar one. The afferent impulses give rise to a sensation which links itself to the previously impressed sensations (now become ideas), and a train of thought is aroused. After travelling through this ill-understood nexus between the afferent and efferent impulses, the latter excite the organs of speech.

In these various processes there is normally almost always a consciousness of the changes that are going on. The changes include sensation, perception, ideation, and what is known as volition.

Again, here, as in the second class of reflexes, the afferent impulse need not be constantly acting. It may start the machinery of ideation, which will then continue to act and send out more or less of expressive efferent impulses. Thus, a single frightful sight may give rise to prolonged feelings of terror, which in turn are expressed through various efferent channels for a long while.

In the *first class* of reflexes, consciousness and volition never enter.

In the *second class*, consciousness and volition may attend the inception of the process, but not necessarily, or generally, the rest of it.

In the *third class*, consciousness is always, in normal conditions, present, and acts of volition generally modify the play of afferent and efferent impulses.

In hypnotic conditions the mental state is made up entirely of the reflex phenomena described above, entirely undisturbed by volitional interference.

2. The nervous system is a mechanism for liberating, and at the same time co-ordinating and regulating, the various special energies or functions of the body. That it may do this more perfectly, and perhaps for other reasons, the brain, with its highly complicated powers, is developed. This nervous system seems capable of bringing into activity (or making kinetic) a certain amount of energy, which is normally distributed throughout the nervous system, more or less equally. Thus, it can at once move muscles, and can keep all the special senses and the mind itself moderately active. We can walk about, can see, hear, feel, and think at nearly the same moment. But it cannot make any of the special functions of the body particularly active, it cannot lib-

erate nervous energy largely in one particular direction without the other parts suffering. While watching intently, we cannot feel, or taste, or hear with any great degree of perfection. While reflecting deeply, the special senses are somewhat dulled. If the nervous system is busy in sending out powerful or delicately adjusted motor impulses, its other duties are somewhat neglected. I am only expressing, in physiological language, the very commonplace fact that we can only do one thing well at a time. And, furthermore, that we have the power, by exercise of our will, of directing the nervous energies almost exclusively in one or two directions. That is to say, we have the power of concentrating the attention and our muscular movements.

Now, this mobility, so to speak, of the nervous or mental energies, this capacity of being turned into one channel and acting very powerfully there, is most conspicuously brought out in the phenomena of trance. It is a leading characteristic of the state, as was shown by Dr. George M. Beard.

Morbid Anatomy.—The underlying changes of the hypnotic condition are unknown, and will probably long remain so. Hypnotism is no doubt associated with changes in the vascularity of different parts of the brain, and with rapid breaking down of nerve tissue. Animals constantly subjected to hypnotic influence become demented (Harting, Milne-Edwards).

Diagnosis.—As hypnotic states may be imitated, and as injuries or crimes may be done during this state, it is very important to be able accurately to distinguish it. Since the phenomena are all subjective, this is very difficult. The methods of value are these: 1. Careful examination of the general phenomena by experts while the subject is in the alleged hypnotic state. 2. Testing the muscular hyperexcitability by percussing motor points. 3. Tests of alleged anæsthesia by sudden burning, or pinching, or injuring the subject. 4. Tests of the tetanic muscular rigidity by the revolving tambour. In the hypnotic state the hand may be extended and held with perfect steadiness, while in conscious states a tremor soon appears. 5. Tests with glasses and other apparatus may be made to determine alleged anæsthesiæ of the special senses.

V. The Hyperhypnoses.—*Drowsiness, Morbidly Prolonged or Profound Sleep, Narcolepsy, Abnormal Attacks of Sleep, Lethargy, Coma, Carus, Cataphora, the Sleeping Sickness.*—Persons may be subject to sensations of drowsiness which continue with them nearly the whole of the day, or come on at certain times during the day.

Other persons sleep too profoundly, or too long.

Again, certain individuals are attacked suddenly with a desire to sleep, which they cannot resist. These paroxysms come and go like epileptic seizures, and they may even take the place of such seizures. Sometimes these paroxysms simply affect the sleep at night. The person goes to bed, but can with difficulty be awakened the next day, and if left unmolested, he sleeps till noon or later. Such phenomena may be repeated for several successive days.

Finally, cases occur in which persons pass into a state of apparent sleep, which lasts for weeks or months.

These different states will be discussed under the heads of:

1. Morbid drowsiness.
2. Morbidly deep sleep.
3. Paroxysmal somnolence, narcolepsy, and epileptic somnolence.
4. Hysterical or trance sleep.
5. We have besides, symptomatic morbid somnolence, from organic brain disease, including the sleeping sickness of Africa.

1. *Morbid Drowsiness.*—This is a very common symptom, which may be due to any one of the following causes: 1. Old age, when there is a weakened heart or diseased arteries, with cerebral mal-nutrition. 2. The diseased vascular conditions which precede cerebral hæmorrhage. 3. The cerebral mal-nutrition or inflammations occurring before or during certain forms of insanity. 4. Various toxæmiæ, *e.g.*, malarial, uræmic, cholæmic, and syphilitic. 5. Dyspepsia and gastric repletion. 6. Diabetes. 7. Obesity. 8. Insolation. 9. Cerebral anæmia and hyperæmia. 10. Exhausting diseases. 11. Concussion of the brain. 12. Climatic conditions, cold, etc.

A very common cause of drowsiness is dyspepsia attended with some torpidity of the liver, the condition popularly known as "biliousness." Another frequent cause is malarial infection, which perhaps acts indirectly by impairing the functional activity of the liver.

Drowsiness from these causes oftenest comes on in the afternoon.

Anæmia is attended with drowsiness during the day, while there is often insomnia at night.

Syphilis is more likely to cause insomnia, but in its third stage somnolent conditions may be produced which are of serious significance.

Drowsiness occurs from the effects of severe cold. It sometimes develops when persons change their surroundings, especially on going to the seashore, for low levels and a high degree of atmospheric pressure seem to promote sleep. The drowsy state that sometimes follows concussion of the brain is a familiar phenomenon.

Some persons, no doubt, acquire the habit of drowsiness. At first the trouble may have been induced by indigestion, "biliousness," or malarial infection, but it persists after the cause is removed. Such persons can hardly sit through a lecture, a church service, or any exercise requiring quiet and attention. As the morbid drowsiness here described is only symptomatic, its treatment need not be discussed. Such remedies as coca, coffee, tea, atropia, glonoin, do not produce results equal to expectations.

2. *Morbidly Deep Sleep.*—Certain persons, when they sleep, pass into an almost lethargic slumber. In this state the spinal centres do not appear to share, but are abnormally excitable, from the lessening of cerebral inhibition. Consequently emissions occur, or there is nocturnal enuresis. As we have already stated, it is believed by some that sleep-drunkenness and even somnambulism occur in those states of morbidly deep sleep. Persons who sleep in this way often sleep a longer time than normal. They are awakened with difficulty, and then suffer with headache or disagreeable sensations throughout the day.

This disorder of sleep is most liable to occur in the young and in those of nervous temperament. It often seems to be a congenital condition, for which nothing can be done. In other cases it results from over-feeding and indolent habits. Treatment is much the same as that indicated for sleep-drunkenness and somnambulism.

The following case, described to me by Dr. Sibert, of South Hill, Ala., illustrates this type: A married woman, aged twenty-eight, of good family history and in good health, except for some anæmia from lactation, had suffered from excessive sleep since six years previously, when she was first confined. The hyperhypnotic state was manifested only during the night, and only as a profound slumber, from which it was exceedingly difficult, even by the roughest handling and the infliction of pain, to arouse her. There was no history of vascular, digestive, or cerebral disorder. It was thought that the condition was due to cerebral anæmia, induced by protracted nursing, but the difficulty was not worse during lactation than it was during the intervals. She improved after weaning her child, under blood and nerve tonics.

Instances in which persons retire at the usual hour, but can with great difficulty be roused in time for the ordinary duties of the day, are not rare. Some of these are illustrations of the vice of indolence, but in other cases there is an absolute need of nine, ten, or even fourteen hours of sleep. Here is a case in point: A young officer, otherwise healthy, could not possibly get along without fourteen hours of sleep. He slept until noon every day and lost his commission in consequence (Quoted by T. More Madden: *Dublin Journal of Medical Sciences*).

Some cases of this kind, it should be remembered, are prodromal of insanity.

3. *Paroxysmal Sleep, Narcolepsy, Sleep-epilepsy.*—It sometimes happens that persons suffer from sudden at-

tacks of unconquerable drowsiness; they fall off into slumber despite every effort of the will. These are more than drowsy sensations, for sleep, or a state resembling it, cannot be kept off. Some of these cases are of a purely nervous character, *i.e.*, the trouble is not due to a humoral poison or to organic disease, but to a paroxysmal change in the nervous centres, of a vascular or chemical character, causing sleep. It may be that the patient is epileptic and the sleep-seizure takes the place of the ordinary epileptic spasms. An illustration of this is the following:

The patient was about twenty years of age, and had been subjected for a couple of years to attacks of falling asleep for a few minutes in any position, often while standing, and when not tired. There did not appear to be anything pathological about them except their occurrence when the patient was not tired. She married at about the age of twenty-two or twenty-three years, and then began to suffer from infrequent, well-marked epileptic attacks. Her brother subsequently was found to be also suffering from epilepsy. The patient herself appeared to be entirely healthy in all other respects (L. Putzel).

Other cases are illustrations of a pure sleep neurosis or narcolepsy, as described by Gelineau. A case in point is the following:

The patient was a man aged thirty-eight. Family and early personal history good. No syphilis. Married, and had two children. Moderate drinker. Had had acute articular rheumatism. Three years ago had a fight and a fall. Two years ago his symptoms began. He would fall asleep whenever he undertook to eat, walk, or go to the theatre. Anything particularly exciting his attention would throw him into a sleep. He would sleep a little, then wake. He had one or two attacks daily, accompanied by dizziness. He often had attacks of dizziness. Intelligence, memory, and consciousness were not lost during the attacks (Gelineau: *Gazette des Hôp.*, July 8, 1880).

While Gelineau's case might have had something of a hysterical or mesmeric element, the following is quite free from such causes. It was apparently neurasthenic in origin:

The patient was a physician who had suffered from this condition for fifteen years. He was habitually overcome by an uncontrollable desire to sleep during the daytime, no matter how *mal apropos* the time or place; this desire he would fight against with all his power of control, but would finally yield to sopor. Even in the dentist's chair, while a sensitive tooth was being "scraped," he had fallen asleep. Often in the rounds of daily practice he would feel this lethargy creeping over him at critical moments, as, for instance, when his services were most needed at confinements, and would be forced to yield to it and sleep. It was impossible, for the same reason, for him to read for but a short time, and he had been obliged to abandon study and mental work entirely. He had other symptoms of brain exhaustion, such as forgetfulness, frontal headache, etc. There was no evidence of organic disease (W. J. Morton).

Cases of epileptic sleep, narcolepsy, and allied forms are not of frequent occurrence. Females are rather more often affected than males, and the susceptible age is from fifteen to forty. The disorder is brought on sometimes by fright, over-strain, and humoral poisons acting on a predisposed nervous system.

The course is chronic, and relief is not always obtained. It should be remembered that syphilis, malaria, or anæmia, and indigestion may be elements in the trouble which are important, if not fundamental. Bromides are often useful factors in treatment. Change of occupation, of mode of life, or of climate, may be essential to a cure.

4. *Hysterical, Cataleptic, or Trance Sleep, Lethargy.*—Most of the so-called cases of prolonged sleep, lasting for days or weeks, are cases of spontaneously developed mesmeric sleep in hysterical women, or cases of incipient insanity (katatonia or stuporous melancholia). The phenomena in these cases may take almost any of the forms of the mesmeric condition. The patient may be cataleptic, or lethargic, or in a somnambulic condition. The mental state is essentially the same as that in hypnotism, and, though reported as cases of prolonged somnolence, as sleeping girls, etc., these really are to be classed among the parahypnotic.

The subjects of trance sleep are mostly women. Among 26 cases collected by myself, the males were 5; females, 21. The age ranged from sixteen to thirty-two.

Trance sleep shows itself in several ways:

Thus there is a set of cases of trance lethargy so-called, in which the patients are plunged into a deep and prolonged unconsciousness, lasting from one day to several years. These are "sleeping girls," and fasting girls.

Another class includes those who apparently are the victims of a too ready susceptibility to mesmeric suggestion, or who get into a morbid habit of going into mesmeric sleep spontaneously.

A third class includes the patients who suffer from somnolence or drowsiness in other irregular forms. These patients are evidently hysterical, but their somnolent symptoms appear in peculiar ways.

In these states there may be a lowering of bodily temperature, slowing of respiratory and heart action, and excessive sluggishness of the action of the bowels. The patients can hear and may respond to suggestions, but they are apparently insensible to painful impressions, and do not appear to smell, taste, hear, or see. The eyes are closed and turned upward, and the pupils contracted as in normal sleep. Many variations, however, occur in the physiological phenomena of these states.

The duration of the attacks of trance lethargy is from a few hours to ten years (case of sleeping girl of Trouville, *Lancet*, June, 1881). Ordinarily, however, profound trance sleep lasts not more than a few days, while those cases in which the sleep is from mesmeric suggestion last but a few hours.

Cases illustrating the above types are here given:

Case I.—A woman, aged twenty-four, large, well formed. At the age of eighteen she fell into a trance sleep lasting forty days; at the age of twenty another attack lasted fifty days. All the latter time she was insensible, could not be roused, and had to be fed. When twenty-eight years old she fell into another lethargy, which lasted several months. The respiration was very shallow, pulse slow, organic life at a low ebb (M. Blondet: *Gaz. hebdomadaire*, October 28, 1864, p. 726).

Case II.—A young lady, aged seventeen, while in church was suddenly seized with a desire to sleep. She went home, went to bed, and slept three days. No catalepsy. She awoke, was well for a month; then went into a sleep again (Lasègue: *Gaz. des Hôp.*, January 3, 1882).

Case III.—Mrs. M., aged thirty-two, mother of six children, of good family and personal history. Had had no symptoms of hysteria. Six weeks after confinement she suddenly fell into a trance sleep, which lasted for several months. Reflexes were not quite abolished at first, and she could then swallow food. Later she had to be fed. She slept within her trance, *i.e.*, at night she would snore. No cataleptic or other rigidity. She had some color (W. T. Gairdner: *Lancet*, December 22, 1883; January 5 and 12, 1884).

Case IV.—Lasègue cites the case of a young lady who used to fall asleep at 8 P.M. precisely, no matter what she did or how much she slept at other times; also the case of a Belgian countess, who for two years fell asleep daily at 9 P.M., no matter what she was doing.

Under this head of mesmeric sleep, I would refer to the curious facts of sleep following some mechanical irritation. I have known a young man who would fall into apparent sleep whenever a cleansing solution was thrown into his antrum. Dentists can relate many instances of unconquerable somnolence in patients on whom they are operating by no ordinary soporific methods.

5. *Morbid Sleep from Organic Disease.*—Prolonged and excessive sleep occurs as the result of syphilis of the brain, brain tumors, and the degenerative changes in old

age and insanity. Morbid somnolence and stupor are not very frequent in cerebral syphilis, but are quite characteristic. The patient in some cases lies or sits all day in a semi-soporous state; in other cases he walks about, but continually falls asleep at his task. This state of partial sleep may pass off or end in complete stupor (Wood). It does not necessarily signify a serious issue, even though it last for weeks.

Somnolence or sleep is a rare symptom in cases of cerebral tumors other than syphilitic. Conditions of drowsiness or stupor have been noted especially in tumors of the corpora quadrigemina, and the parietal lobes (Putnam-Jacobi).

Organic diseases of the brain tend to produce conditions of mental weakness, hebetude, or comatose states, rather than anything allied to sleep.

The Sleeping Sickness, Sleeping Dropsy, Maladie du Sommeil.—This is a peculiar disorder apparently infectious in character, which occurs among the negroes of the western coast of Africa. The disease has been transported to other regions, but is endemic only in Africa. It begins gradually with some headache and malaise. Soon there is felt a drowsiness after meals. This increases until the patient lies for nearly the whole time in a stupor. When awake he is dull and apathetic. There seems to be no fever, and the temperature may even be subnormal; the pulse, too, is not rapid; the skin is dry, the tongue moist but coated, the bowels regular. The eyes become congested and prominent. The cervical glands are enlarged. The disease ends in coma, and finally death. Recovery rarely occurs. Sometimes the course of the disease is more violent, and toward the end there are epileptic convulsions and muscular tremors. Autopsies have revealed no definite pathological changes. The history of the disease has been given by Clark, "Trans. of London Epidemiolog. Society;" Guérin, De la Maladie du Sommeil, 1869.

Accidents of Sleep.—Owing to the fact that sleep is a resting state of the organism, and that many of its functions are lowered, or their cerebral control lessened, peculiar crises, or physiological and pathological disturbances of nervous equilibrium occur. Attacks of gout, of asthma, and of pulmonary hæmorrhage are most liable to occur during the early morning hours. Deaths and suicides occur oftener in the forenoon, but births oftener at night. Epileptic and eclamptic attacks occur with much frequency at night. Involuntary emissions of spermatic fluid, orgasmic crises, incontinence of urine, are among the pathological incidents of sleep.

SMALL-POX. Synonyms: Latin, Variola; French, Petite vérole; German, Pocken.

Definition.—Small-pox is an acute febrile, eruptive, contagious disease, the product of a specific poison in the blood of a patient suffering from this malady. It is generated solely by means of a specific virus, and is communicated by this virus from one individual to another after direct or indirect contact. The exanthem of small pox passes through four stages, namely, papule, vesicle, pustule, and scab, and usually leaves the face permanently scarred. The disease runs a definite course, and cannot be cut short by medicines. One attack of variola usually destroys the susceptibility of the individual to the disease during the remainder of his life.

History.—Small-pox, by reason of the malignant nature of the poison, and the general susceptibility to it of individuals of all ages, races, classes, and conditions, is the most loathsome and fatal disease known to man. It is a very ancient malady, though its origin is unknown. It is no part of the purpose of this treatise to enter into an exhaustive examination of the question as to when variola first appeared among mankind. De Haen, Willan, Moore, and Barron, contend that it was known to the ancient Greeks and Romans; while, on the other hand, Friend, Mead, Good, and Adams, insist that the ancient Greeks and Romans were unacquainted with it. Rhazes, an Arabian physician, who practised medicine about the year 910 A. D., was one of the most celebrated of the earlier writers on small-pox. The natural history of the disease was delineated by him with remarkable perspicuity when we consider the date of his writings and the status of medical knowledge at that time. Rhazes contends that Galen was familiar with variola, and quotes extracts from his first, fourth, ninth, and fourteenth books as evidence of the fact. He says: "As to any physician who says that the excellent Galen has made no mention of the small-pox, and was entirely ignorant of this disease, surely he must be one of those who have either never read his works at all, or who have passed them over very cursorily." Rhazes mentions Ahrun of Alexandria, and Mesue of Bagdad, among other previous writers on small-pox. Variola cannot be positively traced to a period anterior to the Christian era. Since its first appearance among mankind small-pox has never disappeared, and from Europe and Asia has been carried to the uttermost parts of the inhabited world. Small-pox existed in England in the first part of the thirteenth century, and in Germany in the latter part of the fifteenth century. From Europe the disease was brought to the United States soon after the discovery of America. It appeared in Mexico in 1527. Wherever it has existed it has been the greatest scourge of mankind. For centuries prior to Jenner's discovery of vaccination in 1798, small-pox had been regarded as the king of fatal diseases. M. de La Condamine says that small-pox was the cause of one-tenth of all the deaths among the human race. He further says: "Among those who outlive it many either totally or partially lose their sight or hearing; many are left consumptive, weakly, sickly, or maimed; many are disfigured for life by horrid scars, and become shocking objects to those who approach them. Immense numbers lose their eyesight by it." Half a million deaths were annually caused in Europe from small-pox prior to the discovery of vaccination. Macaulay, in speaking of small-pox in England, says: "The havoc of the plague had been far more rapid, but the plague visited our shores only one or twice within living memory, but the small-pox was always present, filling the church-yards with corpses, leaving on those whose lives it spares the hideous traces of its power, turning the babe into a changeling at which the mother shuddered, and making the eyes and cheeks of the betrothed maiden objects of horror to her lover."

Rosen says that in Sweden one-tenth of all the deaths

were from small-pox. We are assured that this disease concurred with fire and sword, and famine and blood-hounds, to complete the depopulation of Santo Domingo.

In the sixteenth century small-pox fell upon Mexico, and in a few years three million five hundred thousand of the population yielded up their lives to it, leaving in some places scarcely enough people alive to bury the dead. Brazil, in 1653, was invaded by small-pox, and in some instances whole races of men were carried to their graves by it. The Province of Quito, in a few years, lost one hundred thousand of her Indian population by this one disease. In 1707 Iceland was invaded by small-pox, and desolation and ruin followed in its wake for years, causing in that year the death of eighteen thousand out of a total population of fifty thousand. The fearful fatality of the disease is evidenced by the following extract: "In one island they found one girl, with the small-pox on her, and her three little brothers; the father having first buried all the people in the place, had laid himself and his smallest sick child in the grave, raised with stones, and ordered the girl to cover him." Greenland, in 1734, lost more than two-thirds of her population by small-pox. We are told, also, that one-sixth part of the inhabitants of Ceylon died of small-pox during one epidemic. Siberia has an equally lamentable history, and Kamschatka has also suffered severely from this terrible disease. One-tenth of all deaths in France, prior to the discovery of vaccination, were from small-pox. This country has been most cruelly and fearfully scourged by small-pox, the details of which must be too well known to need repetition here; whole tribes of our Indian population were swept out of existence by it. Europe, in the century preceding the discovery of vaccination, lost in deaths from small-pox 50,000,000 of her population. But it is unnecessary to continue the recital of such details. Enough has been presented to justify Macaulay in calling small-pox "the most terrible of all the ministers of death." Whenever and wherever it appeared in the past, in a community unprotected by vaccination, it was, as so well described by Alexander McKenzie, "as a fire consuming the dry grass of the field. The infection spread with a rapidity which no flight could escape, and with a fatal effect which nothing could resist." This disease had but one feature which was not repulsive; that one was that it was no respecter of persons. Reaching to the royal throne of France it laid Louis XV. in the grave. In Mexico it treated the Emperor similarly. In England it invaded the household of William III., killed his wife Mary and several others of his family, and would not leave the palace until it had attacked the king and maimed and disfigured him for life. The hovel of poverty was in this respect the equal of the palace of wealth, for small-pox was the terror of every household.

Long-suffering mankind eventually became hopeless of escape from the dread monster. When civilized man was thus hopeless, need we wonder that the untutored savage despaired also? McKenzie says of the Indians: "It was not uncommon for the father of a family whom the infection had not reached, to call them around him, to represent the cruel sufferings and horrid fate of their relations, from the influence of some evil spirit who was preparing to extirpate their race, and to incite them to baffle death, with all its horrors, by their own poniards. At the same time, if their hearts failed them in this necessary act, he was himself ready to perform the deed of mercy with his own hand, as the last act of affection, and instantly to follow them to the common place of rest and refuge from human evil."

After centuries of havoc from small-pox variolous inoculation was introduced, and the mortality was in consequence greatly lessened.

Inoculation.—In no field of human research can a more curious phenomenon be found than is shown here. That a man should be compelled to take small-pox in order to save his live is surprising indeed, but such was the intention, and the wonderful reduction of mortality among the individuals so treated fully testified to the propriety of the measure. Inoculation is the placing of the virus of small-pox, by puncture, under the skin, in the blood of the subject inoculated. The purpose of inoculation was to produce a modified form of small-pox which would afterward confer upon the subject so treated exemption from a malignant attack. This weapon is of great antiquity. Kirkpatrick says of it, "Some poor, unlearned, but heaven-taught mortal, some Chinese, Hindoo, or Circassian, first hit upon it." It is admitted to have been practised for a long but unknown number of years in Hindoostan. The Chinese had for hundreds of years used crusts or scabs of small-pox, placed in the nose, for the purpose of inoculation. Of inoculation, in 1717, the wife of the English Ambassador to the court of Turkey, writing to her home, says, "The small-pox, so fatal and general among us, is here entirely harmless by the intervention of engrafting, which is the term they give it. Every year thousands undergo the operation, and the French Ambassador says pleasantly, that they take the small-pox here by way of diversion, as they take the waters in other countries. There is no example of any one who has died of it." Dr. Simon says of this measure, "to the present time it remains one of the most interesting and least explained facts of pathology that the specific contagion or ferment of small-pox, so uncontrollable in its operations when it enters a man in the ordinary way of his breathing an infected atmosphere, becomes for the most part disarmed of its virulence when it is artificially introduced into the system through a puncture of the skin." By resort to inoculation the mortality among those so treated was reduced from one death in every three cases of natural small-pox, to one death in every three hundred cases of inoculated small-pox. Some authorities give the protective powers of inoculation as representing one death in every one thousand cases. Thus it will be seen that the practice of inoculation offered to the individual, doomed to take small-pox, a far greater security against death than any measure in use prior to the introduction of vaccination. While the security against death to the individual in whom small-pox was inevitable was most wonderfully augmented by inoculation, yet to the country at large the practice of variolous inoculation was a curse instead of a blessing—for inoculated small-pox lost none of its fatal power of conveying malignant variola to all unprotected persons. The Royal College of Physicians of London, in 1807 (report on vaccination) says, "However beneficial the inoculation of small-pox may have been to individuals, it appears to have kept up a constant source of contagion, which has been the means of increasing the number of deaths by what is called the natural disease." Dr. Heberden says that, in the first thirty years of the eighteenth century, before inoculation became general, the deaths from small-pox to every 1,000 deaths were 74; for an equal period during the general practice of inoculation, at the end of the eighteenth century, the deaths from small-pox were 95 to 1,000 deaths—an increase in the proportion of 5 to 4. After the discovery of vaccination, it being so much superior to inoculation, the latter practice was made unlawful.

Vaccination.—Of this weapon of defense against small-pox, Simon, after speaking of the mysterious effects of inoculation, says of vaccination: "Equally strange and inexplicable is the further and greater change which this ferment undergoes in passing through the textures of a cow; a change which renders it incapable, when retransplanted to the human system, of any longer propagating itself by effluvia, while it retains its capability of propagation by inoculation, and its power of protecting the system against its own further action thereon."

Vaccination differs entirely in purpose and value from inoculation. The objects of vaccination are: 1, Prevention of small-pox; 2, control of that disease when prevention is not obtained. As already seen, the only purpose or value of variolous inoculation was the mitigation of the severity of small-pox in the subject inoculated.

Vaccination will be briefly considered in the latter part of this treatise.

Etiology.—Small-pox is disseminated by breathing an atmosphere infected with the virus, by contact with an

infected person, clothing, bedding, etc., or by direct inoculation of an unprotected individual. It is a disease *sui generis,* and can be propagated solely by its own specific virus. The poison of variola resides in the exanthem, the breath, and the exhalations of the body. Attempts to produce the disease by vaccinations with the blood and secretions from the body of a small-pox patient have resulted negatively. Variola is transmissible by inoculation with the contents of the pustule; but the pus of a small-pox pustule may be rubbed on the skin of an unvaccinated person without producing the disease, unless the skin has been abraded. If, however, the matter from the pustule be brought in contact with the mucous membrane, variola will almost certainly be contracted. The disease may be transmitted to persons who have never been in immediate contact with small-pox patients or with infected materials. Competent observers claim that the disease may be disseminated over a city through the medium of the atmosphere. I have never observed any fact tending to confirm this statement. Cases are recorded in which the disease has been contracted when individuals have never approached nearer than within three feet of the small-pox patient in the open air. The virus of variola is tenacious of life; it is not always killed by the process of drying, and when protected from the atmosphere has been known to retain its vitality for years. The poison clings to clothing, bedding, etc., and will remain active for a long time in these articles if they are not chemically disinfected or exposed to the disinfectant power of the atmosphere. The disease is therefore portable. The virus of small-pox enters the system by absorption through the mucous membrane of the respiratory tract. The effect of the poison of variola, as to the lightness or severity of symptoms, varies with the constitutional condition or degree of susceptibility of the individual. If an unvaccinated person be exposed to varioloid he may contract malignant small-pox, and, on the other hand, an individual who has never been vaccinated may be exposed to malignant variola and only take varioloid. This inequality of individual predisposition has been observed from the earliest period of the written history of the disease. A small fraction of mankind seems to be wholly insusceptible to small-pox. Every practitioner of experience has met with occasional instances in which unvaccinated individuals have been repeatedly exposed to variola and yet failed to take it. I have known two physicians who could never be successfully vaccinated, notwithstanding repeated efforts to inoculate them with vaccinia. These physicians have on several occasions attended cases of small-pox and failed to take the disease. These instances of individual insusceptibility to vaccinia and variola are among the rare experiences of medical practice, and only serve to illustrate occasional exceptions to the rule of well-nigh universal susceptibility of the human race to both diseases. Some few individuals evidence a remarkable susceptibility to small-pox. While in the vast majority of persons one attack of the disease is fully protective against a second one, yet there are some few who have had several attacks of variola. Well-authenticated cases have been recorded in which individuals have had as many as four attacks of small-pox. I have seen only four cases of second attacks of variola, two of which proved fatal. In the latter instances a long number of years intervened between the invasions, but in each person the face was badly "pock-marked" by the first attack. As a general rule, a subsequent attack of variola in the same individual runs a mild course, though in some instances it is more malignant than the first one.

A successful vaccination generally protects the individual against small-pox during life, though the exceptions to this rule are numerous, and therefore revaccination should be universally practised. If a person has been successfully vaccinated in infancy or childhood, revaccination should be practised at puberty. Nothing definite is known as to the exact nature of the small-pox poison. Much speculation has been indulged in by the pathologists on this point, but every investigator has failed to solve the problem. Cohnheim and Weigert claimed that the micrococci in the vesicles are the specific contagious elements of variola. We have no satisfactory proof that either vegetable germs or bacteria constitute the essential elements of the disease. Much difference of opinion exists among practitioners as to the earliest time at which a small-pox patient can infect an unprotected person. Many believe that the poison is given off during the primary fever; others that it becomes active during the suppurative period, and this opinion is generally entertained by the profession; there are, however, a few practitioners who claim that it occurs at the period of desiccation.

Morbid Anatomy.—The description of the lesions of small-pox by Loomis ("Practical Medicine") is of such excellence that I have taken the liberty of quoting it entire in this section: "Besides those anatomical lesions which occur upon the mucous membranes and skin, there is more or less intense congestion of the lungs, brain, liver, spleen, and kidneys. In the hæmorrhagic form of small-pox small hæmorrhages occur in nearly all the viscera, with ecchymoses in the serous membranes, and blood-stained fluid in the serous cavities. The mucous membrane of the stomach and rectum is oftenest the seat of these extravasations.

"The characteristic anatomical lesion of small-pox is to be found upon the mucous membranes and upon the skin. This lesion is usually spoken of as the eruption. It does not differ essentially in the different varieties; the modifications which are met with are due rather to its duration and the order of its development. These surface lesions pass through regular stages of development and decline.

"The first step in the formation of a small-pox pustule is congestion of the skin in discrete spots; the vessels of the corium are dilated and tortuous, and the connective tissue of the papillæ, in the centre of the congested zone, shows more or less œdema. The non-elevated red spot (looking at first like a flea-bite) is a macule. Next, the skin is elevated at these (macular) points and a papule forms, from changes in the cells of the rete Malpighii. Soon the papule becomes a vesicle; in its centre the epidermis becomes distended with serum and cells. As the effusion increases the cells change; the horny layer above is raised, and the summit of the papule becomes the centre of the vesicle. The changed cell elements are pressed, separated, and massed into groups from pressure of the effusion, and a stringy meshwork is formed in the vesicle. Meanwhile proliferation of the adjoining cells forms a peripheral wall for the vesicle, the contents of which soon become turbid.

"Umbilication of the vesicles now occurs. Trabeculæ slowly spread from roof to floor of the vesicle, and hold down its centre, while marginal cell-proliferation and the accumulation of serum bulge out its periphery. After the vesicles are fully formed, pus-cells appear in them, and, as a result, the vesicles change in color, and become pustules. At the same time an inflammatory process, more or less extensive, is going on in the walls of the pustule, and in the surrounding cellular tissue, which terminates in a destruction of tissue at the point where the papillary congestion first occurred. If only the superficial layer of the skin is involved, the infiltration of pus-cells into the vesicle and the formation of the pustule may take place without extension of the inflammation into the cellular tissue beneath, and necrosis or death of the part will not follow; but if the inflammation extends into the deeper tissues, a slough will be produced, which necessarily will be followed by a cicatrix and pitting. After the pustule is formed the inflammatory products begin to dry down, and a crust is formed which contracts in the central portion, and the same umbilicated appearance is presented that is seen in the umbilicated vesicle. The incrustation begins at the centre. The crusts are made up of dried pus-cells and detritus. After a time these crusts are separated by the ordinary changes which occur in the subsidence of an inflammatory process, and recovery is complete, except that there is left behind a cicatrix like that formed under any other circumstances. These pustules may be formed upon any mu-

Small-Pox.

cous membrane. They occur oftenest in the nose, mouth, trachea, bronchial tubes, and larynx.

"There is nothing specific or essentially different in the development of the pustules in hæmorrhagic small-pox, except that they contain blood instead of serum or pus. In the hæmorrhagic variety larger or smaller hæmorrhages take place into the cellular tissues and into the cutis; in the milder forms they take place only in the layer beneath the papillæ, while in the severer forms they take place beneath all the cutaneous layers; even the subcutaneous fat may be infiltrated with blood. No changes in the walls of the vessels have as yet been discovered which will account for these hæmorrhages. These extravasations most frequently occur in those cases in which death takes place before the period of pustulation is reached. In hæmorrhagic variola blood extravasations occur into the substance of all the organs, the marrow of the bones, and on mucous and serous surfaces, and infarctions in the lungs are the rule. Hyperæmia and œdema of the brain sometimes occur."

Symptoms and Course.—During the period of incubation, which is ordinarily nine days in inoculated small-pox, and fourteen days in the non-inoculated variety, the health of the patient is about as usual.

The first stage of variola is ushered in with a chill, high fever, severe head-ache, and intense pain in the lumbar and sacral regions. The chill is more violent than is witnessed in any other eruptive disease. The temperature reaches 102° F. to 103° F. on the first day; on the second day 104° F., and on the third day the thermometer may indicate 106° F. With the elevation of temperature the pulse becomes full and frequent, beating from 120 to 140 or 160 per minute. The patient complains of nausea, vomiting, sore throat, and photophobia. The high fever and severe constitutional disturbance cause great restlessness and occasionally delirium. Convulsions not infrequently occur in children. The face is flushed, the conjunctivæ are congested, and the carotid arteries throb violently. By the end of the second day redness and swelling of the tonsils and soft palate are observed. The redness and swelling may extend into the larynx, when hoarseness with stridulous cough occurs. The initial fever and the constitutional perturbation reach their greatest height by the end of the third day, when the eruption begins to show itself. The prodromal symptoms are usually very severe, but the intensity of the initial symptoms is not always indicative of the severity of the attack, for it is occasionally observed that the prodromal symptoms of mild cases are of considerable violence. During this period in the history of the disease there are no symptoms present by which a diagnosis of variola may be positively made, for there are no characteristic affections of the mucous surfaces in the prodromal stage of variola, such as may be detected in the initial stage of scarlet fever or of measles. The violent pain in the sacral and lumbar regions is, however, so characteristic of variola that we should suspect the existence of the disease when it is present.

Stage of Eruption.—On the third day from the commencement of the initial fever the exanthem begins to appear on the face, scalp, and neck. When the eruption first makes its appearance it is in the shape of slightly elevated papules about the size of millet-seeds, and of a reddish color. Whenever the exanthem is copious the red spots lie close together and almost unite with one another, resembling the eruption of measles, and the disease is liable at this stage to be mistaken for measles. Usually within twelve hours after the papules have appeared on the face they extend to the trunk and limbs, though the eruption on these parts is not so copious as on the face. The eruption on the mucous membranes generally begins at the same time as upon the skin, but, in consequence of the slight disturbance it at this time produces, is frequently not detected. The papules in the mouth soon cause increased flow of saliva, in the pharynx difficulty in swallowing, in the larynx hoarseness and cough, and on the conjunctivæ lachrymation and photophobia. By the end of the first day of the efflorescence the papules become larger, have a more livid color, and to the finger passed over them impart a sensation as if there were shot beneath the skin. These papules gradually enlarge, and on the third day become vesicular. The vesicles soon become umbilicated and contain a lactescent fluid.

Stage of Suppuration.—By the sixth day of the efflorescence the vesicles begin to lose their umbilicated appearance, assume a globular shape, and become turbid from admixture of purulent matter. By the eighth day the pustules are fully matured. The skin surrounding the eruption becomes red, swollen, and œdematous; each pustule has a broad base, and in case of confluent or semi-confluent small-pox is closely set against, or runs into its fellows. During this stage the patient suffers from profuse salivation, swallowing is accomplished with great difficulty, the nose is plugged up with pustules, the voice is husky or inaudible, the cough croupy and distressing, and there is marked dyspnœa; the eyes are red, discharging muco-pus, and are extremely sensitive to even a faint light. When the exanthem covers the face it is swollen into a shapeless mass, the eyes are closed, and the features of the patient are unrecognizable. No more repulsive sight can be witnessed than that of a patient in this stage of variola. The eyes, nose, lips, ears, cheeks, hands, feet, and genitalia, present one mass of horrid deformity. The suppurative or secondary fever comes on with the maturation of the pustules. A chill ordinarily precedes the secondary fever. This fever is distinctly remittent in type, reaching its greatest height in the evening. The temperature is usually higher than in the initial stage, and may reach 107° F. The pulse increases simultaneously with the temperature, ranging from 120 to 150 beats per minute. At this time the patient is in the most critical period of the disease; the high fever and constitutional perturbation continue until the stage of desiccation. The temperature and pulse begin to decline as desiccation commences, and when the crusts are being thrown off have about reached the normal. A subsequent marked elevation of temperature is indicative of some complication, such as erysipelas, pneumonia, etc.

Stage of Desiccation.—The process of desiccation ordinarily commences on the twelfth day, and is first observed on those parts of the body on which the eruption appeared earliest. The desiccative process usually occupies from eight to fourteen days, the length of time being governed by the degree of pustulation. Just prior to, or at the time of the beginning of, desiccation many of the pustules rupture, and the exuded fluid dries into hardened brown or yellowish crusts. This crust may be so extensive as to cover the entire face. As desiccation advances the swelling of the skin lessens, and the constitutional disturbance markedly subsides. Cicatrization of the pustules advances beneath the crusts, and the crusts are finally separated and thrown off, leaving the site of each of the pustules of a reddish-brown or violet color, with elevated margins and depressed centre. If the skin has not been deeply invaded these blotches gradually lose their abnormal color, leaving only shining white scars which sooner or later disappear; if, however, the skin beneath the pustules has been destroyed the face will be permanently pock-marked. By the time desiccation has been completed the patient is convalescent, and usually regains his former health within a month.

The above history is an outline of a typical case of variola discreta, and is the type most usually met with among the unvaccinated. It is unnecessary to attempt to present an outline of the history of each type of variola met with, and described by various writers. But three other types will be described, viz., variola confluens, variola hæmorrhagica, and varioloid.

Variola Confluens.—This type differs from the discrete variety in that the eruption and constitutional symptoms are much more severe than in variola discreta. Ordinarily the initial fever is much more violent than in the discrete variety, and is of shorter duration, usually lasting not more than two days. The initial fever frequently reaches 106° F. or 108° F. for a limited period of time, and then falls to 103° F. or 104° F. Likewise the development of the eruption in this type occurs from twelve to eighteen hours earlier, and spreads over the

body more rapidly, frequently appearing at the same time on the face, trunk, and limbs. The papules which first mark the disease are often so thickly set upon the face, scalp, neck, and hands on the first day of eruption that they run into one another. By the end of the second day the skin is intensely red and greatly swollen, and large flat vesicles rapidly develop and coalesce into large tracts of eruption. Suppuration rapidly ensues. The entire face has one continuous covering, the patient having the appearance of one wearing a mask. Notwithstanding complete coalescence of the exanthem on the face and hands, the eruption on the remainder of the body is usually either discrete or semi-confluent. Where the eruption on the body generally is confluent, there is scarcely any hope of the patient's recovery. Pustulation of more than one-fourth of the body will, as a rule, produce death. Confluent variola is a very fatal disease, the mortality ranging from fifty to seventy-five per cent. In the onset, and throughout the entire course of the disease, the confluent type shows a marked difference in the intensity of symptoms from the discrete variety. In addition to the more vehement fever and delirium the nervous and muscular systems show the greater depression of the vital powers. The mucous membranes are attacked with greater severity, the eruption in the mouth and throat is confluent, and frequently a diphtheritic exudation spreads over the soft palate, tonsils, posterior wall of the pharynx, and the nasal cavity. The larynx is usually invaded, and the marked severity of this complication is often evidenced by submucous abscesses, necrosis of the cartilages, or œdema glottidis. The eyes are more severely affected in this type, the eruption appearing thickly upon the lids, and the severe inflammation not infrequently results in keratitis with perforation. In the mouth the severity of the disease is manifested by profuse salivation, great difficulty in swallowing food or medicine, and not infrequently by inflammation of the parotid gland. Variola confluens is prone to a number of complications, such as bronchitis, pneumonia, pleurisy, pericarditis, diarrhœa, albuminuria, etc. The secondary fever is greater than in the discrete type, frequently reaching 108° F. Many patients succumb before the eruption makes its appearance, but the majority who die live until the stage of desiccation is reached—death resulting then from exhaustion or from one of the numerous complications which beset this type of variola. In those who live the process of desiccation is more slowly accomplished, and the face is horribly pock-marked. The hair is ordinarily destroyed and permanent baldness is a frequent sequel of this affection. Convalescence from variola confluens is tedious and protracted.

Variola Hæmorrhagica.—The difference between variola hæmorrhagica and the other types of small-pox is in the character of the eruption, and not in the initial fever nor in the constitutional symptoms. It is simply a modification of the other varieties of small-pox. The hæmorrhage into the eruption is observed to take place under various circumstances. In some cases the exanthem becomes hæmorrhagic upon the appearance of the papules, in other cases when the vesicular stage is reached, while in yet other cases, only when the pustules are fully formed. In some cases the entire eruption is hæmorrhagic, while in others one-half, or even a very small portion of the efflorescence, shows this complication. The hæmorrhagic eruption, as a rule, begins upon the lower limbs. Petechiæ and ecchymoses usually appear between the hæmorrhagic pocks, and livid spots or patches on the mucous membranes, particularly in the mouth and throat. Diphtheritic exudations frequently form in the tonsils, pharynx, and nasal cavity. The gums become spongy, and readily bleed as in scurvy. Hæmorrhages take place from the nose, stomach, lungs, kidneys, rectum, or uterus. The amount and persistency of the hæmorrhage vary with different cases. Prior to the appearance of the hæmorrhage, it is impossible to predict this form of small-pox. The initial fever is ordinarily mild, and throughout the subsequent course of the malady the temperature will rarely exceed 102° F.; when the hæmorrhage has been profuse the temperature falls below the normal. The contrast between the temperature and pulse-rate is marked; while the temperature is but little above, at, or below the norm the pulse is feeble, and beating from 140 to 160 per minute. The breathing is rapid, the countenance pinched and sunken, and occasionally there is delirium, but, as a general rule, the intellect remains clear to the end of the scene. This is a very fatal disease; the vast majority of patients die, death usually occurring on or before the fifth day.

Varioloid.—Varioloid is small-pox modified by a previous attack of vaccinia, a previous attack of variola, or by a degree of personal insusceptibility. There is no ground whatsoever for the old claim that it is essentially different from variola vera. Varioloid is milder in its course and shorter in duration than is the unmodified variety, and it presents many striking departures from a typical case of variola. The duration of the initial fever is usually two days; the temperature rarely reaches 102° F., falling ordinarily to the normal by the end of the second day. Occasionally the initial fever is as high as in unmodified small-pox. The secondary fever of variola is frequently absent in this type, and when it occurs is but slight, and continues ordinarily not more than twenty-four hours. The exanthem in its development and character differs markedly from that of variola. Unlike variola the eruption in varioloid usually appears simultaneously on the face, chest, and limbs. The exanthem rarely passes through all the stages usually witnessed in the unmodified variety; it may not progress beyond the papular stage, or it may, and usually does become vesicular; not infrequently it becomes pustular, but the pustules are dwarfed, and, while they are surrounded by a distinctly red areola, the skin is neither tense nor œdematous, and the pustules readily dry up. Desiccation usually commences from the fifth to the seventh day. The pitting usually resulting from variola rarely occurs after varioloid, though occasionally deep and permanent scarring of the face is witnessed. The eruption on the mucous membranes is but slight, and causes markedly less disturbance than in unmodified small-pox. When the exanthem passes through all the stages of variola the distinction between the two affections is to be found in the milder constitutional symptoms, and the smaller number of pocks in varioloid. The mortality from varioloid is very small.

Differential Diagnosis.—Until the characteristic exanthem of the disease appears it is impossible to make a positive diagnosis of small-pox. It is, of course, important to make a diagnosis as early as possible in order that the necessary sanitary precautions against the spread of the disease may be instituted. On the other hand, the physician should not be too hasty in making a diagnosis, for if he should arrive at an incorrect opinion the patient may be taken to a small-pox hospital and thereby contract the disease, when he would not have been subjected to such an unwarrantable risk had the medical attendant waited—as he should have done—until a positive diagnosis could have been made. In mistakes of this kind, which have not been infrequent in the history of medicine, the physician is, under the law, liable to pecuniary damages, and will suffer much detriment to his reputation for professional skill and acumen. There is no justification for undue haste in diagnosticating this malady. The medical attendant will have discharged his full duty by isolating the patient and awaiting the development of the stage of variola at which he can prudently decide the nature of the disease. How soon can small-pox be recognized? A practitioner who has had considerable experience in small-pox may occasionally be able to detect it the second day after the first appearance of the eruption, but such a diagnosis is always, and under all circumstances, unless there be knowledge of direct exposure of the person to variola, extremely hazardous, and the doctor who values his reputation will never be guilty of such rashness. At this stage of the affection there is nothing in either the initial symptoms or the exanthem by which he can positively reach a diagnosis. In the absence of a knowledge of direct exposure to variola the only prudent course is to isolate the patient and await

Small-Pox.

the vesicular stage of the exanthem before expressing a positive opinion on the subject. The wisdom of this course is abundantly attested by the experience of the London Small-pox Hospital. Marson says on this subject: "Upward of twenty diseases have been mistaken within the past few years, in the early stage of the disease, for small-pox, and the patients have been sent as having small-pox to the small-pox hospital." Such mistakes show an appalling amount of ignorance or carelessness on the part of their authors, and should serve as warnings to practitioners who pride themselves on their ability to make an early diagnosis in variola. When the characteristic eruption has appeared there are but few diseases which are liable to be mistaken for small-pox. These diseases are: measles, varicella, pustular syphilis, and febrile lichen.

Diagnosis of Small-pox from Measles.—Prior to the vesicular eruption of variola it is liable to be mistaken for measles. If the physician awaits the time for the vesicles to appear, and under these circumstances he should invariably do so, such a mistake would be inexcusable. During the papular stage of variola the eruption of measles simulates that of the former. The catarrhal symptoms (bronchial, nasal, and conjunctival) of measles should suffice to point out to the doctor the probable nature of the disease, for these symptoms are invariably absent in the early stage of uncomplicated small-pox. The thermometer offers valuable assistance in making a diagnosis between these affections. In variola the temperature declines when the papular eruption appears, while in measles the thermometer shows that the fever continues to rise after the exanthem appears. Furthermore, the temperature of variola is ordinarily two or more degrees higher than that of measles. As a rule, the exanthem of small-pox appears on the third day, while in measles it appears on the fourth day. Then, too, the eruption of measles is more superficial, and is not so distinctly felt as in variola. The intense pain in the sacral and lumbar regions is so characteristic of small-pox that this symptom should cause the attendant to suspect small-pox.

Diagnosis of Variola from Varicella.—While some writers of the present day contend for the identity of variola and varicella, the great majority of the profession deny this assertion. In the whole range of medical science no proposition can be more clearly established than that varicella is a disease *sui generis*. The diagnosis of varicella from light cases of small-pox is often a perplexing and difficult problem. While they are essentially different diseases, they frequently prevail as epidemics at the same time, and, as the characteristic eruption of each affection closely resembles that of the other, the diagnosis of variola from varicella is a problem frequently presented to the physician for solution. The distinction between these diseases is well-defined, and by the exercise of care they should not be confounded. In varicella the initial fever is, as a rule, absent, but when it occurs it is very slight, while in variola it is invariably present and more intense than in the former. In varicella the initial fever rarely extends beyond twenty-four hours, while in the lightest cases of variola it lasts fully two days. Intense pain in the sacral and lumbar regions is almost invariable in variola, and absent in varicella. But it is in the character of the eruption that the most striking difference between the two diseases is manifested. In varicella the eruption has less hardness than in variola, and the shotty feel of variola is absent. Furthermore, there is but a slight red base, if any, to the pock of varicella, while in variola the red base is prominent and always present. The exanthem of varicella becomes vesicular within twenty-four hours from its first appearance as a papule, and it rarely proceeds beyond the stage of vesiculation, while in variola the eruption only occasionally stops with the development of the vesicular stage. Umbilication of some of the vesicles is observed in varicella, while in variola umbilication is found in nearly all the pocks. Again, the vesicles of varicella are much larger than in variola, and have a superficial appearance as if the skin had been raised by having had boiling water spattered over it.

Diagnosis of Variola from Febrile Lichen. — Febrile lichen bears a close resemblance to the papular eruption of variola. The exanthem of febrile lichen appears as small, slightly red papules, ordinarily of the size of millet-seeds. In diagnosticating small-pox from lichen, time is an important factor. The eruption of lichen follows within from twenty-four to forty-eight hours after the initial illness, and never passes through the papular, vesicular, and pustular stages characteristic of variola. In lichen the eruption practically contains no fluid, and even when this is present it is so unlike that of variola that after two or three days from the beginning of the exanthem it would be impossible for a skilful physician to mistake it for small-pox.

Diagnosis of Variola from Syphilis.—Occasionally the practitioner is called upon to diagnosticate variola from pustular syphilitic eruptions. At times this is a very difficult task. In June, 1887, I saw, in consultation with my brother, Dr. W. H. Foster, a negro man affected with a pustular syphilitic eruption which was in all appearances like a severe case of discrete variola on the eighth day of the eruption. The face, trunk, and limbs were thickly studded with pustules, fully four-fifths of which were umbilicated. The man had high fever, (104° F.), pulse 140 per minute, severe pain in lumbar region, nausea, vomiting, sore throat, nasal catarrh, and marked redness of the eyes. The first symptom noticed by the patient was a hard chill. I have for years been familiar with the exanthem of variola, and yet must confess that we arrived at a diagnosis only by exclusion. Inquiry developed the fact that the patient had contracted syphilis four months previously, and that the eruption in question appeared a week or ten days prior to the time I saw him. Examination showed an indurated chancre beneath the prepuce. Upon the syphilitic history and the absence of contact with variola we were enabled to exclude small-pox. This eruption continued upon the man fully three months. In 1885, I saw, with Dr. G. C. Dugas, another very similar case.

It is unnecessary to enter into a discussion of the differential diagnosis of small-pox and scarlatina, typhus fever, meningitis, acute miliary tuberculosis, etc. If the physician awaits the appearance of the characteristic eruption of small-pox he can never confound these diseases with variola. As previously stated, the practitioner is not warranted in proclaiming a positive diagnosis of small-pox until the vesicular stage is reached, unless there is evidence of contact with variola.

PROGNOSIS.—In prognosticating the result of a given case of small-pox the practitioner should be guided by a consideration of the following points:

Age.—The age of the patient materially affects the prognosis. The mortality among infants is frightful, reaching fully 90 per cent. In childhood, up to twelve years of age, the mortality will reach 40 per cent. of unvaccinated cases. Likewise old age is an important factor, the mortality reaching 75 per cent. of all persons beyond sixty years of age.

Sex.—In non-pregnant females the mortality will not exceed that of the male sex. Pregnant females, however, show a vastly greater death-rate, for, superadded to the disease, abortion, miscarriage, or childbirth has great influence upon the results of variola.

Vaccination.—Vaccination is a most important factor in determining the chances of death from variola.

The death-rate in cases of post-vaccinal small-pox varies greatly with the length of time which has intervened between the attacks of vaccinia and variola, and the shorter this period is, the less will be the mortality. Marson claims that the mortality in post-vaccinal small-pox is greatly influenced by the number of insertions of the vaccine virus. From an examination into 4,896 cases of variola, following vaccination, he says the percentage of mortality was as follows

	Per cent.
Having 1 vaccine cicatrix	7.73
" 2 " cicatrices	4.70
" 3 " "	1.95
" 4 or more "	0.55

I do not agree with Marson as to the influence of the number of vaccine cicatrices. In this section vaccinia is introduced by only one puncture, and I have never seen a fatal case of variola in a person who had been vaccinated within ten years prior to the attack of small-pox.

Marson shows by elaborate statistics that the ratio of death risk, where there has been no vaccination, to that after the most defective vaccination, is as three to one; to that after the best vaccination, as seventy to one.

The Type of Small-pox.—There can be no question that the type of variola has great influence in determining the death-rate. Taking a large number of cases the mortality will reach fifty per cent. in the confluent variety, ten per cent. in the semi-confluent type, and seven per cent. in the discrete variety. Marson, from the records of the London Small-pox Hospital from 1836 to 1851, inclusive, reports that among 2,654 cases of confluent, semi-confluent, and discrete varieties of small-pox there were 996 deaths, being a mortality of thirty-seven per cent. Recovery from hæmorrhagic small-pox is rarely witnessed. Death from varioloid is almost unknown at the present day.

Constitutional Condition.—The condition of the constitution of the patient at the time of contracting small-pox has an important bearing upon the prognosis. In persons suffering from consumption, scrofula, syphilis, the hæmorrhagic diathesis, etc., recovery is very exceptional.

Lesions of the Mucous Membranes.—Lesions of the mucous membranes exert a decided influence upon the death-rate. Œdema glottidis, diphtheritic exudations, pneumonia, etc., increase greatly the fatality of the original disease.

TREATMENT.—The treatment of small-pox embraces two important, though widely divergent indications, viz:

1. Palliative treatment, and
2. Prophylaxis.

Palliative Treatment.—There is unquestionably no curative treatment known to medical science for small-pox. The treatment is wholly symptomatic, and must be prescribed with a view of palliating the severity of the symptoms. The idea of a former generation, that medicines could cut short the course of this malady, has very properly been abandoned. Sweating, vomiting, purging, and bleeding the patient, with a view of aborting variola, are not advocated by any reputable physician of the present time. Stiemer has recently, however, asserted that the administration of large doses of quinine during the stage of invasion will modify and shorten the course of small-pox. Quinine when given in large doses will reduce the temperature, but cannot cut short the course of the disease. While we have no medicine which can shorten the course of variola, I nevertheless, from personal experience, subscribe to Marson's claim of the abortive power of vaccination, if performed within three days after the first exposure of the patient to small-pox. Marson says, on this point: "Suppose an unvaccinated person to inhale the germ of variola on Monday; if he be vaccinated as late as the following Wednesday, the vaccination will be in time to prevent small-pox being developed; if it be put off until Thursday, the small-pox will appear, but will be modified; if vaccination be put off until Friday, it will be of no use; it will not have had time to reach the stage of areola, the index of safety, before the illness of small-pox begins; this we have seen over and over again, and know it to be the exact state of the question."

I can add several cases from my own experience which demonstrate the correctness of Marson's statement. I vaccinated two children, aged twelve and fourteen years respectively, three days after exposure to semi-confluent small-pox. In each case the vaccinia pursued a typical course, yet the inital fever of variola appeared and lasted two days. The temperature reached 101° F. and 103° F. in these cases. One patient developed five pustules of variola, the other fourteen pustules. Secondary fever was absent in both cases. Furthermore I have on three occasions vaccinated persons who were sleeping in the same room with small-pox patients, and those so vaccinated failed to take variola. But to thus successfully combat small-pox, vaccine virus must be used which will develop a vaccine vesicle that will reach the areola stage within ten days—the period of incubation in small-pox is fourteen days. The lymph of humanized vaccine virus rarely shows delayed vaccinal results—bovine virus frequently does. Dry lymph from any source has this objection of delay in "taking." The greater certainty of humanized virus to "take" promptly gives it a great advantage over bovine virus. In all cases coming to the physician's attention at the time of exposure it is his solemn duty to put Marson's suggestion into practice.

As soon as a person has contracted small-pox he should, if possible, be placed in a large, well-ventilated room, from which all books, unnecessary clothing, bedding, furniture, and other household articles have been previously removed. The temperature of the room should be kept constantly at 65 or 70 degrees Fahrenheit. The old plan of keeping the patient heavily covered and constantly sweating, and the room dark and unventilated, is a great mistake and should be scrupulously avoided. The covering of the patient should be light, and the bedding and clothing frequently changed. When the chill comes on he should be warmly covered, and sinapisms should be applied to the whole length of the spinal column. During the febrile stage high temperature should be combated with large doses of quinine and digitalis. For an adult forty grains of quinine may be given within four hours, together with twenty-drop doses of tincture of digitalis every eight hours until the temperature is markedly reduced. The antipyretic power of quinine in the exanthemata cannot be denied by any one who has fully tested it. But to produce this effect it must be given in large doses, *i.e.*, ten grains every hour until forty grains shall have been taken. The antipyretic effect of the quinine will be manifested within six hours after its administration, and in twelve hours the maximum reduction of temperature will be reached. The temperature so reduced will generally remain stationary for at least twelve hours.

The temperature can be lowered at least two degrees by this treatment. If the fever again rises to 104° F., the quinine and digitalis should be repeated. Antipyrine has a wonderful effect in reducing temperature. When administered for this purpose it should be prescribed in twenty-grain doses, hourly, for three hours, to an adult. Thus administered it will reduce the temperature for a period varying from twelve to twenty hours. Whenever the fever reaches 104° F., a general warm bath at 100° F. will temporarily reduce it. These baths should be continued for from five to ten minutes, and should be repeated as found necessary. During the febrile stage of variola convulsions frequently occur in children. This fact should be constantly borne in mind by the practitioner, and their occurrence should be forestalled by the administration of hydrate of chloral and bromide of potassium, or paregoric.

After the appearance of the exanthem the treatment must be varied to meet the type of the disease to be combated.

In varioloid, medicines are scarcely ever indicated. The patient should have milk, eggs, and other easily digested articles of food. Confinement to bed is ordinarily unnecessary in this type of variola.

In severe cases of small-pox both local and internal treatment must be prescribed.

Local Treatment.—After trials with various agents as local applications to the exanthem on the surface of the body, I am satisfied that a mixture of carbolic acid and glycerine is the best. A mixture composed of thirty-two grains of crystallized carbolic acid to one pint of glycerine should be brushed three times daily over those portions of the body most thickly studded with pustules. This mixture, owing to the anæsthetic properties of carbolic acid, markedly controls the itching and pain of the eruption, and the glycerine softens the hardened crusts. Various plans of treatment have been advocated for preventing the face from being pock-marked. With some writers the old plan of the Arabs, of opening each pustule, is advised; others recommend the opening and cauterization of each pustule; some advocate painting the surface

with tincture of iodine, with the view of aborting the vesicles by producing coagulation of their contents; others recommend mercurial plasters, solutions of gutta-percha, nitrate of silver, collodion, etc. After various trials I am thoroughly convinced that no local treatment has the power to prevent pitting of the skin. If the papillæ are invaded by the variolous inflammation deep and permanent pock-marks result, no matter what local treatment has been used. If, however, the pustules are superficial the pock-marks will be very slight, even when no local applications have been made. I have repeatedly witnessed very slight pitting follow severe variola where no local treatment had been used. Zülzer says the internal use of xylol will coagulate the contents of the pustules and thereby cut short their development. This claim lacks confirmation. I have never tried it.

The exanthem in the mouth and throat causes pain and difficulty in swallowing. For the relief of these symptoms gargles of warm water, or astringent solutions should be used. This treatment is of course only palliative, for we can no more abort the eruption in the mouth and throat than on the skin. The diet of the patient should be carefully directed by the physician. The disease will tax the strength to the utmost, and therefore nutritious food properly prepared should be freely administered. Milk, eggs, soup, beef tea, gruel, oatmeal, prunes, baked or stewed apples, etc., furnish excellent food for the variolous patient.

Delirium, restlessness, weak and rapid pulse, shrunken features with marked prostration, demand free and fearless use of alcoholic liquors. This treatment offers the patient the only hope of recovery. The amount of alcoholic stimulants to be administered in adynamic states of variola must be decided by the degree of vital depression to be combated.

Constipation should be relieved by mild saline purgatives or enemata. If diarrhœa exists it should be controlled with opium.

If sleeplessness is marked it should be relieved with a mixture of hydrate of chloral and bromide of potassium, or morphine; where copious expectoration or salivation exists, opiates should be given with caution.

Abscesses frequently form in the subcutaneous tissues during the course of variola. The scalp is a favorite location of these abscesses, which when they first appear are small, but continue to enlarge and show but little disposition to point. They should be freely opened when first discovered. When the eruption is copious on the head, or when abscesses form under the scalp, the hair should be cut close to the skin. Numerous boils, terminating in foul ulcers with free discharge of pus, occur in many cases of variola. Boils should be promptly lanced. The depressing effects of suppuration should be combated with full doses of quinine, iron, wine, and concentrated nourishment. As a local application to these abscesses, lint kept wet with black wash is the best.

If erysipelas, pleurisy, pneumonia, etc., complicate an attack of small-pox they should be treated on general principles. Among the most serious complications of small-pox are ophthalmia and ulceration of the cornea. Variolous ophthalmia should be treated by frequently washing the eyes with warm water, and by an astringent collyrium of sulphate of zinc used after each washing. A solution of atropine should be dropped into the eyes as found necessary, when the inflammation is intense. To mitigate the irritation on the eyelids the vesicles should be punctured and the lids frequently covered with cold cream. When the cornea is implicated and perforation is threatened, attempts should be made by local treatment to subdue the inflammation and stop the advance of the ulcer. Atropine should be freely dropped in the eyes, and the lids kept closed with a compress bandage. The eyes should be cleansed several times daily, and a mild solution of sulphate of zinc, two grains to the ounce of water, should be instilled after each cleansing.

Prophylaxis.—Judged by mortuary statistics, the present therapeutic management of small-pox in unvaccinated patients shows but slight improvement over that of one hundred years ago. By judicious symptomatic treatment many cases can be conducted to a favorable termination which would otherwise prove fatal. Prevention is the end to be reached in combating this malady. In the whole field of sanitary science the prevention and control of small-pox are the most certainly attainable, if the efforts of the sanitarian are wisely planned and faithfully executed. In the prevention of the spread of variola the most important of the hygienic considerations to be regarded, are: 1, Isolation; 2, disinfection; 3, vaccination.

Isolation.—No matter how absolute the protection afforded by vaccination there will always be great and insurmountable difficulties in the way of enforcement of this measure among the people generally in this country, where individual ignorance and prejudice are allowed to contravene the public welfare. Therefore, the sanitarian must be prepared to enforce additional measures of prevention and control of small-pox. If a case, or cases, of variola be introduced into a community, the disease cannot spread if the patient be promptly isolated and all infected materials immediately disinfected or destroyed.

Whenever a case of small-pox occurs in a family, the physician's first duty is to isolate the patient and provide nurses and attendants who have been successfully vaccinated or have previously had the disease. If others in the family have not yet been vaccinated they should be vaccinated at once. Those who have previously been vaccinated should be promptly revaccinated. If the small-pox patient be so situated that he can be safely isolated and provided with proper attention, he may be permitted to remain at home for treatment, but the sanitary authorities should furnish a reliable guard to compel isolation and compliance with all necessary sanitary precautions. If isolation at home is impossible, then a properly organized hospital is the only place where such a patient can, with due regard to public safety, be treated. For such purpose a public small-pox hospital is a necessity in every city. It should be located remote from the thickly settled parts of the city, and, if possible, beyond the city limits. This institution should be provided with every necessary comfort, so as to induce patients to cheerfully seek shelter therein. Whenever a case of variola is allowed to remain at home, a large poster should be placed on the door to warn people not to enter or linger there.

In the management of this disease among the poor the greatest possible care and vigilance must be exercised on the part of the municipality. Whenever a case has been found and is to be conveyed to hospital this should be done in a closed ambulance—to use an open conveyance would be criminally negligent. Infected clothing, bedding, etc., may be taken with the patient to the hospital, though it is safer to burn them in the sick-room. When the clothing and household articles of the poor have been destroyed, the public treasury should replace them, for they were destroyed in furtherance of public safety. In burning infected articles and replacing them with new ones, the sanitary authorities will make a most prudent and economical expenditure of money—an expenditure which will be returned to them more than a thousandfold. When infected persons or materials are being taken to hospital, the ambulance should be rapidly driven through the most sparsely inhabited portions of the city contiguous to the hospital, and the police should go ahead and clear the streets until the ambulance has passed. Isolation of small-pox patients is absolutely necessary in preventing the spread of the disease. Without doubt variola can be promptly "stamped out" of a community. But to do this the first cases must be immediately dealt with by isolation, disinfection, and vaccination. To obtain early information of the existence of small-pox the municipality should require physicians and families to promptly report to the sanitary authorities all cases known to them. When a case is found its source must be traced, and thus other cases will be detected. When a case of variola is found the sanitary officer should carefully ascertain the name and residence of every person who has been exposed to it. An officer should be specially charged with the duty of finding every

such exposed person, and should make daily visits to every one of them until the period of incubation is passed. Every person who has been exposed to the disease should be vaccinated, and if formerly vaccinated the operation should be repeated. Every such person refusing to be vaccinated should be quarantined for fourteen days—the period of incubation in variola. Where a person has been exposed to small-pox, and is living in the same house with other families, such family should be quarantined until the period of danger is over. To safely quarantine such persons it may be necessary to confine them in a quarantine station. For this purpose every municipality should maintain a quarantine hospital, near the small-pox hospital, but sufficiently distant to insure safety to its inmates. The sanitary officer should remove persons to the quarantine hospital only when public safety absolutely demands the exercise of this precaution.

Disinfection.—Watson truly says "there is no contagion so strong and sure as that of small-pox." The contagious element exists in the exhalations of the body and in the vesicles, pustules, and scabs. These sources of the disease contaminate the air of the sick-room, and strongly adhere to everything therein. The vitality of the small-pox poison is truly remarkable, if protected from the air, as in instances where infected clothing has been packed away, it can retain its infective power for several years.

The sanitarian has in chemistry, under these surroundings, an indispensable ally. There is no question of our ability to kill every particle of the contagion of small-pox if chemical action is properly adjusted to its task. To do this successfully disinfectants must be brought directly in contact with the contagious matter. Every discharge which passes from the mouth, nose, kidneys or bowels of the patient must be received in suitable receptacles charged with a powerful disinfectant. Every handkerchief, towel, sheet, article of clothing, drinking- or eating-vessel must be purified by heat and disinfectants. If the patient is kept at home, a sheet saturated with a strong solution of carbolic acid should be hung over the door openings outside the sick-room, to prevent the contagious exhalations from passing into other parts of the house.

The sputa and excretions of the kidneys and bowels should be received into vessels containing a sufficient quantity of strong copperas solution, two pounds to the gallon of water. Under no circumstances should excreta be passed into a water-closet or thrown into the privy vault or yard until an additional quantity of copperas water has been added to them. The quantity of the disinfectant should be at least eight times more than that of the excreta.

All eating- or drinking-vessels used in the sick-room should be thoroughly disinfected with a disinfectant solution, and afterward washed in hot water before being carried from the room. Such of the articles as are necessary should be kept and used in the sick-room until the recovery and discharge of the patient.

Every piece of bed- or body-linen from the patient or nurses, or which has been in any part of the sick-room, must be kept in a solution of carbolic acid for two hours and boiled in water for half an hour, before being taken from the patient's room.

Bits of cloth, instead of handkerchiefs, should be used and burned immediately when soiled.

The patient should not be regarded as free from liability to infect others until every scab or scale has been removed. The hair should then be carefully combed so as to remove all particles adhering to the scalp. The whole body should then be washed in a weak disinfectant solution and the patient should hastily go into an adjoining room and dress with clothing undoubtedly free from contagious particles.

Immediately upon the patient leaving the room it should be disinfected and cleaned. To effectually purify the clothing, bedding, etc., hang every article upon lines placed across the room. If there is a carpet on the floor take it up and burn it in the fireplace. Then stop up the fireplace and shut down the windows. Put two pounds of sulphur in an iron pot over a larger vessel holding water, and drop a quantity of live coals into the pot containing the sulphur, and then hastily leave the room and close the door behind you. The room should now be closed for twenty-four hours in order that the disinfectant thus generated may invade every crevice and fully impregnate all materials therein. After twenty-four hours open the windows (closing all others adjacent thereto), and then have the clothing and bedding, which can be washed, put into tubs containing solutions of carbolic acid, chloride of zinc, or copperas, and boiled for one hour in water. These articles should then be taken into a large open space, as far from the thickly inhabited portion of the town as possible, and sunned. There is always danger in the pillows and mattresses, for they cannot be thoroughly fumigated nor can they be washed, therefore these articles should be burned. All stuffed furniture in the room should be taken apart and the upholstering materials burned. Wash all the furniture and the floor with a disinfectant solution. If the walls be papered wash off every particle of such covering and then whitewash the walls. The walls, even when painted, should be washed with a disinfectant solution. After the above precautions are taken, open the windows for free ventilation and leave the room unoccupied for one month.

If the patient should die, the corpse should be thoroughly washed with a strong solution of chloride of zinc or carbolic acid and water, and the body should be wrapped in a sheet fully saturated with one of these disinfectants, and buried at once. Under no circumstances should the body of such a patient be permitted public burial; nor should the corpse be transported from the city by public conveyance—such as cars, boats, etc. Every hearse, hack, or other vehicle in which the body has been conveyed, should be disinfected under the supervision of the sanitary authority immediately after the corpse is removed therefrom.

In waging war against small-pox no alarm or excitement must be felt; it should be met calmly and deliberately. If real skill should direct, and scrupulous conscientiousness execute, the above specified measures of prevention and control, small-pox might simultaneously be introduced into every city in America, and it would be impossible for it to attack any one citizen not already infected.

Vaccination.—In the broad field of natural science no fact is better established than that vaccination, if universally practised, is capable of effectually preventing the appearance of small-pox in man. The history of vaccination, as well as the technique of the operation, will not be discussed in this treatise, inasmuch as the subject, Vaccination, has been assigned to another writer. I must, however, say that, after a large personal experience acquired in making five thousand vaccinations in the public service, I am impressed with the conviction that humanized vaccine virus is decidedly preferable to bovine virus. The facts upon which this opinion is founded are fully presented in a paper, entitled "The Relative Merits of Humanized and Bovine Vaccine Virus," read by me before the Medical Association of the State of Georgia in 1882. This paper may be consulted by referring to the "Transactions of the Medical Association of Georgia, 1882." In view of the prophylactic power of vaccination it should be regarded as an especial and solemn duty upon the part of municipal authorities to annually provide gratuitous vaccination for the indigent poor, and whenever small-pox threatens the community no expenditure of money, within the line of duty compatible with the public good, should be spared by the authorities in order to protect the people under their charge.

The time has not yet arrived, and in democratic America, where the cry of infringment of personal liberty is the shibboleth of the demagogue, the day may never come, when it would be wise to resort to compulsory vaccination. There can be no question but that every unvaccinated person is liable to contract small-pox, and thereby disseminate it among his fellows. This fact constitutes every unvaccinated person a public enemy, and he or she should be dealt with as such. Satisfactory

evidences of successful vaccination should be required of all persons before being allowed to enter public schools, asylums, hospitals, charitable institutions, or municipal, state, or national service. Every immigrant should be required to exhibit like proof before being allowed to land in this country. *Eugene Foster.*

SMELL, THE SENSE OF. The olfactory nerve (so-called) is, like the optic, a prolongation of the cerebrum. Its minute structure is that of the brain-substance, and not of the ordinary cerebro-spinal nerves. It arises by three roots from the posterior part of the anterior lobe of the brain, and forms the olfactory tract which terminates in the bulb, or olfactory ganglion, resting on the cribriform plate of the ethmoid bone. The development of this ganglion is always in proportion to the acuteness of the scent in different animals. It is made up of gray matter, *i.e.*, it is chiefly composed of ganglionic cells.

From it arise about twenty nerve-filaments, which penetrate the cribriform plate and are distributed to the upper third of the anterior nasal chamber. It is the sum total of these fibres which might be more properly called the olfactory nerve. These fibres anastomose freely, they subdivide, and are finally distributed to the "olfactory membrane."

This membrane is considerably thicker than the rest of the nasal mucous membrane. It is only to be found in the upper third of the nasal fossæ, where it extends over the upper, and a portion of the middle, turbinated bones, the septum, and the roof of the fossæ. In animals with acute scent the olfactory region is more extensive than in man. To this membrane exclusively are distributed the terminating branches of the olfactory nerve (see Fig. 2503, on page 212 of Volume V.).

The epithelial covering of this membrane consists of truncated epithelium-cells, and between these, at regular intervals, are to be found peculiarly shaped, slender, nucleated cells ending in rods. These are presumed to be the terminating peripheral apparatus of the olfactory nerve, although their connection with the nerve-filaments has never been satisfactorily demonstrated, owing to the extreme delicacy of the latter. They are analogous to the rods and cones of the retina, and to the hair-cells in the organ of Corti. In the frog they are ciliated. Numerous racemose mucous glands, which keep the membrane in a moist condition, are distributed throughout the olfactory region.

The remaining portion of the nasal chambers is covered by a thin layer of mucous membrane, bearing ciliated columnar epithelium, which is innervated by the fifth nerve. It is provided with simple glands secreting a serous fluid.

That the olfactory region is the one exclusively capable of receiving odorous impressions, and that, consequently, the olfactory is the only nerve endowed with specific olfactive properties, has been proved both by physiological experiments and by pathological anatomy. Dogs in whom the olfactory nerve has been cut refuse meat wrapped up in paper, and are incapable of finding it when hidden. Persons suffering from anosmia due to absence, atrophy, or injury of the olfactory tract or ganglion are deprived of the sense of smell, although they are capable of detecting certain pungent substances, such as bromine, iodine, chloroform, acetic acid, ammonia, etc. There is a difference between the pungent and odorous substances. The former impinge only on the nerve-endings of the fifth nerve, which subserves general sensation; they are not perceived by dogs in whom the nasal branches of that nerve have been divided.

The mechanism of the perception of odorous substances is as little understood as is that of visual and auditory impressions. We know nothing about the nature of odorous substances, and it is impossible to classify them similarly to substances productive of gustation. If we want to describe a certain odor we have to give the name of the substance which produces it.

The act of smelling takes place by the contact of air, laden with odorous particles, with the olfactory portion of the nasal chambers. The diffusion of this air is facilitated by the projecting inferior turbinated bone. By it the ascending air-current is directed against the septum nasi; striking this, it is again deflected, and scattered throughout the recesses of the upper anterior fossæ.

Odorous particles give rise to olfaction only when suspended in gaseous media. Scented water poured into the nose (the patient being in the recumbent position), and kept there by the reflex closure of the nasal fossa by the soft palate, is not smelled, nor does a scented air-current passing from the pharynx through the nares give rise to an odorous impression. Thus, persons having habitually an offensive breath do not perceive it themselves. There is, however, another explanation of this: An odor starting from the air-passages is perceived in the beginning of the trouble, but soon the olfactory nerve becomes accustomed to it, and there is no further perception of it. A patient having cancer of the stomach was greatly annoyed at first by the offensive smell of the material vomited; but soon he became accustomed to the bad odor, and ceased to be aware of it.

Smell is intensified by sniffing. Within certain limits it may be stated that the more quickly the air containing odorous substances passes over the olfactory membrane, the more acute is olfaction. Persons on whom tracheotomy has been performed, and who breathe through a cannula, do not smell at all. Continuous smelling of the same substance, especially when fragrant, gives rise to discomfort and pain in the forehead. At the same time the nerve becomes exhausted, and the sense of smell for that particular substance is temporarily lost. Water, when kept in contact with the olfactory membrane, will also abolish olfaction for a short time. Probably it causes the delicate olfactive rods to swell up, and interferes in this way with their function.

When several odorous substances are mixed, we do not smell a mixture of them, but we perceive them alternately and individually.

Whether an impression can be produced on the olfactory membrane by mechanical or electrical stimulation, corresponding to the visual and auditory sensations excited by the same means, is questionable. It is claimed by some that electrical stimulation of the olfactory region excites a sensation resembling that produced by the emanations from phosphorus.

Subjective odorous sensations are quite frequent, and occur even in the healthy; but most often they are met with in the hysterical and the insane.

In regard to acuteness of smell, man is inferior to most of the higher animals; this is partly due to the neglect of the cultivation of this sense. Hysterical patients are sometimes endowed with a remarkably acute sense of smell; persons who are both blind and deaf, and who are consequently compelled to cultivate and rely on the other senses, have been known to almost equal the dog in the acuteness of smell.

There is an intimate relation between smell and taste, and, in fact, all so-called taste, except that of sweet, sour, bitter, and salt substances, is in reality smell. Delicate flavors that make so many dishes attractive cannot be appreciated when the nose is plugged, or when a person suffers from coryza or anosmia. Thus, vanilla, freshly prepared roast beef, the bouquet of wines, etc., can be relished only by those whose olfactory sense is unimpaired.

That there is an anatomical connection between the organs of smell and taste is evinced by the fact that the odor of sapid substances produces reflexly a flow of saliva.

For perfect olfaction a moist condition of the olfactory membrane is indispensable.

As might be expected, carnivora are possessed of a more acute smell for animal substances than the herbivora, who have a quicker perception of the odor of plants.

L. Bremer.

SNAILS. A popular term applied to those forms of the gasteropod mollusks, belonging chiefly to the order *Pulmonata*, which are provided with a shell. They are divided into the land, fresh-water, and marine species, belonging respectively to the sub-orders *Geophila*, *Lim-*

nophila, and *Thalassophila*. There are some few terrestrial species and a large number of fresh-water and marine forms, belonging to the order *Azygobranchia*, to which the term snail is also sometimes applied. The fresh-water and marine forms are perhaps more commonly known as periwinkles and whelks, while allied genera not provided with a shell are ordinarily spoken of as slugs.

The order *Pulmonata* is characterized by a lingual membrane provided with numerous teeth arranged in many uniform transverse rows; mouth usually supplied with one or more horny jaws, a respiratory organ in the form of a closed chamber lined with pulmonic vessels on the back of the animal and covered by the shell when present—the edge of the mantle being attached—the entrance to the air-chamber being through an opening in the side closed by a valve. The operculum is almost universally absent. The tentacles and eye-peduncles are retractile or contractile. The shell varies in form, and is sometimes rudimentary or wanting. They are hermaphrodites, with reciprocal impregnation, generally oviparous, and all forms, whether terrestrial, fluviatile, or marine, respire free air.

The American species of terrestrial snails live mostly in the forest sheltered under the trunks of fallen trees, layers of decayed leaves, stones, or in the soil itself. They are, as a rule, solitary in their habits; only exceptionally, as sometimes in the early days of spring, do they congregate in considerable numbers in warm and sunny situations, but these assemblies do not last more than a few days; they then scatter and again resume for the rest of the year their solitary mode of living. They are rarely seen abroad except on damp dark days or at twilight, and, indeed, they almost disappear as the forests are cut down, and seem to flee the approach of man.

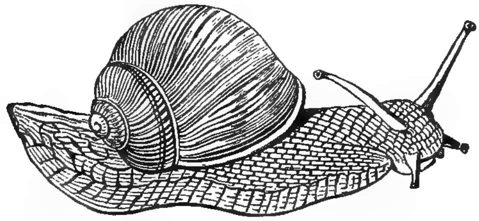

FIG. 3557.—Helix Pomatia Linn.; the European Vineyard Snail, the one most extensively eaten. (From Keferstein.)

The European species, on the other hand, follow in the track of cultivation and are common in gardens and fields, on walls and hedges, and other places exposed to the action of light. It is probably owing to this radical difference in their habits of life that the large majority of our species are so plain and uniformly dull-colored, while the European species are brightly colored. In size the snails vary from those minute species a quarter of an inch or less in length to the gigantic African species belonging to the genera Achatina and Balinus, which sometimes attain the length of eight inches.

The eggs are laid in the early spring. Some few forms are viviparous. As soon as hatched, which takes place in from twenty to thirty days, the young snail devotes himself strictly to the business of eating. He first devours his own shell, and then, according as his instinct leads him, begins on either vegetable or animal food. The majority of them prefer vegetable food, though it is certain that some forms are also fond of animal food, and sometimes prey upon earthworms, their own eggs, or even upon each other. The amount they can eat is enormous, as can well be testified to by the gardener, who often finds a whole field of vegetables almost destroyed in a single night. As might be expected from this, their rate of growth is very rapid, and they frequently double in size within a week. At the first approach of frost they retire into secluded and sheltered spots under logs, stones, or partially burrow into the soil, withdraw into their shells, and dispose themselves for their annual sleep or hibernation, only to be awakened again in from four to six months by the warmth of spring.

They possess the power of secreting a mucus-like material from the general surface of the body at will. The slugs have this function developed to a much greater degree, and it is used by them as a means of defence. Whenever a foreign substance touches them they secrete a quantity of the mucus, which forms a kind of membrane interposed between themselves and the irritating substance. This mucoid material is a non-conductor of heat and impervious for a time to liquids, so that by its means they are enabled for a considerable time to withstand the action of corrosive gases, alcohol, and even boiling water. The fresh-water and marine forms live on the rocks and aquatic plants at the bottoms of ponds and rivers, and along the sea-shore, where they may be seen in immense numbers when at any time, as at ebb-tide, the rocks are exposed.

There are a large number of species of snails which have been used as food. Most of these belong to the genus Helix, of which more than twelve hundred species have been described. Few of the American forms have been so used, partly for the reason that it has never become the custom here, and partly, probably, from the curious fact already mentioned, that the forms indigenous to this country are mostly solitary and do not collect in herds or communities. Many of the European species, on the contrary, herd together in immense numbers and so are very easy to collect and peculiarly adapted to colonization. The "edible snail," *Helix pomatia*, is the one most commonly eaten in Europe, but *H. aspersa* and *H. hortensis* are also very generally used. The first of these has, I believe, never been introduced into this country, but *aspersa* and *hortensis* both have been, and are now found in considerable numbers in certain localities. They retain their habits of congregation, and will no doubt in time be much more generally used as an article of diet than they are at present.

FIG. 3558.—Pomatia Aspersa. (From Binney.)

The ancient Greeks and Romans considered snails as one of their greatest delicacies, and imported them from all parts of the then known world to be reared and fattened in their extensive snail-ponds. In many parts of Africa the large species which are indigenous there are used as a daily food all the year round. At the present time in Austria, France, Switzerland, Spain, and Italy, the collection, rearing, and preparing them for market affords occupation to a large number of people. An idea of the extent of the industry may be gained from the fact that from Ulm alone some 4,000,000 are annually exported, and about 90,000 pounds are sold in the Paris markets every year.

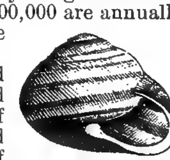

FIG. 3559. — Tachea Hortensis. (From Binney.)

The wild snails are collected and placed in small plots of land cleared of trees and covered with heaps of moss and pine-twigs, and separated from each other by moats, or trails of sawdust, for which snails have a natural antipathy. They are kept here and fed on fresh grass, cabbage-leaves, mint, and other aromatic herbs. In the course of a week or ten days they have become quite obese and, besides, have attained a very delicate flavor; they are then starved for a few days to allow them to get rid of excrementitious matter, when they are ready for the market. To prepare them for the table they are well washed, then broiled, baked, or boiled, shell and all, when they are either extracted and served with various suitable sauces, or are placed on the table entire, to be removed at the time of eating by placing the shell to the mouth and drawing out the animal by sucking it.

The sea-snails are not so extensively used as food, though in England the common periwinkle (*Littorina littorea*) is consumed in immense quantities by the poorer

classes on the coasts as well as in London. About three thousand tons of them, valued at £15,000, are annually shipped to London alone.

There has been a number of cases of poisoning from eating snails which have been allowed to feed on hemlock and belladonna, so that now there has been an inspector appointed in Paris whose business it is to see that they are in fit condition for consumption.

In some persons the ingestion of snails brings on marked attacks of urticaria—the same as is seen in certain cases after eating clams, oysters, and other shell-fish. In these cases it will be understood that there is a more or less marked idiosyncrasy in the person.

An idea of the nutritive value of these mollusks may be gained from the following analysis of the "edible snail," made by Mr. Charles Mene:

Water	72.747
Nitrogeneous matter	17.652
Fatty substances	1.125
Non-nitrogeneous matter	6.300
Salts	2.176
Nitrogen	2.823

In some parts of the world the snail has more or less of a reputation as a "cure" for consumption, concerning which it is only necessary to say that it may be considered as a food of some value as affording a change of diet. *William Barnes.*

SNAKEROOT, BLACK (*Cimicifuga*, U. S. Ph.; *Cimicifugæ Rhizoma*, Br. Ph.; Black Cohosh, etc.); *Cimicifuga racemosa* Elliott; order *Ranunculaceæ* (*Actæa racemosa* Linn.). This is a large, perennial herb, arising from a thick, knotted, horizontal, fleshy rootstock, which gives off numerous cylindrical, branched rootlets from its lower surface, and develops several leafy stems and buds upon the upper. The aërial stems are slender, upright, from one to two and a half metres high, smooth, and cylindrical; they bear two or three ternately compound leaves, the lower very large, twice or thrice primate; the upper ones successively smaller and more simple; leaflets pointed, serrate, ovate, or more or less three-lobed. Inflorescence of one or several long, slender, upright, cylindrical racemes (25 to 50 centimetres long). Flowers very numerous, something over a centimetre across, consisting of four white, concave sepals, which drop as they expand; very numerous, free, slender, spreading stamens, and a single, one-celled, ovoid, pistil, containing several ovules. Petals none, a few of the outer stamens somewhat petaloid.

Black Snakeroot is a common American plant, growing in Canada and in most of the United States. It is collected in various parts of the country, and has been used as a medicine for nearly a century.

The officinal description of the dried rhizome is as follows: "The rhizome is horizontal, hard, two inches (5 centimetres) or more long, about one inch (25 millimetres thick, with numerous, stout, upright, or curved branches, terminated by a cup-shaped scar, and with numerous wiry, brittle, obtusely quadrangular rootlets, about one-twelfth of an inch (2 millimetres) thick; the whole brownish-black, nearly inodorous, and having a bitter, acrid taste. Rhizome and branches have a smooth fracture, with a large pith, surrounded by numerous, sublinear, whitish wood-rays, and a thin, firm bark. The rootlets break with a short fracture, have a thick bark, and contain a ligneous cord branching into about four rays" (U. S. Ph.). Cimicifuga, it is said, should be collected in the autumn; it should be used moderately fresh, as it grows much less active with the lapse of time.

Composition.—Not satisfactorily determined—*starch*, *sugar*, *gum*, *resin*, which were early recognized, are common vegetable derivatives, and found in most plants. Couard obtained a neutral, crystalline, very acrid substance (allied perhaps to *anemonin*). Trimble, working more recently, was unable to get Couard's crystals, but obtained an acrid, amorphous substance. No alkaloid appears to be present, unless Couard's crystalline substance proves to be such, as surmised by Mr. Falck, who has recently (1884) obtained it from the fresh rhizome.

Action and Use.—There is no question that recently dried, or still better, fresh, Cimicifuga is an active substance. Vomiting, diarrhœa, and cardiac depression are caused by large doses; faintness, restlessness, and dizziness, foul breath, and dryness of the pharynx are common results. Smaller doses are said to be tonic, to improve the appetite and digestion, and to strengthen the heart's action. It is reputed to be aphrodisiac and ecbolic, but is not at all reliable in these directions. The most important and acknowledged uses of Cimicifuga are, however, established empirically. It has for many years had a reputation in chorea, and is generally believed to be useful in that obstinate disease. It is also given in chronic rheumatism, and occasionally in pulmonary troubles.

Administration.—The dose is one or two grams of the dried drug; a Fluid Extract (*Extractum Cimicifugæ Fluidum*, U. S. Ph.), and a Tincture (*Tinctura Cimicifugæ*, U. S. Ph.; strength, $\frac{1}{5}$) are available preparations. The precipitated resin, miscalled *cimicifugin*, is in general use by the "Eclectics," and occasionally called for by other physicians. Dose about a decigram.

Allied Plants.—See Aconite.

Allied Drugs.—Colchicum, various alteratives, etc., besides several other *Ranunculaceæ*. *W. P. Bolles.*

SNAKEROOT, VIRGINIA (*Serpentaria*, U. S. Ph.; *Serpentariæ Rhizoma*, Br. Ph.; *Aristoloche Serpentaire ou Serpentaire de Virginie*, Codex Med.). *Aristolochia Serpentaria* Linn., order *Aristolochiaceæ*, is a perennial herb, a foot or so high, from a knotty, horizontal, aromatic rhizome. The stems are slender, flexuose, branching at the base. The leaves of various shapes between ovate and narrow-lanceolate, with heart- or halberd-shaped bases; petiolate entire. Flowers lateral, on slender, straggling, crooked peduncles in the axes of bracts, near the surface of the ground, about an inch long, consisting of a dull purple, single perianth (calyx), whose curved tube has a wasp-like constriction near the middle, and a very oblique, spreading, three-lobed border, of six short stamens connected with the style in three pairs, and a three-celled, many-ovuled, inferior ovary. It is a native of the United States, especially of Pennsylvania, Virginia, and Kentucky, where much of the drug is collected. In the South and West *A. reticulata* Nutt. furnishes a somewhat larger and coarser product. Serpentary is one of the numerous, usually innocent, remedies which have a historical reputation for snake and mad-dog bites. It has been known in medicine for about two hundred years.

The rhizome, as collected for use, is about an inch long, and an eighth or more in diameter, brittle, and tortuous. Section shows excentric wood. Its upper surface has the remains or scars of several stems; its lower is covered with a dense skein of long, slender, fibrous rootlets. All have a dull brown color, an aromatic odor, and a warm, bitter, camphoraceous taste. The rootlets of *Aristolochia reticulata* Nuttall, the Southern or Red River snakeroot, also officinal, are coarser, longer, and less matted together than those above described. Snakeroot is often carelessly collected, leaves and stems may be mixed with it, or Pinkroot, Ladies' Slipper, and other similar-looking rhizomes may be collected with it by accident or for fraud. They are easily distinguished with a little care.

Composition.—Half a per cent. of *essential oil*, about as much *resin*, a little *tannin*, and a *bitter principle* are found in this drug; to the first and last it probably owes its value.

Action and Use.—It is difficult to make this out as anything more than a pleasant, aromatic, bitter tonic. In ounce doses it deranges the digestion, and may cause vomiting, colic, and diarrhœa. Its former employment has been largely as an alterative in various chronic diseases, in rheumatism, and intermittent fever. It is one of the ingredients of the Compound Tincture of Cinchona. Dose, of the powdered drug itself, say two or three grams. Its preparations are: a Fluid Extract (*Ex-*

tractum Serpentariæ Fluidum, U. S. Ph., strength, $\frac{1}{1}$), and a Tincture (*Tinctura Serpentariæ*, U. S. Ph.; strength, $\frac{1}{10}$).

ALLIED PLANTS.—The genus is a large one, of one hundred and eighty, mostly tropical, plants, of both hemispheres. A number of them have aromatic-bitter properties similar to the above, and have been used as medicines. The neighboring genus *Asarum*, represented here by *Asarum canadense* Linn., and in Europe by *A. europæum*, has similar aromatic-bitter properties.

ALLIED DRUGS.—Sweet-Flag, Ladies' Slipper, Cascarilla, Boldo, and many others. *W. P. Bolles.*

FIG. 3560.—Virginia Snakeroot, about one-half natural size. (Baillon.)

SOAP. When natural fats or oils are decomposed by treatment with salifiable bases, they split up into the alcoholic body *glycerin*, on the one hand, and a series of *acids* on the other—principally oleic, palmitic, and stearic acid, in varying proportions, according to the nature of the fat, which acids then unite with the base used in effecting the decomposition of the fat, to form salts—oleates, palmitates, or stearates, or all combined, as the case may be. Such salts are generically called *soaps*, but in common parlance the name soap is applied only to the fatty salts of the alkali bases—potassa, soda, and ammonia, which, in contradistinction to the soaps derived from earthy and metallic bases, are soluble in "soft" water and in alcohol. Of the alkali soaps, furthermore, ammonia soap is used only in the preparation called *liniment of ammonia*, or *volatile liniment* (see AMMONIA), so that the soaps in common use as such are narrowed down to soda and potassa-soaps.

Between soda-soaps and potassa-soaps, as distinct classes, the broad distinction is that soda-soaps tend to be comparatively hard, and potassa-soaps soft, so that the phrase *hard soap* is applied generically to soda-soaps, and *soft soap* to potassa-soaps. But the consistence of soaps is also markedly affected by the nature of the fat used in the manufacture, in the way that fats rich in olein, as is the case with oils, tend to yield softish soaps, whereas those rich in stearin and palmitin, typified by the solid fats, such as tallow, furnish soaps of greater consistence.

Soaps are bodies of a well-known characteristic odor and disagreeable alkaline taste. They dissolve in alcohol and in "soft" water, but in "hard" waters they suffer decomposition by the calcic salts present, and the lime-soap resulting floats in insoluble flocculi on the surface of the water. Soaps are, in general, decomposed by acids, by earthy bases and salts of the earths, and by the heavy metals. The useful property of soaps is that they attack grease, dirt, and dried animal débris, probably by virtue of their free alkalinity, and so affect those substances as to render them soluble in water, and thus readily removable.

The kinds of soap officinal in the U. S. Pharmacopœia for use in technical medicine are as follows: Under the simple title *Sapo*, Soap, is recognized "soap prepared from soda and olive-oil." Such a soap corresponds to what is commercially called *Castile*, or *Spanish*, soap, and is described as "a white or whitish solid, hard, yet easily cut when fresh, having a slight, peculiar odor free from rancidity, a disagreeable, alkaline taste, and an alkaline reaction. Readily soluble in water and in alcohol" (U. S. Ph.). This description applies to the so-called *white* Castile soap, which is a purer and daintier soap than the *marbled* variety, although, containing, as it does, more water, it is not so strong. The marbling of the latter kind of soap is due to streaks of an insoluble iron soap, whose presence constitutes an impurity.

Castile soap is locally detergent, and, by virtue of its free alkalinity, mildly irritant to tender surfaces. Taken internally, it is innocent in moderate quantity, and tends only to relax the bowels and neutralize acid in the primæ viæ. Locally, free ablutions of soap and water are beneficial in certain forms of skin-disease, such as acne, and, as regards internal giving, the principal application of soap is as a ready and innocent alkali to administer in cases of poisoning by any of the strong acids. A strong aqueous solution—one part of soap to four or five of water—should in such cases be very freely administered pending the arrival of more powerful and appropriate alkaline antidotes. Soap and water is also much used as a cathartic enema, but in sensitive conditions of the rectum may irritate. Pharmaceutically, soap is much used as an excipient in pill-composition, but due regard must be paid to its chemical susceptibilities, as above detailed. From Castile soap are made the following officinal preparations: *Emplastrum Saponis*, Soap Plaster, is compounded of soap, one part, and lead-plaster, nine parts, mutually

incorporated when in the fluid condition, and the product evaporated to the proper consistence. Soap-plaster is a feebly active plaster, devoid of specific medicinal properties. *Linimentum Saponis*, Soap Liniment, contains, in one hundred parts, ten of soap, five of camphor, one of oil of rosemary, seventy of alcohol, and the rest water. This preparation makes an excellent gently stimulant embrocation, and takes the place of the *camphorated soap liniment*, or so-called *opodeldoc* of older revisions of the Pharmacopœia, an article substantially the same in composition as the present, but prepared from the common white soap made of animal fat, instead of from Castile soap.

The second variety of soap officinal is entitled *Sapo Viridis*, Green Soap, and is defined to be "soap prepared from potassa and fixed oils." The definition is a broad one, including all potassa ("soft") soaps, but the varieties suitable for medical use are those made from vegetable oils, in contradistinction to those prepared from animal fats. Green soap is thus described: "A soft, greenish-yellow, unctuous jelly, having a peculiar odor, which should be free from rancidity, and an alkaline reaction. Soluble in water and in alcohol, without leaving more than a small residue of insoluble matter" (U. S. Ph.). The green soap in common medicinal use is of German importation, as is also its medicinal reputation. This form of soap is more strongly alkaline, and therefore more detergent, on the one hand, and more irritating to sensitive tissues on the other, than the hard soda-soaps. Severe pain is easily excited upon tender surfaces, such as that of an eczematous patch of skin, by applications of green soap. The medicinal use of the soap is as a detergent and "alterative" application in certain forms of skin-disease, notably in *eczema rubrum*. The part is commonly washed with the green soap, and afterward dressed with some bland substance, such as ointment of oxide of zinc.

From green soap is prepared an officinal *Tinctura Saponis Viridis*, Tincture of Green Soap, which is an alcoholic solution of green soap, sixty-five per cent., and oil of lavender, two per cent. The preparation is used as a local application to the skin, instead of an extemporaneous solution of the soap. *Edward Curtis.*

SOAP BARK (*Quillaia*, U. S. Ph.; *Panama, Bois de*, Codex Med.), the bark of *Quillaya Saponaria* Molini, order *Rosaceæ*, is a good-sized, evergreen tree, with alternate stipulate, ovate, leathery leaves, polygamous; regular flowers arranged in small cymes, and a stellate fruit of five diverging carpels. The perfect flowers have a five-lobed, valvate calyx; five imbricated, narrow, spatulate petals, a conspicuous five-lobed glandular disc; between the lobes of this disc are five stamens opposite the petals, and arising from the lobes five more opposite the sepals. Ovary five-celled, many-ovuled. Seeds flattened, conspicuously winged. The central flower of each cyme is perfect, the lateral are usually staminate. This species is a native of Central America and of the tropical parts of South America, Peru, Brazil, Chili, etc. It is of common occurrence, and its bark has been known to be useful in washing for a long time.

Soap Bark is imported in considerable quantities, for various purposes connected with manufacture—sizing, cleansing, etc.—and has of late found a not very commendable place in syrups for aerated waters, and in beers, to make them hold their froth. It is a recent addition to the officinal list, and is described as follows: "Flat, large pieces, about one-fifth of an inch (5 millimetres) thick; outer surface brownish-white, often with small patches of brown cork attached, otherwise smooth; inner surface whitish, smooth; fracture splintery, checkered with pale brownish bast-fibres, embedded in white tissue; inodorous, very acrid and sternutatory."

This bark contains, as its only valuable derivative, *Saponin* (*Quillain*) to the extent of eight per cent.—a white, amorphous, neutral powder, of, at first, a sweetish, afterward sharp, burning taste. It is odorless, but provokes violent sneezing. Water dissolves it readily, and even with so little as one-tenth of one per cent. holds its bubbles like soap-suds. Strong alcohol dissolves it but little, ether almost none. Saponin is a glucoside, and yields *Sapogenin* upon treatment with diluted acids. It is also claimed by recent analysts that it is not a pure compound, but a mixture of *quillaic acid, sapotoxin*, and others, of

FIG. 3561.—Soap-bark Tree. (Baillon).

which the two named are active muscle-poisons, especially if administered subcutaneously.

USES.—Soap Bark, or an infusion or tincture made from it, is useful as a detergent in washing fine linens, laces, etc., cleaning the surface of paintings and other fine work of that kind. It is also an ingredient of some cosmetic preparations—lotions, hair-washes, etc. Its use in syrups has been referred to; it has been further employed to a small extent as an emulsifying agent. Physiologically it is a pretty active substance, paralyzing voluntary muscles with considerable rapidity, and producing local anæsthesia. It is also a local irritant. These properties have not, however, been put to therapeutic use. As an expectorant, in small doses, it has been recommended, also as an alterative in place of sarsaparilla, but its value is at least doubtful.

ALLIED PLANTS.—See ROSES.

ALLIED DRUGS.—SOAPWORT (see next article). *Saponaria officinalis* Linn., and numerous other plants of the Pink family contain saponin in their roots. So do the Polygalas (see SENEGA). It is also found in individual species of several other orders. There is some doubt as to the exact identity of the saponin of these different plants, as the different names given to it will show—*Struthiin, Polygalin, Githagin, Monninin*, etc.

See also SARSAPARILLA. *W. P. Bolles.*

SOAPWORT (*Saponaire officinale*, Codex Med.; "Bouncing Bet"), *Saponaria officinalis* Linn., order *Caryophyllaceæ*, is a very well-known European perennial herb, freely naturalized here, and often a troublesome weed around the edges of gardens and in rich waste places. It is about two feet high, with ovate, opposite, usually sessile, three- or five-nerved leaves, and cymes of large white, or pink-colored, pink-like flowers clustered at the top of the stem. All parts of the plant, but especially the roots, contain the neutral, amorphous, white, acrid, sternutatory substance *saponin*, described in the preceding article. Soapwort may be used, like Quillaia, to make

a viscous suds-like solution for washing or sizing. It is also said to be employed in the preparation of mucilaginous expectorant teas (*tisanes*).

ALLIED PLANTS.—The order to which *Saponaria* belongs contains a large number of rather bland, mucilaginous, or at least saponin-containing plants, few of which have any medicinal value, but many of them are favorite and beautiful flowers, *e.g.*, Pinks, of many kinds. *Agrostemma* and *Gypsophila* are genera notable for the amount of saponin they contain.

ALLIED DRUGS.—Quillaia, Sarsaparilla, Senega.

W. P. Bolles.

SODEN, Province of Hesse-Nassau, Prussia. This watering-place, lying in the valley of the Taunus, at an elevation of four hundred and sixty feet above tide-water, is well protected on the north from cold winds, and enjoys, in consequence, a very mild climate. In midsummer, indeed, it is sometimes too hot for comfort, and the pleasantest times of the year for a stay at Soden are the spring and fall.

The mineral springs are twenty-four in number, and differ considerably in the proportion of mineral ingredients and in the temperature of their waters. The waters are saline, and contain also varying proportions of alkaline and ferrous carbonates. The proportion of sodium chloride runs all the way from 2.4 to 14.6 parts per thousand, and that of ferrous carbonate from 0.009 to 0.04 part in a thousand. The temperature of the different springs varies between 59° and 86° F.

The diseases for the relief of which Soden is visited are chiefly chronic affections of the respiratory organs. Advanced pulmonary phthisis is, however, seldom benefited by a stay at this resort. Chronic catarrhal affections of the digestive tract, and anæmia and debility occurring during convalescence from acute diseases, also furnish indications for a course of treatment at Soden. The therapeutic methods employed are similar to those in use in other German spas. The season extends from May to November. *T. L. S.*

SODIUM. I. GENERAL MEDICINAL PROPERTIES OF THE COMPOUNDS OF SODIUM.—From the close chemical alliance between sodium and potassium, theory would assign to compounds of sodium physiological properties similar in kind to the corresponding potassic compounds, but less strongly pronounced. The prediction is true in that the sodic effects, such as they are, are potassic effects weakened; but an inference that all the potassic effects, in kind, will be reproduced to some degree in the action of sodium, will not hold. Referring to the article Potassium, the notable effects of that metal are irritation, catharsis, cardiac paresis, general motor paresis, oxidation quickening, and, toxicologically, general toxæmia. Sodium, in comparison, is irritant, salt for salt, in decidedly less degree; is purgative in only slightly less degree; paralyzes heart and motor function so very little that the action only appears at all in excessive dosage in animal experimentation; scarcely seems to quicken oxidation at all, nor, even in fullest dosage, to impoverish the blood after the manner of potassium. So far, however, as concerns those compounds of sodium that are alkaline in reaction, or which, as in the case of citrates, acetates, and tartrates, are converted into an alkaline compound in the blood, the degree of alkalinity is but little less than that of the analogous potassic compounds, and hence the effects that follow, simply from the fact of such alkalinity, are, with sodic compounds, well pronounced. But yet, therapeutically, so far as constitutional alkalizing is concerned, the diseases calling for alkaline medication are also specifically benefited by the specific potassium effects, so that in their case sodic salts, though efficiently alkaline enough, still cannot compete in curative power with their potassic rivals.

II. THE MEDICINALLY USED COMPOUNDS OF SODIUM.—As in the case of potassium, those compounds only will be here discussed whose effects are either *sui generis* to the compound, or are determined mainly by the basic radicle. Such salts, officinal in the U. S. Pharmacopœia, are the following: *Hydroxide* (hydrate), *carbonates*, normal and acid, (pyro-) *borate*, *acetate*, *potassio-sodic tartrate*, *sulphate*, *phosphate*, *pyrophosphate*, *nitrate*, and *chlorate*. Of these the potassio-sodic tartrate (Rochelle salt) will be found discussed under the title POTASSIUM. Other sodic salts, whose properties are mainly derived from the acid radicle of the composition, are treated of under the title of such radicle. Such pharmacopœial salts are the following: *Arseniate*, see ARSENIC; *benzoate*, see BENZOIC ACID; *bromide*, see BROMIDES; *chloride*, see CHLORIDES; *hypophosphite*, see HYPOPHOSPHITES; *hyposulphite*, see SULPHITES; *iodide*, see IODIDES; *salicylate*, see SALICYLIC ACID; *santoninate*, see WORMSEED; *silicate*, see SILICATES; sulphite, see SULPHITES; sulpho-carbolates, see SULPHO-CARBOLATES.

Sodic Hydroxide (Hydrate): NaOH.—This substance, commonly called *Caustic Soda*, is officinal in the U. S. Pharmacopœia, in solid condition, under the title *Soda*, Soda, and in about five per cent. aqueous solution, as *Liquor Sodæ*, Solution of Soda. Soda is "a white, hard, opaque solid, generally in form of fibrous pieces, or of white cylindrical pencils, deliquescent in moist air, but in dry air becoming dry and effiorescent, odorless, having an intensely acrid and caustic taste, and a strongly alkaline reaction. Soluble in 1.7 part of water at 15° C. (59° F.), and in 0.8 part of boiling water; very soluble in alcohol. When heated nearly to a red heat, it melts, forming an oily liquid. At a strong red heat, it is slowly volatilized unchanged. Its aqueous solution dropped into solution of tartaric acid, so that the latter remains in excess, produces neither a precipitate nor cloudiness" (U. S. Ph.). Soda "should be kept in well-stopped bottles made of hard glass." Soda is commonly made by evaporating an aqueous solution of the substance, until the water is driven off and the hydroxide remains in a state of fusion, and then either pouring the viscid fluid into cylindrical moulds or allowing it to harden *en masse*. Solution of soda may be made by dissolving soda in water, but is commonly prepared from the carbonate by decomposition with lime in the presence of water. Calcic carbonate precipitates, and the solution of soda, clarified by straining and settling, is separated by siphonage. Solution of soda is "a clear, colorless liquid, odorless, having a very acrid and caustic taste, and a strongly alkaline reaction. Specific gravity about 1.059" (U. S. Ph.).

Soda and its solution are powerfully alkaline and caustic, like potassa, but to a somewhat inferior degree. Soda is available as a caustic, to be used after the manner of potassa, but potassa being the stronger agent, is generally preferred. Solution of soda is possible as a local alkali for the skin or the stomach, but the carbonates are almost always used in preference. If given internally, the dose of solution of soda would range from 1.00 to 4.00 Gm. (fifteen to sixty minims), largely diluted. In considerable quantity, undiluted, solution of soda would prove a caustic poison, with symptoms generally similar to those of poisoning by potassa.

Normal Sodic Carbonate: $Na_2CO_3.10H_2O$.—Sodic carbonate in crystals or effloresced powder is officinal in the U. S. Pharmacopœia as *Sodii Carbonas*, Carbonate of Sodium; and the effloresced powder, baked "at a temperature of about 45° C. (113° F.)" until it has lost one-half its weight by the driving off of its water of crystallization, is also officinal under the title of *Sodii Carbonas Exsiccatus*, Dried Carbonate of Sodium. Sodic carbonate is the salt commonly called *sal soda* or *washing soda*, and is obtained in part from natural deposits—"native soda," so called—in part from the ashes of certain plants growing in or near the sea, the impure yield of which constitutes *barilla* or *kelp*, and in part by artificial making from sodic chloride, sodic sulphate, or the mineral *cryolite*. Sodic carbonate occurs as "large, colorless, monoclinic crystals, rapidly efflorescing in dry air, and falling into a white powder, odorless, having a sharp, alkaline taste, and an alkaline reaction. Soluble in 1.6 parts of water at 15° C. (59° F.), in 0.09 part at 38° C. (100.4° F.), and in 0.25 part of boiling water; insoluble in alcohol. When heated to about 35° C. (95° F.), the

salt melts; on further heating, all the water (62.9 per cent.) gradually escapes, and, at a red heat, the anhydrous residue fuses. A fragment of the salt imparts an intense yellow color to a non-luminous flame. The aqueous solution strongly effervesces on the addition of an acid" (U. S. Ph.). The dried salt of the Pharmacopœia, a fused mass as first prepared, finally presents itself as a white powder. Both forms of the carbonate should be kept in well-stopped bottles.

Sodic carbonate combines, very purely, strong alkalinity with absence of specific qualities of any kind except the irritation or even causticity in concentrated application which is inherent in a powerful soluble alkali. Its uses are solely those of a local alkali, and are practically confined to external employment in lotion or ointment in skin-affections. Lotions average two per cent. in strength, and ointments between two and ten, the basis being lard. For internal use, the acid carbonate, next to be described, is preferred, because of its more agreeable flavor and milder action. In considerable quantity and strong solution the normal carbonate is a corrosive poison.

Acid Sodic Carbonate: $NaHCO_3$.—This salt, the well-known *cooking-soda*, so called, is officinal in the U. S. Pharmacopœia in two grades of purity. One, corresponding to ninety-five per cent. of the pure salt, is entitled *Sodii Bicarbonas Venalis*, Commercial Bicarbonate of Sodium; and the other, made from this commercial variety by a process of purification, and corresponding to ninety-nine per cent. of pure salt, is called by the unqualified title *Sodii Bicarbonas*, Bicarbonate of Sodium. This carbonate is derived primarily from the normal salt by artificially forcing upon the latter carbon dioxide gas. Bicarbonate of sodium occurs as "a white, opaque powder, permanent in the air, odorless, having a cooling, mildly saline taste, and a slightly alkaline reaction. Soluble in twelve parts of water at 15° C. (59° F.), and insoluble in alcohol. It is decomposed by hot water. When heated to about 70° C. (158° F.), the salt begins to lose moisture and carbonic acid gas, and, on continued heating, loses about thirty-seven per cent. in weight. At a red heat the anhydrous residue melts; and a fragment of the salt imparts an intense yellow color to a non-luminous flame. The aqueous solution, on being heated disengages carbonic acid, and finally contains carbonate of sodium" (U. S. Ph.).

The bicarbonate of sodium, is purely alkaline, like the normal salt, but to a less degree, and by reason of that fact is far less irritant. In all ordinary dosage it is indeed practically free from danger. Its taste also is mildly mawkish only, instead of harshly alkaline. For these various reasons this salt is a favorite one for stomachic alkalizing, as in acid dyspepsia or diarrhœa. It is also much used to make alkaline lotions for the skin. Internally from 1.00 to 4.00 Gm. (fifteen to sixty grains), may be given at a dose in water, and externally washes or ointments may be made in the same manner and of the same strengths, as in the case of the normal carbonate. Both of the carbonates are incompatible with acids and acidulous salts, lime-water, ammonic chloride, and salts of the metals, and metals of the earths.

Troches of the bicarbonate—*Trochisci Sodii Bicarbonatis*—are officinal in the U. S. Pharmacopœia, each troche containing 0.20 Gm. (three grains) of the salt. The salt is also an ingredient of the pharmacopœial preparations, *Mistura Rhei et Sodæ*, for which see Rhubarb, and *Pulvis Effervescens Compositus*, for which see *Potassio-Sodic Tartrate*, under Potassium.

Sodic (Pyro-) Borate: $Na_2B_4O_7, 10H_2O$.—This salt—the familiar substance *borax*—is officinal in the U. S. Pharmacopœia as *Sodii Boras*, Borate of Sodium. It occurs as "colorless, transparent, shining, monoclinic prisms, slightly efflorescent in dry air, odorless, having a mild, cooling, sweetish, afterward somewhat alkaline taste, and an alkaline reaction. Soluble in 16 parts of water at 15° C. (59° F.), and in 0.5 part of boiling water; insoluble in alcohol. At 80° C. (176° F.) it is soluble in one part of glycerin. When heated, the powdered salt begins to lose water, then melts; on further heating, swells up and forms a white porous mass, which, at a red heat, fuses to a colorless glass, with complete loss of water of crystallization (47.1 per cent.). A fragment of the salt imparts an intense yellow color to a non-luminous flame. The saturated aqueous solution, on the addition of sulphuric acid, deposits shining crystalline scales, which impart a green color to the flame of alcohol" (U. S. Ph.). Borax occurs native in Persia and adjacent neighborhoods as a saline efflorescence of the borders of lakes, and in California as a crystalline deposit at the bottom of a small lake. It is also made from other native borates.

Borax is locally bland and constitutionally innocent, and its medicinal virtues seem to reside in the combination of feeble alkalinity with a fair degree of antiseptic power derived from its acid radicle. Borax works well as a mild detergent alkali in skin-diseases or catarrhs, and ulcerations of mucous membranes, particularly of the mouth. A lump held in the mouth and slowly sucked seems to excite the secretions of pharynx and larynx, and in case of huskiness from dry catarrh of these parts temporarily restores something of the natural quality to the voice—an important matter to a singer or speaker affected with a cold. Internally, borax may be used as a feeble alkali, and it has been accredited also with a power to promote menstruation, correct dysmenorrhœa, and excite uterine contractions—a power which until better substantiated than at present, it is wisest not to trust to in an emergency. Borax may be given internally in doses of from 1.00 to 3.00 Gm. (fifteen to forty-five grains), and, externally, may be applied in lotions ranging from one to six per cent. in strength (limit of solubility in water), or in ointment of thirty per cent. strength. Borax has been experimented with, among a host of other substances, for the purposes of "antiseptic surgery," and has been experimentally found to prevent the development of microzymes in aqueous solution of from one-half to one per cent. strength.[1]

Sodic Acetate: $NaC_2H_3O_2.3H_2O$.—The salt is officinal in the U. S. Pharmacopœia as *Sodii Acetas*, Acetate of Sodium. It occurs as "large, colorless, transparent, monoclinic prisms, efflorescent in dry air, odorless, having a saline, bitter taste, and a neutral or faintly alkaline reaction. Soluble in 3 parts of water, and in 30 parts of alcohol at 15° C. (59° F.); in 1 part of boiling water, and in 2 parts of boiling alcohol. When heated, the salt melts, and on further heating loses all its water (39.7 per cent.), and falls into a white powder. At a higher temperature this powder again melts, and, at a red heat, it is decomposed, with the evolution of empyreumatic, inflammable vapors, leaving a blackened residue of an alkaline reaction, which imparts to a non-luminous flame an intense yellow color, not appearing more than transiently red when observed through a blue glass. On adding sulphuric acid to a concentrated solution of the salt, and heating, vapor of acetic acid is evolved. A solution of the salt is rendered deep red by ferric chloride, and, on boiling, a red precipitate is formed" (U. S. Ph.). Sodic acetate hardly merits the foregoing detailed description, since it is very rarely used in medicine. Its purpose would be as a constitutional sodic alkali, its acid, as in the case of other alkaline acetates, undergoing conversion, in the blood, to carbonic. It may be administered in doses of from 2.00 to 4.00 Gm. (thirty to sixty grains).

Potassio-sodic Tartrate. (See under POTASSIUM.)

Normal Sodic Sulphate: $Na_2SO_4.10H_2O$.—This salt, commonly called *Glauber's Salt*, is officinal in the U. S. Pharmacopœia as *Sodii Sulphas*, Sulphate of Sodium. It occurs in "large, colorless, transparent, monoclinic prisms, rapidly efflorescing on exposure to air, and ultimately falling into a white powder, odorless, having a cooling, saline, and somewhat bitter taste, and a neutral reaction. Soluble in 2.8 parts of water at 15° C. (59° F.), in 0.25 part of water at 33° C. (91.4° F.), and in 0.4 part of boiling water; insoluble in alcohol. When heated to about 30° C. (86° F.), the salt melts, and, on further heating, gradually loses all its water (55.9 per cent.). At a red heat the anhydrous salt melts without decomposition. A fragment of the salt imparts to a non-luminous flame an intense yellow color, not appearing more than tran-

siently red when observed through a blue glass. The aqueous solution yields, with test-solution of chloride of barium, a white precipitate, insoluble in nitric acid" (U. S. Ph.). The salt should be kept in well-stopped bottles. Sodic sulphate is formed as a by-product in the manufacture of many chemicals. It is a salt of low diffusion-power, and hence in full dose, in comparatively strong solution, is a purgative. As such it is, like the other alkaline sulphates, powerful in action, producing watery stools, with nausea and griping. From its sickening taste it has been almost wholly superseded by the less disagreeable magnesic sulphate (Epsom salt). From 15.00 to 30.00 Gm. (half to one ounce) is a full purgative dose, to be taken in aqueous solution, aromatized or slightly acidified to disguise the nauseous bitter taste of the salt. Sodic sulphate is a purgative ingredient of many mineral waters.

(Di-) Sodic (Ortho-) Phosphate: $Na_2HPO_4.12H_2O$.—This salt, the common tribasic phosphate, so called, or *tasteless purging salt*, is officinal in the U. S. Pharmacopœia as *Sodii Phosphas*, Phosphate of Sodium. It occurs in "large, colorless, transparent, monoclinic prisms, speedily efflorescing and becoming opaque on exposure to air, odorless, having a cooling, saline, and feebly alkaline taste, and a slightly alkaline reaction. Soluble in six parts of water at 15° C. (59° F.), and in two parts of boiling water; insoluble in alcohol. When heated to about 40° C. (104° F.) the salt melts, yielding a clear liquid, and, on continued heating to near 100° C. (212° F.), it loses all its water of crystallization (60.3 per cent.). A fragment of the salt imparts to a non-luminous flame an intense yellow color, not appearing more than transiently red when observed through a blue glass" (U. S. Ph.). Sodic phosphate is made from the calcic phosphate of calcined bone, by decomposition by sulphuric acid. It should be kept in well-stopped bottles in a cool place.

Sodic phosphate is a bland salt, of low diffusion-power, whose prominent physiological properties are to purge mildly, and, as animal experimentation has shown,[2] to quite notably excite the secretion of bile. At the same time it is feebly alkaline, and possessed of a clean, non-nauseous, salty taste, quite like that of common salt. Therapeutically this phosphate may be used for the general purposes of the milder saline purges, and, more specially, has also proved of avail, even in non-purgative doses, to correct bowel-derangements associated with acidity and assumed sluggishness of the liver. From its mildness and not unpleasant taste it is particularly convenient for giving to young children. Mixed with foods, such as soup, in lieu of common salt, it may be administered in moderate quantity without suspicion. As a purge the dose for an adult is about 30.00 Gm. (one ounce); but for corrective purposes, much less—even so little as 0.65 Gm. (ten grains)—given a number of times through the day, may suffice.

Normal Sodic Pyrophosphate: $Na_4P_2O_7.10H_2O$.—The salt is officinal in the U. S. Pharmacopœia as *Sodii Pyrophosphas*, Pyrophosphate of Sodium. It is not used in medicine, and is officinal for pharmaceutical purposes only to prepare ferric pyrophosphate.

Sodic Nitrate: $NaNO_3$.—The salt is officinal in the U. S. Pharmacopœia as *Sodii Nitras*, Nitrate of Sodium. It occurs in "colorless, transparent, rhombohedral crystals, slightly deliquescent in damp air, odorless, having a cooling, saline, and slightly bitter taste, and a neutral reaction. Soluble in 1.3 part of water at 15° C. (59° F.), and in 0.6 part of boiling water; scarcely soluble in cold, but soluble in 40 parts of boiling alcohol. When heated to about 312° C. (594° F.), the salt melts, and on further heating it is decomposed, giving off oxygen and leaving a residue which emits nitrous vapors on the addition of sulphuric acid. Thrown upon red-hot coals the salt deflagrates. A fragment of the salt imparts to a non-luminous flame an intense yellow color, not appearing more than transiently red when observed through a blue glass" (U. S. Ph.). The salt should be kept in well-stopped bottles. Sodic nitrate is the salt called *cubic nitre*, and is obtained from South America, where it occurs native. It is a salt of high diffusion-power, and in its physiological relations closely resembles ordinary nitre (potassic nitrate), except that it is, of course, devoid of the characteristic properties of a potassic salt as such. Its use in medicine has so far been an empirical employment in dysentery, in which disease 30.00 Gm. (one ounce) of the salt has been given divided in frequent doses throughout the day, in dilute aqueous solution. It is not a standard medicine.

Sodic Chlorate: $NaClO_3$.—The salt is officinal in the U. S. Pharmacopœia as *Sodii Chloras*, Chlorate of Sodium. It occurs in "colorless, transparent, tetrahedrons of the regular system, permanent in dry air, odorless, having a cooling, saline taste, and a neutral reaction. Soluble in 1.1 parts of water, and in 40 parts of alcohol at 15° C. (59° F.); in 0.5 part of boiling water, and in 43 parts of boiling alcohol. When heated, the salt melts and afterward gives off a portion of its oxygen, finally leaving a residue of a neutral reaction completely soluble in water. A fragment of this residue imparts to a non-luminous flame an intense yellow color, not appearing more than transiently red when observed through a blue glass" (U. S. Ph.). The salt "should be kept in well-stopped bottles, and should not be triturated with readily oxidizable or combustible substances." Sodic chlorate has the peculiar medicinal properties of the potassic salt of the same acid, except in regard to the effects of potassium compounds as such. It is important only because of its excess of solubility as compared with potassic chlorate. The medicinal uses are the same as those of the latter-named salt, which see under Potassium.

SOILS IN THEIR RELATION TO HEALTH. It would be impossible to thoroughly understand and predict the effect of soils on health, under the constantly varying conditions of civilized life, without a knowledge of their origin, composition, and characteristics.

DEFINITION OF SOIL.—Soils may be defined as débris resulting from the action of natural forces on the rocks covering the surface of the earth. This disintegration is constantly going on; mountains are being broken down by the action of frost and heat; the disrupted pieces are being carried down the slopes and broken into finer pieces by the streams and torrents; and the finer particles are being carried still farther by the rivers, till they are deposited either along the banks in alluvial flats, or in deltas. In the early history of this planet the ocean was the great destroyer, beating against the rocks that had been elevated by the shrinking of the earth's crust; breaking them down and grinding them into fine particles and finally carrying away the lighter portions and depositing them in quiet bays and lagoons. It might be supposed that soils would resemble the underlying rocks, *i.e.*, sandy soils superimposed on sandstone, marls on limestone, and the like. This, however, is not always the case; soils of different kinds being scattered seemingly at random over the face of the globe.

STRUCTURE OF SOILS.—"Soil, examined mechanically, is found to consist entirely of particles of all shapes and sizes, from stones and pebbles down to the finest powder, and on account of their extreme irregularity of shape, they cannot lie so close to one another as to prevent there being passages between them, owing to which circumstance soil in the mass is more or less *porous*." Even the smallest particles are "not always solid, but are much more frequently porous, like soil in the mass." "A considerable portion of this finely divided part of the soil, *the impalpable matter* as it is generally called, is found, by the aid of the microscope, to consist of broken-down vegetable tissue; so that when a small portion of the finest dust from a garden or field is placed under the microscope, we have exhibited to us particles of every variety of shape and structure" ("Minutes of Information on Drainage"). The spaces that exist between these particles, or the "pores" of the soil, may be divided into two classes: "First, the large ones which exist between the particles; and, second, the very minute ones which

occur in the particles themselves." "The larger pores—those between the particles of soil—communicate most freely with each other, so that they form canals; the small pores, however freely they may communicate with one another in the interior of the particle in which they occur, have no distinct connection with the pores of the surrounding particles."

COMPOSITION OF SOILS.—The particles described above may be divided into two great classes: Organic and inorganic. "The organic part of soils, called 'humus' by some writers, is derived chiefly from the remains of vegetables and animals which have lived and died in or upon the soil; which have been spread over it by rains; or which have been added by the hands of man for the purpose of increasing its natural fertility" ("Elements of Agricultural Chemistry and Geology," J. F. W. Johnson). The proportion of this organic matter varies in different soils; as, for instance, in peaty soils it forms fifty to seventy per cent. of the whole weight, while in ordinary good soil it does not rise much above eight per cent. Humus furnishes carbonic acid, ammonia, and some other compounds.

The *inorganic* part of soils may be divided into those substances which are soluble and those which are not soluble in water. The soluble portion consists mainly of common salt, gypsum, sulphate of soda, and sulphate of magnesia, with traces of the chlorides of calcium, magnesium, and potassium, and of soda, potash, lime, and magnesia in combination with nitric and phosphoric, and with humic and other organic acids. This soluble portion is so great in some countries as to form a white incrustation on the surface of the ground in hot seasons. The insoluble portion of soils rarely forms less than ninety-five per cent. by weight, and consists mainly of silica, alumina (usually thirty to thirty-five per cent.) and lime, in the form of sand, clay, and lime.

CLASSIFICATION OF SOILS.—Soils are classified according to the proportion of these three constituents (sand, clay, and lime), as they are "all either sandstones, limestones, or clays of different degrees of hardness, or a mixture in different proportions of two or more of them." A *sandy soil* is any dry soil not unusually rich in vegetable matter, and containing not more than ten per cent. of clay. A *sandy loam* is similar to the above, but contains from ten to forty per cent. of clay. A *loamy* soil contains seventy to eighty-five per cent. of clay; a *clay loam* seventy to eighty-five per cent. A proportion of from eighty-five to ninety-five per cent. of clay makes a *strong clay* soil, and where no sand is present we have a pure *agricultural clay*. Soil containing more than five per cent. of carbonate of lime is called a *marl;* more than twenty per cent., a *calcareous soil.*

PHYSICAL CHARACTERISTICS.—The density of different soils varies greatly, as, for example, dry peaty soils weigh less and are less dense than sands and marls. The absorbing power also varies greatly, strong clays taking up and retaining nearly three times as much water as sandy soils. The temperature of dry soils is usually ten degrees higher that than of wet soils. A dry soil may have a temperature of 90° to 100° F. when the thermometer registers 60° or 70° F. in the shade in the air above it. By *capillary action* water rises from ten to eighteen inches in different kinds of soils. Where this action is great, a wet subsoil will render the soil above it cold. *Evaporation* takes place from soils as it does from the surface of water, but its rate varies according to the nature of the soil. A silicious sand, for instance, loses its water three times as rapidly as a clay soil. All soils diminish in bulk or shrink more or less in drying. Sand scarcely shrinks at all, while peat loses one-fifth of its bulk. Clay, in shrinking, cracks; a property that is of great service in draining cold, retentive soils. *Absorption of moisture from the air* by soils takes place at night, when they extract from it a portion of the water they have lost by evaporation during the day. This power, however, varies in different soils, as do all other physical characteristics, sand absorbing the least and peat the most.

WATER IN THE SOIL.—Water in the soil is principally derived from rain or snow, which, falling on the surface, sinks into the ground until it meets with either an impervious stratum or with the upper level of the "ground-water," after which its movements are governed by identically the same laws as those affecting the flow of water on the surface of the ground. Moisture in soils is that condition in which the pores of the particles (already described) are filled with water. The term "ground-water" is applied to the water filling the interstices between the particles. This ground-water may be likened to a vast subterranean lake; its level constantly rises and falls as a consequence of the influx of surface-water, evaporation, influence of the tide, and many other causes. The height of the "plane of saturation," as the surface of the ground-water is called, is shown by the depth of the surface of the water in wells below the ground. This is not always a certain indication, as local causes at times influence the height of water in wells. Friction in the pores of the soil retards the flow and gives an inclination to the plane of saturation, varying with the nature of the geological formation, but in all cases as great as that of the streams flowing along the adjacent lines of natural surface-drainage. The inclination of the plane of saturation is about fifteen feet per mile in chalk; in sand, as on Long Island, N. Y., it is between five and eight feet per mile. When the slope is less than that of the adjacent stream, the stream dries up. That ground-water is constantly flowing into streams throughout their entire course was shown by a series of measurements of the Cache la Poudre River, Colorado, made by G. G. Anderson in connection with irrigation-works. The inflow from the ground, in a distance of forty miles in which no tributaries entered the river, no allowance being made for evaporation or other loss, was sixty-eight per cent. of the quantity of water flowing in the river at the head of the section under examination.

The inclination of the surface of the underground water is independent of the position of the underlying strata or of the inclination of the surface of the ground.

"The rapidity with which rain-water sinks through the soil evidently varies with circumstances; in rather dense chalks it has been supposed to move three feet downward every year; but in the sand its movements must be quicker" (Parkes).

The quantity of water the soil will absorb from rain is dependent on: 1, The character of the soil, whether porous or otherwise; 2, the inclination of the surface, a steep slope allowing the water to pass off rapidly, while a more gentle slope gives time for it to be absorbed by the ground; 3, the quantity of water already in the soil; 4, the character of the rainfall, whether gentle and not overtaxing the absorbing power of the soil, or heavy and flooding the surface and passing rapidly to the nearest water-course; 5, the season of the year, evaporation being more rapid in summer than in winter.

The temperature of the ground-water approximates the mean temperature of the atmosphere for the year.

The evidences of a saturated soil are: 1, Wet spots on dry land; 2, cracks and fissures of the surface in dry weather; 3, a wet condition of the land remaining after rains.

The disadvantages of an excess of moisture in the soil, as given in the Second and Third Reports of the Metropolitan Sanitary Commission, are:

"1. Excess of moisture, even on lands not evidently wet, is a cause of fogs and damps.

"2. Dampness serves as a medium of conveyance for any decomposing matter that may be evolved and adds to the injurious effects of such matter in the air; in other words, the excess of moisture may be said to increase or aggravate atmospheric impurities.

"3. The evaporation of the surplus moisture lowers the temperature, produces chills, and creates or aggravates the sudden and injurious changes or fluctuations of temperature by which health is injured."

"The influence of humidity of the soil on diseases usually affected by this condition seems to be very much modified in localities with a stratum through which salt-water freely percolates, such as the flat, sandy sites of some sea-side towns. Investigations have determined this

point, at least so far as phthisical complaints are concerned. The principal reason assigned is the free circulation of the water through the pores of the soil, caused by the alternate rise and fall of the tide, whereby stagnation of water and changes in the soil, which would otherwise occur, are prevented. The peculiar character of the water and the conditions of the atmosphere may have some modifying influence. In such places deep subsoil drainage is impracticable, even by the aid of pumping" (Ford).

WELLS are devices for reaching or collecting ground-water to be used for the wants of man. Water cannot be drawn from wells unless they are deep enough to reach the level of saturation in the soil. For this reason wells vary in depth. All the conditions affecting the purity of the soil affect also the purity of the well-waters of that locality, for well-water is ground-water. Wells may be likened to a drain set on end, into which the ground-water flows from all directions. The soil thus drained resembles a cone in shape, with its apex at the bottom of the well and its base at the surface of the ground. The distance from which wells draw water depends on the porosity of the soil, on the depth below the plane of saturation to which they are carried, and on the draft made on them by man. In sand, the water of a well has been affected at a distance of three hundred feet from the source of contamination. The less rain there is, the lower the plane of saturation sinks, and the greater, then, will be the distance from which a well will draw its water. Hence it is that in droughts there is more danger of pollution than during rainy seasons. Fox, in his "Sanitary Examinations of Water, Air, and Food," says: "The water of wells is greatly influenced (1) by the height of subsoil water, which is always varying; (2) by the amount of water that is passing through the subsoil of a country; and (3) by heavy downfalls of rain or periods of drought. I have many times found a water pure at one time and impure at another, and this occasional pollution of a water is often due to the periodical washing of filth into a well by heavy rains. The disagreement in the opinions of able analysts inspecting the purity of samples of water, taken perhaps within a short interval of time from the same well, is often due to these causes, which are not sufficiently recognized."

In a series of exhaustive experiments on the supply of wells, made in 1884, by J. C. Hoadley, C.E., it was demonstrated that the quantity of water available was the same whether it was pumped from an open well or from an iron tube driven into the ground to the same depth. It was also shown "that the convergent flow of ground-water not already in contact with the exterior surface of a suction pipe, from any point or from all points, toward and up to wetting contact with such pipes, is due alone to gravitation acting upon a slope toward a depressed surface produced by drawing water out of the pipe and from immediate contact with its outer surface. The sole impelling force is the earth's gravitation. An obstructing force, in addition to the viscidity of water—namely, the interstitial friction of the soil—retards the water-flow, and causes the water surface to take a sensible slope, steeper as the interstitial friction is greater, less steep as the friction is less."

Von Fodor, in order to determine the effect of natural waters on animals when injected hypodermically, subjected rabbits to the influence of comparatively pure well-water, impure water, and sewage. The symptoms produced were wide fluctuations in temperature, with diarrhœa, varying with the impurity of the water. These experiments seemed to show that although the most impure waters, in themselves, possess but slight infecting power, their effect on the individual must be to derange the system and undermine the health and predispose to attacks of disease.

Wells of fresh water near the sea-shore are supplied by the flow of fresh water underground on its way to the sea. The greater pressure of the ground-water, due to the altitude of its gathering-grounds, prevents the passage of sea-water into the soil. Springs of fresh water have been found, forcing their way to the surface, far out at sea. Nichols asserts that "the freshness of the water is not due to the removal of saline matter from infiltering salt-water, and the rise and fall of the water of such wells with the tide is due to the indirect influence of the tide in offering more or less resistance to the outflow of ground-water."

SPRINGS are the natural outbursts of subsoil water in motion, on the surface of the ground. They exist under one of three conditions:

1. The outcrop of a porous or "water-bearing" stratum between two impermeable strata. The water absorbed by the porous stratum at a greater elevation (it may be miles away) is confined in its flow underground by the impermeable strata above and below, until the lower outcrop is reached, when it flows out over the surface as from a pipe.

2. The outcrop of the rim of a depression in an impervious stratum, or "punch-bowl," over which the ground-water, collected in the cavity, flows on the surface.

3. At the base of a hill the inclination of the surface of the plane of saturation becomes suddenly less, the friction in the pores of the soil exerts a greater influence on the velocity, and the ground-water, being unable to pass off entirely through the soil, is forced to the surface by the pressure of the water behind it on the slope.

Springs of the second and third classes are far more liable to be polluted than those of the first class, and in sanitary examinations, considerations that apply to wells should with equal reason be applied to them.

AIR IN THE SOIL.—The intestices between the particles of soil situated between the level of the ground-water and the surface of the ground are filled with air, the quantity of which is dependent on the porosity of the soil. This air being free to move in every direction is in constant motion. As the level of the ground-water sinks, air is drawn into the pores of the soil; as it rises, the air is forced into the atmosphere to make room for the incoming water. "The diurnal changes of heat in the soil," the state of the winds and of the atmosphere, are all factors in this movement. The composition of this air varies greatly in different localities and under different circumstances. As a rule, however, it is very rich in carbonic-acid gas, besides containing marsh gas and some sulphuretted hydrogen. To determine the composition of ground-air and the laws governing the distribution of its elements, Professor W. R. Nichols, in 1875, made a series of experiments in the "Back Bay" district of Boston, Mass., on land made by filling in large areas of mud flats. He says, "The gaseous products of decay which might be expected to be produced from such a mixture of animal and vegetable matter are sulphuretted hydrogen, ammonia, carbonic acid and marsh gas; the first, sulphuretted hydrogen, was not detected even in the air taken fourteen inches from the surface of the ground, *i.e.*, less than six inches from the top of the decaying matter; ammonia was not found in any appreciable amount; there seemed to be a small amount of marsh gas formed, and of carbonic acid a very large quantity was produced. The amount of carbonic acid was greatest in the neighborhood of the decaying matter, and decreased in amount toward the surface of the ground." The observations were repeated at a later period, and showed that the amount of carbonic acid was steadily decreasing, and that marsh gas had entirely disappeared, due probably to the gradual resolving of the organic matters into their elements by the action of oxygen. The effect of diffusion into the atmosphere was shown by the fact that "at a few feet from the ground no excess of carbonic acid could be detected." Other experimenters have found that while the carbonic acid increases with the depth below the surface, the oxygen in the ground-air decreases, so that "at a depth of four metres (thirteen feet) the air would be irrespirable, and would extinguish a light."

To prevent the entrance of ground-air into a dwelling is a matter of the greatest importance. The usual method is to coat the floor of the cellar with cement, concrete, asphalt, or coal-tar pitch. It is a fallacy to suppose that the first two substances accomplish the purpose; they are porous, and the writer's experiments show that

they have little effect in preventing the ingress of ground-air. The last two are, however, admirable for the purpose, as they are impermeable. No building should be erected without a damp-proof course, and the outer-face of the walls below the surface of the ground should be coated with coal-tar pitch. In damp soils it is well, in addition, to lay a tile drain entirely around, and distant some five feet from the house, at a sufficient depth to be below the foundations and to intercept the water in the soil before it reaches the walls. Bailey Denton recommends that a narrow area should be constructed entirely around the building to the depth of the footing courses of the foundations.

The experiments above mentioned are cited to show how greatly contaminated ground-air may become by the presence of decomposing organic matter, and from what has been seen in regard to the movement of the air, it can be readily understood how important it is that ground in the vicinity of dwellings should be as pure as possible.

Chemical Action of Soils.—The action of soils, except the hottest and driest, on animal refuse, as sewage, for example, is to convert the carbon, hydrogen, and nitrogen into carbonic acid, water, ammonia, nitrates and nitrites, and fatty hydrocarbons; most of the sulphur unites with the iron in the soil. "All these compounds are eagerly absorbed by vegetation." If the organic matter is covered constantly with water, decomposition takes place with extreme slowness.

Water in the soil holds in solution organic and saline substances. Piefke has shown that in the passage of surface water for a considerable distance through sand or gravel, the organic matter is gradually destroyed by the action of the undissolved oxygen in the pores of the soil. The experiments of the Rivers Pollution Commission of Great Britain, and of Nichols and other investigators, have proved that the action of sand and gravel on the *saline* matter is *nil*, except in the case of substances that are susceptible to chemical change under these conditions. Bicarbonate of lime, for example, may part with some of its carbonic acid, and deposit carbonate of lime in the pores of the soil.

As an illustration of the purifying qualities of soil may be mentioned the fact, said to have been learned from Indians, that "the fetor of the skunk can be removed from clothing by burying it in the earth."

In connection with the chemical action of soils, the difference between discharging sewage into cesspools and discharging it a few inches below the surface of the ground, as in sub-surface irrigation, should be borne in mind. In both cases are present the four factors in the production of decomposition: heat, air, moisture, and the presence of decomposable organic matters. In the latter case there are two powerful and beneficial agencies at work, active oxygen and vegetation; in the former neither is present, and the products of decomposition, under conditions favorable to the propagation of disease-germs, are allowed to pass away unchanged; the gaseous by diffusion into the atmosphere, and the liquid into the ground-water, to come to the surface once more in water drawn from the nearest well.

Mechanical Action of Soils.—One of the most important characteristics of soils from the sanitary point of view is their filtering capacity, or their ability to eliminate foreign matters, especially low vegetable organisms, from either water or air.

As mechanical filters, soils, and especially sand and gravel, have been used for years; but it is well known that after a time they become saturated with the material retained and then cease to operate. In such a case the passage of comparatively pure water through the saturated filter so taints it that it becomes unfit for use.

In order to study this filtering capacity of soils, Professor Raphael Pumpelly made, in 1881, a very exhaustive series of experiments, which appeared in supplement No. 13 of the *National Board of Health Bulletin*. The points brought out by this investigation were:

"1. The rate of flow of water and of air under given conditions.

"2. The capacity of soils as filters in eliminating organic and inorganic substances from liquids.

"3. Their capacity as filters in eliminating the living low forms of vegetable life, both germs and adult organisms, from ground-water and ground-air."

The bearing of these experiments on health is clearly put by Professor Pumpelly at the beginning of his report.

"When we consider that every vault, cesspool, and cemetery is a centre of pollution to the ground-water which supplies our wells, and, to a certain extent, also the reservoirs for cities, we can appreciate the importance of ascertaining to what extent soils are capable of eliminating the injurious properties contributed by the pollution.

"Through the cellars our houses become, especially in winter, the ventilating chimneys for the surrounding ground, sucking in from all directions the air that has been nearly stagnant in the pores of the soil during the summer. In view of the fact that the ground-air is polluted by vaults, cesspools, and cemeteries in the country, and by the garbage of made ground and defective drains and sewers in cities, it is important that we should determine the extent to which different soils are able to filter the injurious properties out of the air passing through them."

The test employed in these experiments was the rapidity with which an infusion of beef was infected by either air or water passed through the filtering material, which had previously been sterilized. The filters used were sand, charcoal, animal charcoal, asbestos, a mixture of sand and kaolin, kaolin, coal ashes, and loess.

The result of these experiments, as given on page 18 of the Supplement, "shows conclusively the utter worthlessness of sand as a filter for germinal matter," "nor do the sandy or even clayey soils afford us a safeguard against germ-contamination of our well waters, as the experiments with loess, clay, and clay mixtures would probably justify us in concluding, although it must be admitted that we have not here strictly the same physical conditions as in a natural soil which has not been subjected to heat."

"Not only does the amount of radiation differ in different soils, but a change is produced in the heat by the kind of soils. The remarkable researches of Tyndall have shown that the heat radiated from granite passes through aqueous vapor much more readily than the heat radiated by water (though the passage is much more obstructed than in dry air). In other words, the luminous heat rays of the sun pass freely through aqueous vapors, and fall on water and granite; but the absorption produces a change in the heat, so that it issues again from the water and granite changed in quality; it will be most important for physicians if other soils are found to produce analogous changes" (Parkes). "With regard to the effect of temperature of the soil on disease, it can hardly be doubted that it powerfully influences malaria, and probably also aids the progress of cholera."

Pollution of the Soil.—Having described at some length the characteristics of soils and of the water and air that they contain, the innumerable causes of pollution will be readily comprehended. Dr. Ford, in Buck's "Hygiene," divides them into four groups: 1, Excreta; 2, interments; 3, coal gas; 4, surface pollution.

1. Pollution of the soil by excreta is the most frequent and most dangerous of all causes. Broken sewers and leaking cesspools allow liquids saturated with decomposing animal matter to pass into the soil and contaminate both ground-air and ground-water; the latter in all probability to drain into some well, with results that have already been described.

2. The drainage from cemeteries is liable to pollute the water of wells and springs, and it has been shown that, in one or two instances, injury to health has been produced.

3. Soil pollution by coal gas is met with only in large towns and cities; there, however, it is of constant occurrence. Severe illness, somewhat resembling typhoid fever, has been caused by this.

4. The causes of surface defilement are too numerous and too well known to require enumeration. Among them may be mentioned manure heaps, pig-styes, dirty streets, collections of refuse, badly constructed slaughter-houses, etc.

DISEASES AFFECTED BY SOIL.—The diseases influenced by the condition of the soil are: Consumption, paroxysmal fevers, typhoid fever, cholera, dysentery, diphtheria, yellow fever, bilious and remittent fevers.

Consumption is greatly affected by excess of moisture in the soil; in fact, this may be said to be one of its prominent causes. Since the announcement of this relationship, years ago, all observations have gone to prove its truthfulness, and at the present it is so thoroughly understood that space will not be wasted in detailed explanations. A reduction in consumption frequently follows the introduction of systems of sewerage in towns, by which the drainage of the town site is an incidental result. In this way the general death-rate of Newport, South Wales, was reduced twenty-three per cent., while that from phthisis was reduced thirty-two per cent. At Salisbury, England, the general death-rate was reduced nine per cent., and that due to phthisis, forty-nine per cent. Although such gratifying results have attended the introduction of sewers, it is unsafe, for reasons that will be given further on, to combine sewerage with soil drainage. Each should be effected by pipes entirely independent of the other.

Malaria.—One of the most potent factors in the production of malaria is soil moisture; decomposing organic matter must also be present, even if only in small quantities.

The effect of soil moisture and drainage on malarial fevers is very curiously illustrated in the case of the irrigated lands of California. These lands are divided into four general classes:

1. Uplands. The soil is a gravelly clay which, owing to the regular slope of the surface, "remains moist but not water-soaked after irrigation." These lands are almost entirely free from malaria.

2. River bottoms of sand or alluvium, with a subsoil of coarse gravel and a fair surface slope. "The lands of the second class show its existence, but not to a sufficient degree to form a marked feature in the endemic causes of disease. . . ."

3. The sandy bottoms of the San Gabriel River, having the same general characters as Class 2, but having a much less rapid slope, the level of the ground-water being much nearer the surface. The lands of this class "show the presence of malaria in a notably active form, giving a well-marked type to the summer diseases."

4. Cienaga lands or open plains, with a heavy soil of the adobe type, "with occasional springs and bogs, with natural ponds of water," in winter very wet, and in summer irrigated extensively by artesian wells. These lands "develop, with irrigation, a very active form of malaria, the disease being largely of a pronounced malarial type and running often a severe course." The following tabular statement will serve to show the connection between the soil, the malaria, and the drainage of the irrigated lands in California.

Lands.	Class 1.	Class 2.	Class 3.	Class 4.
Distance from ocean	Great.	Considerable.	Slight.	Slight.
Summer temperature	High.	High.	Moderate.	Moderate.
Slope	Considerable.	Slight.	Very little.	Slight.
Subsoil	Pervious.	Pervious.	Pervious.	Impervious.
Effect of irrigation	No malaria.	Considerable malaria.	Malaria.	Much malaria.
Effect of drainage	(No drainage.)	Malaria disappears.	(No drainage.)	Malaria disappears.

"The whole history of irrigation in Southern California goes to impress this lesson: that to escape malaria, drainage must go hand in hand with irrigation; that unless it does, the water which brings wealth brings also disease and death."

Typhoid Fever.—The spread of this disease is caused principally by impure air and water in the soil. Frequent fluctuations in the plane of saturation force ground-air, loaded with the products of the decomposition of organic matter, and carrying with it the germs of the disease, into the atmosphere, to be taken into the system in breathing. Water from wells and other sources of supply is contaminated by the infiltration of polluted ground-water, which, if carrying germs of disease, becomes the vehicle of spreading the contagium. Typhoid fever becomes more prevalent as the quantity of water in the ground diminishes, and gradually disappears on the return of wet seasons. The introduction of systems of water-supply and sewerage in towns materially reduces the mortality from disease.

The relation between ground-air and ground-water and typhoid fever is receiving such constant illustration in practice that more than the mere statement of the facts is unnecessary.

Diphtheria.—Although lack of drainage of the subsoil has not been shown to be the cause of diphtheria, there is no doubt that it is a powerful factor in its production under certain conditions. The disease begins to show itself after a long season of dry weather, when the rains begin, and the level of the ground-water is gradually raised. The following case seems to show that diphtheria may be propagated by water: Dr. R. C. Newton, U.S.A., describes the results of drinking polluted water from two wells near an army post at the West. The wells were sunk "in the most advantageous position to receive the drainage of two filthy cattle yards." In the house supplied with water from one of these wells were five children, four of whom were attacked, three dying. The fifth, the child of a servant in the house, was not allowed by its mother to drink the water and was not attacked. In the family using the other well were a man, his wife and two young children, one a baby eighteen months of age. The father was generally away and was not attacked. The mother and oldest child had chills, and the baby was attacked with diphtheria, but recovered. A careful examination showed that neither of these families could have been exposed to the contagion of diphtheria.

Cholera may be propagated by the pollution of sources of water-supply. This was illustrated during a recent outbreak of the disease in Spain. Madrid, Seville, and Barcelona have pure water-supplies, and, although cholera appeared, it did not gain headway and soon disappeared. The towns of Aranjuez, Valencia, and Granada, on the other hand, depend largely on wells for their water-supply. All suffered severely from the epidemic.

Although both ground-air and ground-water are considered active agents in producing certain specific diseases, as typhoid fever, etc., it nevertheless remains that the fluctuation of the water level is absolutely necessary for the development of these diseases. Pettenkofer has shown that changes in the level of subsoil water are the certain forerunners of epidemic outbreaks of both cholera and typhoid fever; while Baldwin Latham goes so far as to say that the excremental pollution of a soil is "inoperative in producing epidemic disease" if unaided by fluctuations in the plane of saturation. It must not be understood from this, however, that all fluctuations of subsoil water are dangerous to health. Provided the water is constantly moving, very healthful results may be produced by a fluctuation of level, aiding as it does the aëration of the soil. It is the rising and falling of stagnant water that is so pernicious. Acting on these principles, Mr. Latham was able to predict an outbreak of typhoid fever in an English town, which occurred in a violent form three weeks after his notice to the authorities, warning them to be on their guard.

HEALTHFULNESS OF LOCALITIES.—As has already been seen, there are many factors that go to make the healthfulness of localities, making prediction in many cases a matter of great uncertainty. There are, however, certain physical features of the earth's surface that, as has been

shown by experience, may be taken as fair indications of the salubrity of the locality in which they occur. Among these may be classed:

Healthy Localities. Near the top of a slope; a "saddle-back;" sands and gravels; granite; metamorphic and trap formations; slate; sandstone formations; salt marshes, etc.

Suspicious Localities. Gravels and sands filled with water; clay; dense marls; alluvial soils, etc.

Unhealthy Localities. Enclosed valleys; "punch bowls" or depressions in impervious strata; locations among hills where the air is liable to stagnate; ravines—"the worst ravine is a long narrow valley, contracted at its outlet so as to dam up the water behind it;" plains at the foot of hills; depressions in plains; fresh-water marshes at any altitude; soils containing much organic matter and exposed to alternate wettings and dryings; made soils, etc.

Proximity to ponds and streams does not of necessity render a locality unhealthy. If the water is pure and stagnation does not occur, they will not be detrimental to health. If, on the other hand, the surface of a pond is subject to fluctuation in level, whereby large areas of soil are alternately covered and laid bare by the water, evaporation will project into the atmosphere large quantities of impurities from the decaying organic matter in the soil and render the locality unhealthy.

The drainage of a country through its valleys and streams, though naturally good, may be seriously interfered with by the erection of dams, embankments for railroads and common roads, bridge piers, and the like. Unless special precautions are taken, the obstruction of the natural outlets by such works causes the raising of the level of both surface and subsoil water, with the overflow or saturation of large areas of land. An increase in malarial fevers, and in many instances the appearance of these diseases where they were never before known, is the certain result.

Salt marshes are healthy as a rule. If, however, they are underlaid by clay or other impervious strata in which depressions are likely to exist, the ground-water will become more or less stagnant and the locality will be unhealthy.

The filling in of low waterlogged lands, marshes, and similar localities is to be condemned, unless the land is thoroughly drained as a preliminary measure. By filling in without draining, although the level of the ground is raised above the surface of saturation, all other conditions remain the same, and a locality already unhealthy is rendered more so.

All the benefits of a healthy locality may be nullified by a damp cellar. In an examination recently made by the Wisconsin Board of Health, it was discovered that seventy-five per cent. of the cellars in the cities, towns, and villages of that State are either "habitually damp or damp in rainy weather."

Granite, trap, and metamorphic rock, if the slope of the surface is great, allowing water to run off rapidly, make healthy localities. If, however, they contain cracks, "faults" or depressions, ground-water collects in them and, being unable to flow away, stagnates, and malarial conditions are the result.

Limestones also make a healthy locality, when the surface-slope is steep. Marshes, however, are of frequent occurrence, owing to the retention of ground-water in cavities that have been gradually hollowed out by the action of the carbonic acid in the rain falling on them.

Chalk, if free from clay, is said to be healthy. Chalk marl is impermeable, cold, and unhealthy. "Some of the most unhealthy districts in America are on chalk."

Sandstones are usually healthy. If, however, the formation is a thin stratum superimposed on one of an impermeable character, it becomes unhealthy.

Clay is one of the most unhealthy of soils. Ridges of clay are cold and every depression is a marsh.

"Gravel is the healthiest of all sites" (Parkes). Both sand and gravel are extremely healthy when there is no obstruction to the flow of the ground-water through them. They become unhealthy when underlaid by impervious strata, or when they contain decomposing organic matter. Sand and gravel, when containing impurities, are perhaps more unhealthy than less porous soils, as the passage of water and air through them causes the contaminating influence to spread to great distances.

Alluvial soils are unhealthy, as the atmosphere above them is rendered moist by the rapid evaporation; they contain large quantities of organic matter, and there are numerous marshes, especially when the soils are interspersed with clay or other impervious formation.

With the knowledge now in our possession, there is no excuse for building in an unhealthy locality or on an unhealthy site; particularly is this true of isolated buildings where the surrounding ground is under the exclusive control of the owner. In urban districts there is more excuse, but, even there, much may be done to increase the salubrity of the individual houses, if general improvements are impossible.

Vegetation exerts a powerful influence on the health of localities. Marsh miasma is intercepted by a forest, so that "persons living in localities so screened are exempt from attacks of malarial fever." The eucalyptus-tree is a remarkable prophylactic against malaria. The effects of trees on the atmosphere and the soil are: 1. To modify the extremes of temperature. 2. To prevent floods. 3. To aid the drainage of the soil.

Trees are a disadvantage when they are so dense as to prevent the free circulation of air, and when so close to a house as to materially obstruct the sunlight. In temperate climates, under these circumstances, they render a house damp. The fibrous roots of trees oftentimes are of great benefit; traversing the soil in every direction, they increase its porosity and improve its drainage. Vegetation also seizes on and appropriates to its own use organic matter that would otherwise, by slowly decomposing, pollute the soil-air and ground-water.

Improvement of Unhealthy Localities.—The methods that may be employed to increase the healthfulness of a site or locality are concisely stated by Dr. Ford as follows:

"1. By thorough surface and subsoil drainage.

"2. By free access of air and sunlight.

"3. By the use of the well-known means to insure perfect dryness of the walls and basement, and the exclusion of ground-air.

"4. By the regulation of vegetation; that is, by removing or planting trees, etc., according to circumstances of soil, climate, etc., etc.

"5. By preventing the pollution of the soil by the use of the best means for carrying off the surface-water, house-water, and all house-offal, as rapidly as possible."

Since, of all the factors that affect the relationship between soil and disease, ground-water is the most potent and the most readily removed, it follows that the under-drainage of land is of the greatest importance. Sir Edwin Chadwick has said: "In considering the circumstances, external to the residence, which affect the sanitary condition of the population, the importance of a general land-drainage is developed, by the inquiries as to the cause of prevalent diseases, to be of a magnitude of which no conception had been formed at the commencement of the investigation. Its importance is manifested by the severe consequences of its neglect in every part of the country, as well as by its advantages in the increasing salubrity and productiveness wherever the drainage has been skilful and effectual."

Drains.—The drainage of land, being more within the province of the engineer than of the physician, will receive but a passing notice. Draining is usually accomplished by small porous, earthen pipes, laid in rows with open joints at a depth of about five feet below the surface of the ground. The rows are usually laid in the direction of the steepest slope and between thirty and sixty feet apart. The water in the soil overflows into these drains and passes away to a neighboring water-course or other convenient outlet provided for it. When all the water in the soil above the drains has flowed off —which requires a length of time dependent on the po-

rosity of the soil—the level of the surface of saturation will become unvarying and will correspond to the depth of the drains below the surface of the ground. From what has already been said of soils, it is evident that drainage removes the conditions most favorable to the propagation of disease.

In regard to the effect of drainage on the temperature of the atmosphere, the following is taken from "Minutes of Information on Drainage:" "A farmer, being asked the effect on temperature of some new drainage-works, replied that all he knew was, that before the drainage he could never go out at night without a great-coat, and that now he could; so that he considered it made the difference of a great-coat to him."

Drainage-works, while in course of construction, may in certain cases cause outbreaks of fever, which, as soon as the drains begin to do their duty, gradually subside, and at last disappear. A case of this kind, cited by Douglas Galton, occurred in India in 1860, when the peninsula of Kowloon was occupied by the British troops as a sanitarium. Although it was of granite formation and freely exposed to the winds, the troops suffered severely from fever, which was attributed to "the disturbance, in a tropical climate, of the surface of soil impregnated with decaying organic matter." After a time the fever subsided and did not reappear.

The drainage of a town should be entirely separate and distinct from the sewerage. Sewers need not be very far below the surface; but drains should be laid as much as fifteen feet below, to insure the drainage of the deepest cellars. The inverts of sewers are often made hollow to convey away the water that is liable to accumulate in the trenches during construction. These drain the subsoil to a certain extent; but they are not to be desired, as, owing to leaks, they are likely to carry as much sewage as subsoil water. Then, again, sewers are obliged to follow certain lines of grade, while drains, to be most effective, as before stated, should be laid in the direction of the steepest slope. Sewers have sometimes been the occasion of malarial diseases by damming up underground waterways by the trench-fillings, which are more or less puddled and therefore impervious.

If the sewers themselves are intended to drain the subsoil, they must of necessity be made so as to allow the water to enter. This it will do in wet weather, when the head of water outside is greater than that inside the sewer. But during dry weather the reverse will be the case, and the soil will become saturated with sewage. Even should the sewer carry nothing but clear water, the fluctuations in the level of the surface of saturation caused by the above, would produce conditions favorable to the development of disease.

If malaria reappears after works of drainage have been instituted, there is some good and usually removable cause for the occurrence. Mr. William Marshall tells of the reappearance of ague in the Fens some time after it had ceased to exist, though in the *autumn*, instead of the *spring* of the year as formerly, and explains it by the fact that "the drainage had been carried beyond the point of prudence, so that in the summer months, and especially toward harvest, the Fen ditches became *nearly dry*, and the consequence was that we once more got an exhaling surface and a noxious effluvium arising from decaying vegetable matter. This state of things is now quite altered, and the ague has vanished, owing to the farmers making it a rule to let water in from the rivers during the summer months, so as to 'keep a water' always in the Fen ditches."

Examination of Localities.—Dr. Parkes gives the following method for examining a locality:

"1. *Conformation.*—Height above sea-level and elevation of hills above the plain. (Determine by mercurial barometer or aneroid, or, if possible, get the heights from an engineer.) Angle of declivity of hills; amount of hill and plain; number, course, and characters of valleys and ravines in hills; dip of strata; geological formation; water-sheds and courses; exposure to winds; situation, amount, and character of winds; sunlight, amount and duration; rain, amount and frequency; dust.

"2. *Composition.*—Mineralogical characters. Presence of animal or vegetable substances; amount and characters.

"3. *Covering of soil* by trees, brushwood, grass, etc.

"4. *Points for Special Examination.*—Amount of air; of moisture. Height of subsoil water, at the wettest and driest seasons. Changes in level, and rapidity of change of subsoil or ground-water. Condition of vegetable constituents; examination of substances taken up by water, etc."

Frederick N. Owen.

SORRELL (*Oseille commune*, Codex Med.). *Rumex acetosa* Linn., order *Polygonaceæ*. This, the common Sorrell of Europe, is a larger plant than our Red Sorrell, and has more divided leaves, but its properties are practically the same. Both contain oxalic salts, which give a pleasantly sour taste to the herbage, and both have bitter roots. Sorrell has been used as a diuretic, and as a pleasant salad, or flavor for soups. It has no medicinal value.

Allied Plants, etc.—See Rhubarb, Dock, etc.

W. P. Bolles.

SPA, or Spaa, situated in Belgium, not far from the Prussian border, was formerly one of the most popular and fashionable watering-places on the Continent, being a favorite resort with the nobility of all Europe. It lies at an elevation of about one thousand feet above the sea; the climate is not particularly mild, and sudden changes of temperature are common. There are eight chalybeate springs of which therapeutic employment is made, which are known respectively as the Pouhon, Géronstère, Groesbeck, Barisart, Dundas, Sauvenière, Tonnelet, and Prince de Condé. The following is the composition of the Source de Pouhon. A litre of water contains:

	Gramme.
Sodium bicarbonate	0.1266
Potassium bicarbonate	0.0105
Magnesium bicarbonate	0.1674
Calcium bicarbonate	0.1730
Ferrous bicarbonate	0.0714
Sodium sulphate	0.0203
Sodium chloride	0.0256
Silica	0.0629
Total solids	0.6577

The waters are athermal. In addition to the water, employed in the ordinary ways, mud-baths are often prescribed. The principal indication for a course of treatment at Spa is anæmia. The season extends from the first of June to the middle of October. *T. L. S.*

SPANISH FLIES (*Cantharis*, U. S. Ph.; Br. Ph.; *Cantharides*, Ph. G.; *Cantharide*, Codex Med.). This rather inaccurate name is given to *Cantharis vesicatoria* De Geer (*Lytta vesicatoria*), order *Coleoptera*, a brilliant green beetle, with a long, cylindrical body, a disagreeable odor, and powerfully irritant properties. It is about an inch in length, and from one-fifth to a fourth in breadth. It has a good-sized, ovoid, heart-shaped head, filiform, black antennæ of eleven joints, a distinct, rounded thorax, and long, straight wing-covers. Legs provided with five tarsal joints, excepting the two posterior ones, which have only four. Wings large, brown, translucent. The odor, even when long dried, is strong and characteristic. Its larva is yellowish-white, soft, elongated, thirteen-jointed; it has a rounded head, short antennæ, and stout jaws; there seems to be uncertainty whether it feeds

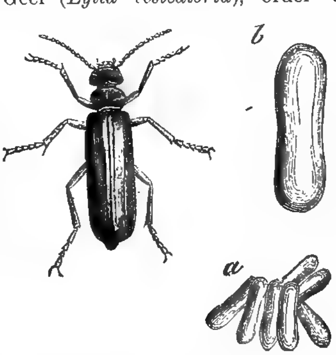

Fig. 3562.—Blistering Beetle, Natural Size; *a*, Eggs, somewhat enlarged; *b*, a single egg, greatly enlarged. (Moquin-Tandon.)

upon roots, honey, bees, or other insects. The perfect beetle appears in great numbers in its native countries, about the middle of summer, upon poplars, ashes, lilacs, privets, and even upon roses and several other domestic shrubs, whose leaves it devours. The acrid effluvium emitted from it can be smelled at a considerable distance, and when the insects are abundant, it is said to be dangerous to persons sitting under the trees where they are.

This beetle is a native of Southern and Middle Europe, Western Asia, etc. It is abundant in Spain, France, Germany, Italy, etc., and in these countries is collected for use. During the middle of warm days it is very active and alert, but in the night and early morning, benumbed by cold and wet, it is very heavy and clumsy. Advantage is taken of this time for collecting the beetles, when they can be beaten or shaken from the shrubs where they hang and caught in sheets or bags held under the boughs. They are then killed by boiling water, steam, vinegar, ether, or some such treatment, and carefully dried by moderate heat.

The drug, as usually found in the market, consists of these bodies whole, excepting what the friction of the transportation has done in the way of rubbing off the antennæ and legs. Ground, it gives a disagreeable-smelling, grayish powder, sprinkled with bright metallic-green specs—the fragments of wing-cases and body. Taste, resinous and acrid.

Blistering beetles were known to the ancients, and have been used for centuries in many different countries, but they have not been generally of this particular species, whose employment is comparatively modern. This, however, from its abundance, and the ease with which it can be collected, as well as on account of its quality, has generally supplanted the others in English and American commerce, at least.

Composition.—A great variety of ordinary animal products, nitrogenous tissues, fat, oil, watery extract, etc., and about one-fourth to one-half per cent. of a well-defined, crystalline, active principle named *Cantharidin.* This energetic poison crystallizes in tables or flakes, is white, colorless, and odorless, and at first has but little taste. It dissolves in twenty-five parts of water, and in upward of three thousand of alcohol; in ether and chloroform it is almost insoluble. Cantharidin is about thirty times as active as cantharides.

Action and Uses.—Cantharides is an intense irritant, whether applied internally or externally; taken into the stomach, it causes heat and burning of the fauces on its way down, then vomiting, often of bloody mucus, intense pain and burning of the stomach and bowels, diarrhœa, fibrinous and bloody stools, and finally urinary distress, strangury, bloody urine, and other evidences of renal and vesical irritation. The genitals are also excited—priapism in the male, swelling of the vulva, etc., in the female; uterine tenesmus or abortion may follow. Erotic sentiments may be, but are not necessarily, aroused. A small, quick pulse, rapid breathing, a hot, dry skin, headache, delirium, coma, and death may follow its introduction. Two grams (30 grs.) of powdered cantharides, or five centigrams ($\frac{3}{4}$ gr.) of cantharidin, would be a dangerous dose. Applied externally, cantharides produces, after a few minutes, redness and slight burning of the skin, followed, in from one-half to five or six hours, by small blisters just beneath the cuticle, which rapidly separate it from the skin and soon coalesce into one large bleb over the whole surface covered by the blister. A small amount of cantharidin is absorbed through the skin, as strangury, hæmaturia, etc., are rather apt to follow very extensive blistering. This medicine, like most active substances, has been given in a great variety of conditions—vesical catarrh, gonorrhœa, dysuria, incontinence of urine, and as a general nervous stimulant. For none of these things is it now in vogue. Externally applied, it is the safest, surest, and in all ways the best vesicant known; easy, comparatively painless, and superficial; never leaving a scar. Large and repeated blisters were formerly used, with a view of "drawing off" serous effusions from the pleura, peritoneum, the joints, etc.; but as derivative effects are not accomplished in so simple and direct a way, it is now principally used as a means of simple counter-irritation.

Administration.—If it is desired to give *Cantharides* internally, the Tincture (*Tinctura Cantharidis*, U. S. Ph., strength, $\frac{6}{100}$) is a suitable form, but the numerous cerates and liniments which follow, show how almost exclusively it is employed externally: *Ceratum Cantharidis*, U. S. Ph., strength, $\frac{35}{100}$; and *Ceratum Extracti Cantharidis*, U. S. Ph., strength, $\frac{30}{100}$; as well as *Charta Cantharidis*, strength, $\frac{1}{17}$, are used for blistering. Liniment of Cantharides, *Linimentum Cantharidis*, U. S. Ph., (fifteen per cent.), is moderately stimulating; and the *Collodium cum Cantharide*, U. S. Ph., (Blistering Collodion), containing sixty per cent., is a fairly active blister, if applied thickly with a brush. For the last dozen years or more the cantharidal cerates of the Pharmacopœia have been almost superseded by a Cantharidal Plaster, prepared upon a large scale by manufacturing pharmacists, with a rubber basis instead of the simple fatty one of those. It is scarcely as uniform or quick in its action as the others, but on account of its convenience, its durability, and ease of handling, it is likely to continue in use. The Tincture of Cantharides, considerably diluted, is a frequent ingredient of "hair renewers" and other cosmetics.

Allied Animals.—The tribe *Cantharidæ* contains numerous poisonous beetles, whose acrid secretions have been put to use as vesicants. Some of these are even more irritant than Cantharis itself. *C. Vittata*, our Potato Beetle, and other species of *Cantharis, Meloe*, the oil-beetles, several species of *Mylabris* ("M. Chiccorii" the "Chinese blistering fly") are examples.

Allied Drugs.—All local irritants: Mustard, Pepper, etc., Croton-oil, Tartar emetic, Iodine, etc., as well as Turpentine in all its various forms.

SPARKLING CATAWBA SPRINGS. *Location and Post-office,* Sparkling Catawba Springs, Catawba County, N. C.

Access.—By the Western North Carolina Railroad to Hickory; thence by stage to the springs, six miles.

Analysis (Howe).—The waters are said to be sulphur and chalybeate.

These springs are situated in Western North Carolina, near the Catawba River, at an elevation of one thousand feet, amid the eastern foot-hills of the Blue Ridge, which form in the distance a pleasant feature in the landscape. The hotel accommodations, consisting of several large buildings and cottages, are ample. There are also plunge, shower, and vapor baths.

G. B. F.

SPARTA SPRINGS. *Location and Post-office,* Sparta, Monroe County, Wis.

Access.—By the Chicago & Northwestern, or the Chicago, Milwaukee & St. Paul Railway.

Analysis (J. M. Hirsh).—One pint contains:

	Grains.
Carbonate of soda	0.026
Carbonate ot magnesia	0.503
Carbonate of iron	1 792
Carbonate of manganese	trace
Carbonate of lime	0.050
Carbonate of ammonia	trace
Carbonate of lithia	0.003
Carbonate of strontia	0.002
Carbonate of baryta	trace
Sulphate of potassa	0.080
Sulphate of soda	0 277
Sulphate of lime	0.022
Chloride of sodium	0.018
Chloride of calcium	0.075
Phosphate of soda	0.008
Phosphate of alumina	0.007
Iodide of sodium	trace
Silica	0.035
Total	2.898

Therapeutic Properties. — An unusually strong, chalybeate water.

These springs are situated in the southwestern portion of Wisconsin, two hundred and fifty miles from Chicago.

The town of Sparta, of about two thousand five hundred inhabitants, affords good hotel accommodations.

G. B. F.

SPEARMINT (*Mentha Viridis*, U. S. Ph.; *Menthe verte*, Codex Med.). The flowering tops and leaves of *Mentha viridis* Linn. (*Mentha Sylvestris, glabra* Koch). Spearmint has narrower, more sessile leaves, slenderer and more spike-like flower clusters, smaller flowers, and a different odor from peppermint, which it otherwise closely resembles. It is a European and Asiatic plant, and has been long under cultivation. It grows in the same gregarious way as peppermint. The following officinal description will serve to distinguish it from other mints: "Leaves about two inches (5 centimetres) long, subsessile, lanceolate, acute, serrate, glandular, nearly smooth; branches quadrangular, mostly light-green; flowers in terminal, interrupted, narrow, acute spikes, with a tubular, sharply five-toothed calyx, a light purplish, four-lobed corolla, and four rather long stamens; aromatic and pungent." Spearmint contains a composite oil analogous to that of peppermint, and it is applicable to the same uses. The oil, and a water, and spirit made from it, are officinal.

ALLIED PLANTS, ETC.—See PEPPERMINT.

SPECTACLES. * *Besicles,* † *lunettes*, French; *die Brille,* ‡ German; *occhiali*, Italian; *perspecillum, conspecillum, vitrum oculare, ocularius*, mediæval Latin—are first mentioned about the close of the thirteenth century. § Seneca mentions the fact that "letters, however minute and indistinct, appear larger and clearer when viewed through a glass globe filled with water," [11] and Pliny notices the use of a sphere of crystal,[12] or glass globe filled with water,[13] as a burning glass. ‖ The first mention of a lens, properly so called, is attributed to the Arabian mathematician Alhazen (*obt.* 1038),[15] who describes the magnifying property of a segment of a sphere of glass.[16] Roger Bacon (*circa* 1267) also mentions the magnifying property of convex lenses,¶ and suggests the benefit to be derived from their use by old persons with weak sight.[18] The step from the use of a convex lens, as a magnifier, to the construction of binocular eye-glasses or spectacles, to be worn by presbyopes in reading, implies a considerable development of the optician's art, in the direction of grinding lenses of relatively long focus. The invention of spectacles is variously attributed to Salvino degli Armati, a Florentine (*obt.* 1317),[19] and to Allessandro della Spina, a Dominican monk of Pisa (*obt.* 1313). The use of concave glasses, similarly mounted in pairs, as a help to myopes in distant vision, must have followed at no very long interval; the date of their first employment is, however, unknown. The necessity for the selection of lenses of different focal length for different persons, as well as for the same person at different periods of life, must also have been very early recognized; but there is no reason for believing that the choice was ever made in any better way than by trying glasses at random, until a pair was found which appeared to be suited to the kind of work for which they were to be used. * Certain it is that spectacles had been in common use for at least a hundred and fifty years before the theory of their action was explained,† and it is only since the middle of the present century that anything like a complete understanding of the subject has been reached.

Spectacle lenses, as late as the eighteenth century, were always, so far as is known, of the plano- or double-convex, or of the plano- or double-concave form.[22] Both the plano-convex and the plano-concave glasses were probably mounted, sometimes with the plane surface and sometimes with the curved surface next the eye. Concavo-convex lenses (menisci), with the convex surface ground to the shorter radius of curvature, were used to some extent in the last century, but with varying practice as regards the side turned next the eye. ‡ [23] Under the name of *periscopic* spectacles, concavo-convex lenses, with the concave surface turned toward the eye, were brought into common use by Wollaston (1804).[24] A special construction of double-convex and double-concave spectacle lenses, made by grinding the two surfaces of the glass to cylindrical curves of equal radii, but with crossed axes, was introduced (before 1830) by Galland de Cherveux;[25] such lenses are still manufactured, but the special advantage once claimed for them, over the several forms of lenses with spherical surfaces, is altogether illusory; their existence in commerce made it possible, however, to furnish a cylindrical surface, on demand, at a time when plano-cylindrical lenses were not yet obtainable. Cylindrical lenses proper, as used for the correction of astigmatism, were first employed by G. Airy, Astronomer Royal (1827),[26] who was himself the subject of compound myopic astigmatism. Airy discussed the relative advantages, in compound astigmatism, of a bi-cylindrical lens of unequal radii of curvature, and a spherico-cylindrical lens; he gave the preference to the latter combination, for reasons which are still generally accepted as

* Chaucer uses the word in the singular number: *a spectakel.*[1]

† From the old French form *bericle*, diminutive of *berille;* Latin, *berillus, beryllus;* Greek, βήρυλλος, the beryl.[2]

‡ From *berillus, beryllus*, βήρυλλος, the beryl; "the colors of the beryl range from blue through soft sea-green to a pale, honey yellow, and in some cases the stones are entirely colorless;" [3] *ocularii vitri aut berillorum:* Guy de Chauliac (1363).[4] The most available material for spectacle-lenses, excepting glass, is rock crystal or quartz, and it is highly probable that this mineral, still largely used under the name of pebble, was the *berillus* of the older opticians; *cf.*, the derivation of "brilliant"—French, *briller*, etc.—from *beryllus.*[5]

§ Spectacles, both convex and concave, were in common use by the Chinese before the opening of commerce with Europe. They were made of a transparent stone, of a color like that of a strong infusion of tea, called *scha-chi* (tea stone), and were tied upon the head by silken cords.[6] Chinese spectacles are now made of rock crystal, and are mounted in heavy frames, evidently borrowed from old European models. Several pairs of Chinese spectacles, of comparatively late fabrication, are preserved in the Museum of the Old East India Marine Society, at Salem, Mass.

The common use of some form of magnifying-glass by the ancients is wellnigh proved by their perfect workmanship, as displayed in the engraving of gems, and a crystal wrought in the form of a convex lens has been actually discovered by Layard, in the ruins of Nimroud.[7] On the other hand, it appears clearly, from the notice on presbyopia and myopia, by Paulus Aegineta (seventh century, A.D.),[8] that they had not applied lenses to the relief of persons laboring under these disabilities.

Pliny's description of the visual defect of the Emperor Nero[9] strongly suggests a case of compound myopic astigmatism, with the meridian of greatest refraction approximately vertical. The statement that Nero was accustomed to view the conflicts in the arena in or upon a smaragdus (Nero princeps gladiatorum pugnas spectabat in zmaragdo),[10] taken in connection with what is said of this gem in the same chapter, would seem to be best explained upon the supposition that the emperor possessed a large and highly polished emerald, very probably of unequal curvature in its two principal diameters, and that he viewed the combatants, in the strong light of the amphitheatre, by reflection from its convex surface. This theory would imply that the use of the gem for this purpose was the result of an observation made by Nero himself, who may, therefore, be accredited with the accidental discovery of an eye-glass suited to the correction of myopia, or of compound myopic astigmatism; the invention would appear to have died with the inventor.

‖ Pliny also mentions the fact that objects seen reflected in a concave mirror appear enlarged.[14]

¶ It has been contended that Roger Bacon may have derived his knowledge of lenses from Flanders.[17]

* Bartisch (1583) protests strongly against the widely spread abuse of spectacles which prevailed at his time.[20]

† "Maurolicus, in his treatise *de lumine et umbra* (1554), considers the crystalline as the principal instrument of vision, and as transmitting to the optic nerve the images of objects; and he explains why some persons are long-sighted and others short-sighted, according to the less or greater convexity of the surfaces of the crystalline, showing that in the former case the rays have not been converged to a focus when they reach the retina, while in the latter they have been converged before they reach it. He explains, also, how the convergency may be hastened in the long-sighted eye by the use of a convex glass, and delayed in the short-sighted by a concave one. These observations of Maurolicus were not known to Kepler, when it was proposed to him, as a question by his patron, Dietrichstein, in what manner spectacles assisted sight? The first answer he gave, as he tells us in his *ad vitellionem paralipomena* (1604), was, that convex glasses were of use by making objects appear larger. But his patron observed, that if objects were by them rendered more distinct, because larger, no person would be benefited by concave glasses, since these diminished objects. . . . He now gave a clear account of the effect of lenses, whether within or without the eye, in making the rays of a pencil of light converge or diverge; and explained, that convex glasses assist the sight of presbyopic persons, by so altering the direction of rays diverging from a near object, that they fall upon the eye as if they had proceeded from a more remote one, that concave glasses benefit the myopic, by producing a contrary effect upon rays which diverge from a distant object, making them fall upon the eye as if they proceeded from a near one." [21]

‡ Aside from the misinterpretation of special optical formulæ, caprice has played a conspicuous part in determining many eccentricities of practice: the business of selling spectacles appears always to have been deeply tainted with quackery.

valid. The common use of cylindrical spectacle lenses dates from the special study of astigmatism by Donders.[27] Quite recently Mr. Borsch, an ingenious practical optician of Philadelphia, has undertaken the manufacture of

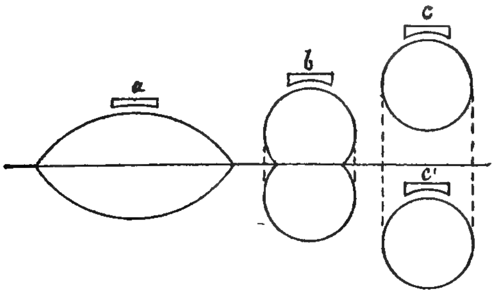

FIG. 3563.

spectacle lenses with a convex or concave surface of unequal radius of curvature in its several meridians, thus combining in one surface the effect usually obtained by the combination of a cylindrical with a spherical surface.[28] The curved surface of such a convex lens represents a small area cut out from a large surface of revolution corresponding to the rounded rim of a wheel; the concave surfaces produced by this method are such as may be worked upon a grinding tool having the form of such a wheel. * Prismatic glasses, first suggested to Donders by his colleague, Krecke, as a possible means of re-establishing binocular vision when it has been lost through the deviation of the visual axes in strabismus, were made the subject of special study by Donders,[30] and have since held a place among the recognized means of dealing with conditions referable to disorders of the external muscular apparatus of the eye. The decentration of ordinary convex or concave lenses, in order to give to the combination of the two spectacle glasses some measure of prismatic effect, was also discussed by Donders.[31] Decentrated convex lenses had already been used in the dissecting spectacles of Brücke,[32] and in the refracting stereoscope of Brewster.[33] Stenopæic spectacles—from στενός, narrow, and ὀπή, a peep-hole—were also introduced by Donders,[34] chiefly for the purpose of admitting to the eye such rays only as correspond to a selected limited area of the cornea or crystalline. Like the so-called *panoptic* spectacles of Serre d'Uzès,[35] they are essentially the same thing as the very old but long disused strabismus goggles (*Schielbrillen — lonchettes*). The snow-goggles of the Esquimaux, which cover the entire front of the eyeball, with the exception of a narrow horizontal slit, are also properly to be regarded as stenopæic spectacles, although designed merely as protectives against the injurious effects of strong sunlight reflected from the snow.

The several forms which have been or may be given to spectacle lenses are shown, for concave and convex lenses respectively, in Figures 3564 and 3565. Of the convex lenses (of positive focus), *a* and *g* (Fig. 3564) are menisci, and may be designated as convex-concave and concave-convex, according as the convex or concave surface is turned toward the eye; *b* and *f*, which have one surface plane, may similarly be designated as convex-plane and plane-convex; *c* and *e* are double-convex lenses, with surfaces of unequal radii of curvature; and *d* is double-convex, with surfaces of equal radii. In concave lenses (of negative focus), we recognize the corresponding forms: Fig. 3565, *–a*, concave-convex, and *–g*, convex-concave; *–b*, concave-plane, and *–f*, plane-concave; *–c* and *–e*, double-concave, with surfaces of unequal radii of curvature, and *–d*, double-concave, with surfaces of equal radii. Of these forms, the two shown in Fig. 3564, *g* (positive meniscus, with the concave surface turned toward the eye), and in Fig. 3565, *–a* (negative concave-convex), are especially designated as periscopic (from περί and σκοπέω) glasses; they offer a

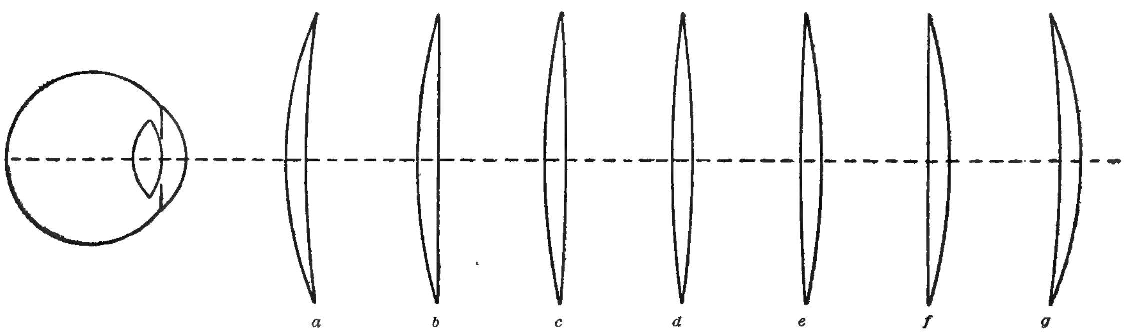

FIG. 3564.

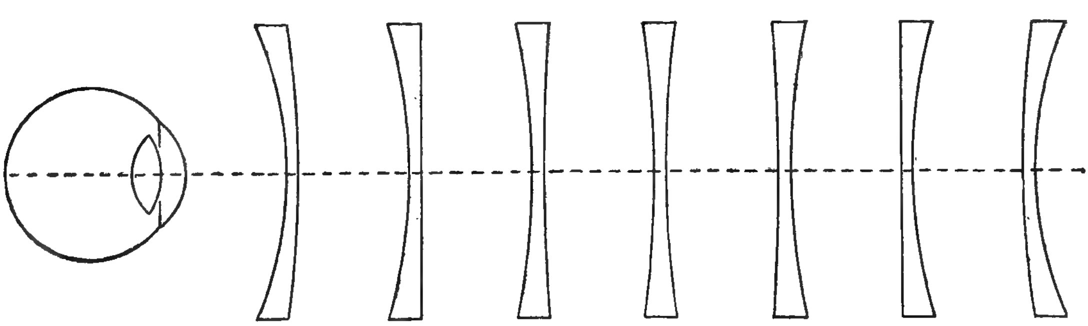

FIG. 3565.

* The entire surface of revolution, as shown in section, takes one of the three forms, Fig. 3563, *a*, *b*, *c*, the last of which is an open ring; the interior surface of such a ring gives a surface (*c′*) convex in one principal meridian and concave in the other, and applicable, therefore, to the correction of mixed astigmatism.[29]

slight advantage when the eyes are so turned as to look obliquely through the right or left half of both glasses. These several forms of lenses, other than the plano-

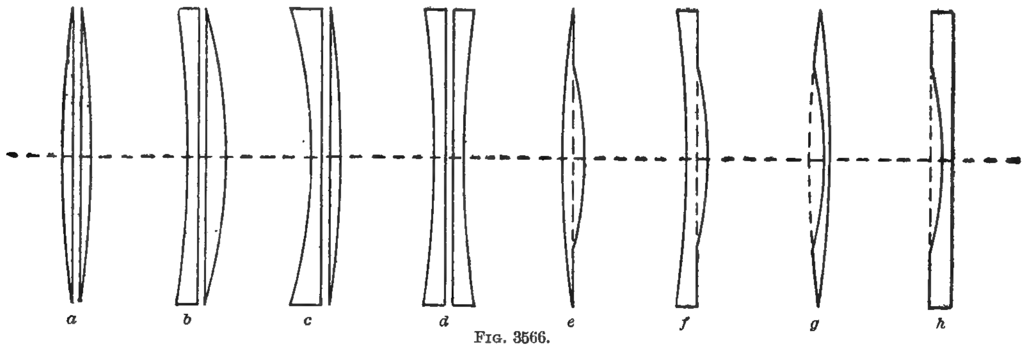

FIG. 3566.

spherical, may all be resolved into combinations of two lenses, each with a spherical and a plane surface, placed with their plane surfaces in contact (Fig. 3566; *a*, *b*, *c*, *d*). Inasmuch as a smaller effective area than that bounded by the usual setting is quite sufficient for most of the uses for which spectacles are worn, it is possible greatly

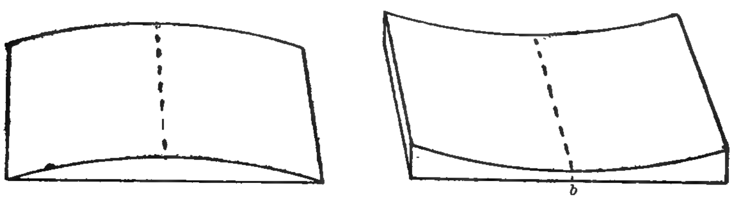

FIG. 3567.

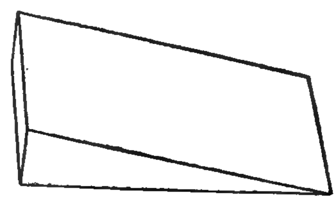

FIG. 3568.

to reduce the weight of the glasses, when required to be of very short focus, by the adoption of forms like those shown in Fig. 3566, *e*, *f*, *g* and *h*.

Cylindrical lenses are found in trade of two forms,

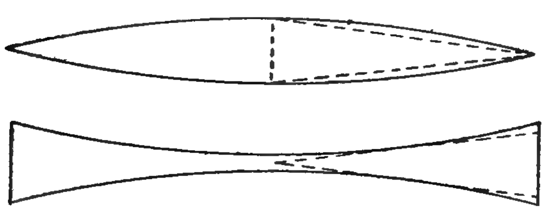

FIG. 3569.

namely, plano-convex and plano-concave (Fig. 3567, *a* and *b*); the dotted line represents the axis of the cylindrical surfaces, which is parallel to the axis of the cylinder of which the lens-surface is a segment. Any required spherical surface, convex or concave, is ground to order by the optician, upon the plane surface of any convex or concave, plano-cylindrical lens. The focal length of a plano-cylindrical lens varies, in its several meridians, from infinity, in the meridian corresponding to the axis, to a least focal length (positive or negative) in the meridian at right angles to the axis. In a spherico-cylindrical lens, with both surfaces of the same kind, *i.e.*, convex or concave, the meridian corre-

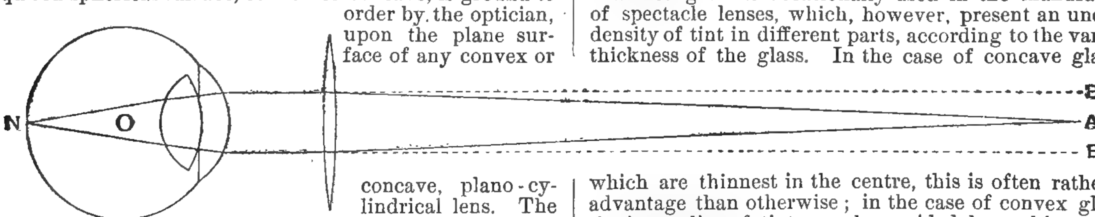

FIG. 3570.

sponding to the axis is that of greatest, and that at right angles to the axis is that of the least (positive or negative), focal length. Cylindrical lenses are sometimes made to order with two cylindrical surfaces of unequal radii of curvature and with crossed axes, but the same optical effect can always be produced with greater ease, and at less cost, by a combination of a single cylindrical (convex or concave) surface with a spherical (convex or concave) surface.*

Prismatic glasses, with plane surfaces, are of the form shown in Fig. 3568; any desired curvature, whether spherical or cylindrical, may be given to either surface, or to both surfaces, of the prism. A prismatic lens with one surface, or both surfaces, ground to a spherical curvature, is equivalent to a lens cut out from a peripheral zone of a spherical lens of greater diameter, as shown in Fig. 3569. A moderate degree of prismatic effect may, therefore, be obtained by the simple expedient of decentering an ordinary spectacle glass; such effects are, in fact, often produced without design, and not infrequently with injurious results, from carelessness in mounting spectacle glasses.

The stenopæic effect may be embodied in any lens, by simply painting over some part of its surface, next the eye, with an opaque, lustreless, black varnish. A partial opacity of the cornea, or a portion of its surface presenting an abnormal curvature, whether original or acquired, may be thus excluded from participation in the formation of the retinal image, with the effect, in some cases, of materially improving the definition of the object.[37]

Tinted glass is occasionally used in the manufacture of spectacle lenses, which, however, present an unequal density of tint in different parts, according to the varying thickness of the glass. In the case of concave glasses, which are thinnest in the centre, this is often rather an advantage than otherwise; in the case of convex glasses the inequality of tint may be avoided by making use of a plano-convex lens to the plane surface of which a thin plate of tinted glass is cemented by means of Canada

* Cylindrical lenses with two cylindrical surfaces, with axes at some other than a right angle, are sometimes prescribed. Such lenses, as well as bi-cylindrical lenses with crossed axes, can always be represented by an optically equivalent combination of a spherical with a cylindrical surface.[36]

balsam. A more elaborate device consists in the cementing of a thin plate of tinted glass between the plane surfaces of two plano-convex (or plano-concave) lenses. Amber has been used as a material for spectacle lenses, notably at Königsberg, about the end of the seventeenth century; the transparency of the amber is said to have been increased by the careful application of heat in a bath of oil or sand.[38]

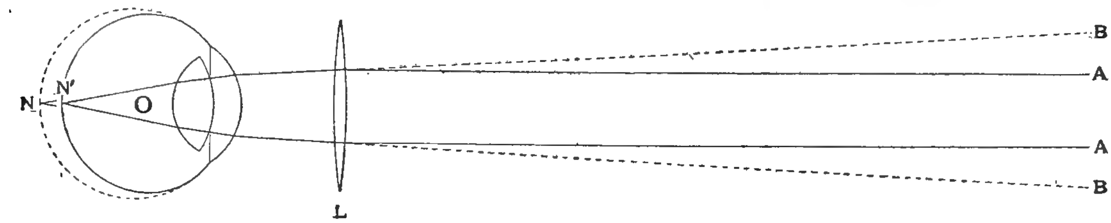

Fig. 3571.

Tinted glasses with parallel surfaces are in common use to temper the light which reaches the eye; they are made either with plane surfaces, like window-glass, or with curved surfaces, like a watch-glass (coquilles). Green was formerly a favorite color, probably from its assimilating the light passing through it to the color of grass and the foliage of trees; blue (the color of the sky) gradually superseded green, and is still much used. A neutral tint, known by the name of London-smoke, has latterly come into common use, and is, in many cases, to be preferred to blue. Glasses of an amber color are also to be found in the shops, generally ground to a dull surface, with the exception of a small, central area.

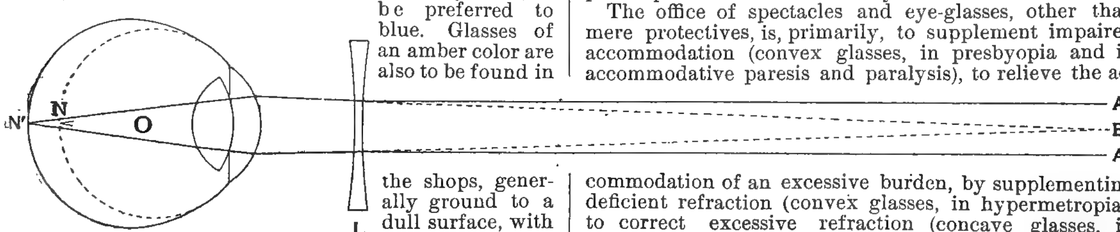

Fig. 3572.

Amber-colored and, still more perfectly, red glasses, by excluding all but the least refrangible rays of the spectrum, may serve (in a strong light) to improve the definition of the retinal image in very low grades of myopia; blue reading glasses, on the other hand, may render some slight degree of aid in low grades of hypermetropia and of presbyopia.[39] Tinted glasses should, as a rule, be mounted in large, oval settings, so as to cover the entire front of the orbit; the coquille form of glass affords more perfect protection than a glass with plane surfaces. Darkly tinted (London-smoke) coquilles are of great use to persons who are exposed to very strong light reflected from sand or from snow, or from the surface of water. Inasmuch as such regularly reflected light is always highly polarized, protective spectacles fitted with thin slices of tourmaline should render valuable service by cutting off the polarized rays, while permitting the unpolarized light, by which objects are actually seen, to pass comparatively unobstructed.[40] London-smoke glass, of so dark a color as to appear quite black in ordinary light, is used in the protective spectacles worn by workmen employed about electric-arc lights, and spectacle glasses made up of several layers of glass of different colors have been found especially useful in observing the intensely brilliant scintillations attending the conversion of pig-iron into steel by the Bessemer process.

All spectacles afford some degree of protection against mechanical injury, and in certain trades it is only by the use of special protectives that the liability to grave accidents to the eyes can be averted. Millers have long been in the habit of wearing large spectacles fitted with thick window-glass when employed in the dangerous work of dressing millstones. Protective spectacles of mica[41] (Cohn, 1868) are especially to be recommended for miners, quarrymen, stone-cutters, boiler-makers, and others engaged in similar dangerous employments. Goggles of finely woven wire-gauze, generally with the fronts glazed with tinted plane glass, are used by railway travellers and others as a protection against flying sparks; goggles made of glass bent to a cylindrical curve of about six inches radius, and furnished with cloth-covered rims to fit closely around the margins of the orbits, are sometimes used as a protection against dust in driving.

Coquille spectacles and eye-glasses, both colorless and tinted, are made also in the meniscus form (with positive focus) and in the concave-convex form (with negative focus); as kept in the shops, they range from about + 8. dioptrics (+ $\frac{1}{5}$) to − 8. dioptrics (− $\frac{1}{5}$). Owing to the shorter radius of curvature of the (concave) surface turned toward the eye, these glasses are more perfectly periscopic than those commonly sold under that name.

The office of spectacles and eye-glasses, other than mere protectives, is, primarily, to supplement impaired accommodation (convex glasses, in presbyopia and in accommodative paresis and paralysis), to relieve the accommodation of an excessive burden, by supplementing deficient refraction (convex glasses, in hypermetropia), to correct excessive refraction (concave glasses, in myopia), and to correct asymmetrical refraction (convex or concave cylindrical glasses, in astigmatism). These several effects are, moreover, often variously combined, as in the use of strong convex glasses, in reading (by hypermetropes with defective accommodation), of partially correcting concave glasses, or, perhaps, of weak convex glasses, in reading (by myopes with defective accommodation), and of glasses of asymmetrical refraction (in compound and mixed astigmatism, and in presbyopia or other accommodative defect occurring in connection with astigmatism).

The action of a convex glass, as used by a presbyope, in reading, is shown in Fig. 3570. Rays emanating from a printed page at A, at such distance from the eye O that the retinal image of the print shall be of sufficient size to admit of its being easily deciphered, are refracted in passing through the lens L (whose focal length must be not less than the distance L A), and are rendered either less divergent—as if they had originated from some point more distant than A—or parallel—as if coming from an

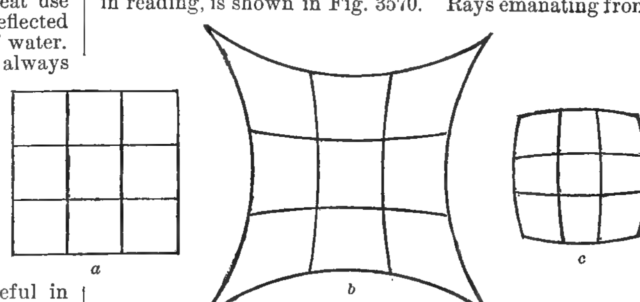

Fig. 3573.

infinite distance. When the focal length of the lens L is equal to the distance L A, the pencils entering the eye

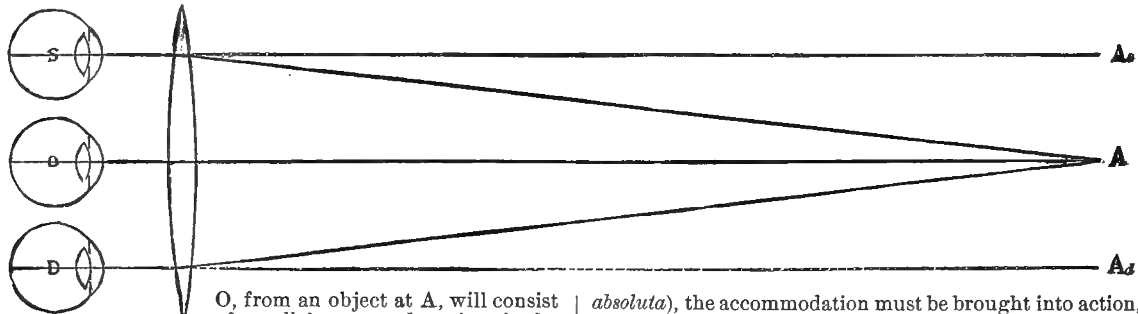

Fig. 3574. L

O, from an object at A, will consist of parallel rays, and a sharply defined retinal image will be formed at N, without exercise of the accommodation. If the focal length of the lens L is greater than the distance L A, the rays forming the several pencils emanating from the object at A will, after refraction by the lens L, be rendered less divergent, as if coming from an object at some distance greater than L A, and the eye O will then be enabled to focus such pencils through the exercise of less accommodation than would

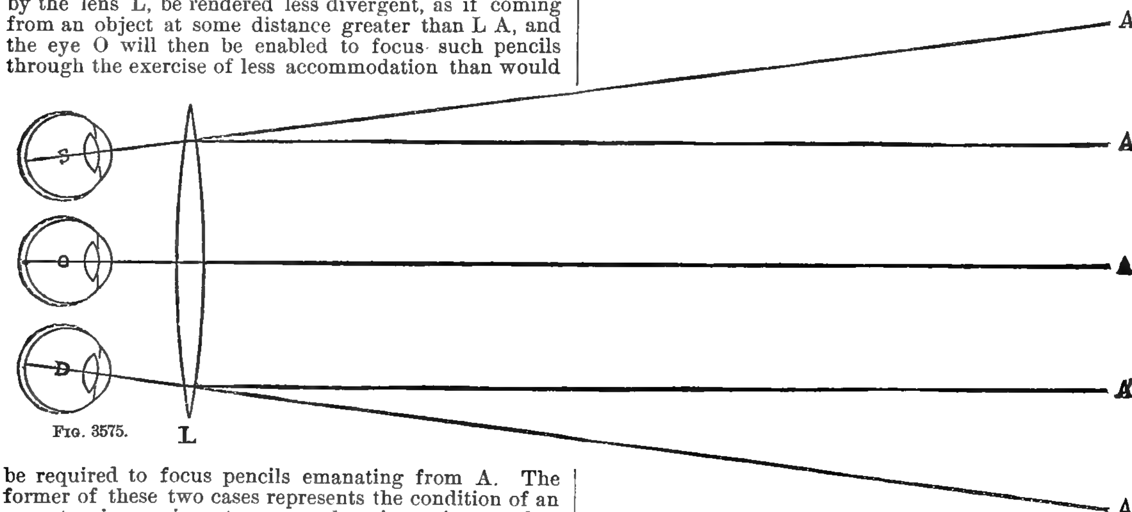

Fig. 3575. L

be required to focus pencils emanating from A. The former of these two cases represents the condition of an emmetropic eye in extreme presbyopia, or in complete paralysis of accommodation; the second case is that of an emmetropic eye in lesser grades of presbyopia, or in a state of weakened accommodation.

The presbyopic eye, when thus adjusted by the convex lens L for the reading distance L A, is, by the very action of the lens, thrown out of adjustment for distinct vision at a distance; a presbyope wearing glasses for

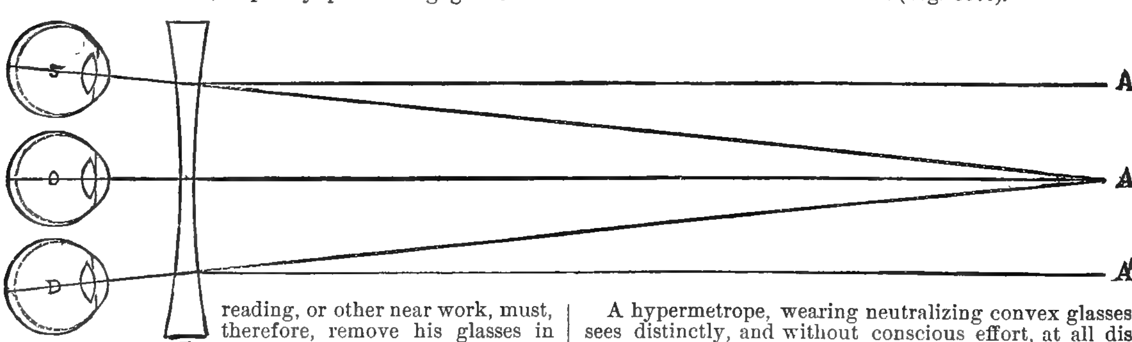

Fig. 3576. L

reading, or other near work, must, therefore, remove his glasses in order to see distinctly at a distance.

Fig. 3571 shows the effect, in distant vision, of a neutralizing convex glass in hypermetropia. A pencil of parallel rays A A, emanating from a distant object, is focussed by an emmetropic eye, without exercise of the accommodation, upon its retina at N. In order to focus the same pencil upon the retina of the hypermetropic eye, at N′ (in all grades of hypermetropia less than H *absoluta*), the accommodation must be brought into action, either wholly or in part.* The neutralizing convex lens L converts the parallel rays of the pencil into rays of such degree of convergence that the hypermetropic eye O can focus them accurately at N′ without using any part of its accommodation; the entire accommodation is thus rendered available to meet the requirements of near vision, and the hypermetropic eye, with its neutralizing glass, becomes virtually emmetropic.

In the extreme case of total presbyopia, or of complete paralysis of accommodation in the hypermetropic eye, a lens equal in power to the sum of the two lenses L (Fig. 3570) and L (Fig. 3571) will be required for distinct vision at the distance L A (Fig. 3570).

A hypermetrope, wearing neutralizing convex glasses, sees distinctly, and without conscious effort, at all distances; when, however, he becomes also presbyopic, the neutralizing convex glasses cease to afford sufficient help in reading, and stronger glasses become necessary. These stronger reading glasses are, however, too strong

* In absolute hypermetropia the total accommodation is insufficient to focus parallel rays.

for distinct vision at a distance; hence, an elderly hypermetrope requires, as a rule, two pairs of convex glasses, the one, neutralizing, for distinct vision at a distance, and another pair, of shorter focus, for reading.

Fig. 3572 shows the use of a neutralizing concave glass, in distant vision, in myopia. The pencil of parallel rays, A A, emanating from a distant object, is focussed by the myopic, as by the emmetropic, eye at the normal position of the retina at N; the actual position of the retina, in the myopic eye, is, however, farther back, as at N'. The myopic eye, in a state of complete accommodative relaxation, can focus only divergent rays, as from an object at some short distance L B, upon its retina, and, by the exercise of its accommodation, can also focus rays diverging from some still nearer point, somewhat within the distance of nearest distinct vision (P) for an emmetropic eye. The neutralizing concave lens L converts the parallel rays of the pencil A A into rays of such degree of divergence as they would have if emanating from B, and thus the myopic eye O is enabled to focus them upon its retina at N'. The farthest point of distinct vision (r) is thus carried off, by the neutralizing concave glass, to an infinite distance, and the near-point (p) is removed to about the distance of the near-point in emmetropia.

When the myopic eye becomes restricted in its range of accommodation, as a result of advancing age, the neutralizing concave glasses must either be laid aside in reading or exchanged for concave glasses of greater focal length (*i.e.*, weaker concave glasses); in myopia of a low grade, it may even become necessary, in reading, to make use of convex glasses, but weaker than those which would be required by an emmetrope of the same age.

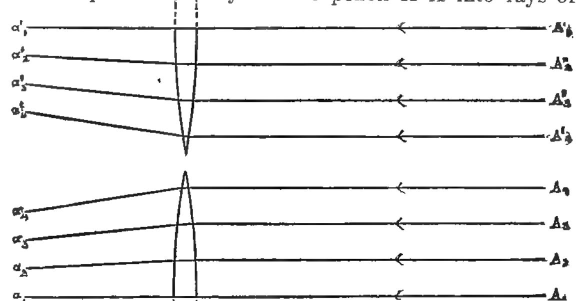

FIG. 3577.

A myope wearing neutralizing concave glasses, like the hypermetrope wearing neutralizing convex glasses, sees distinctly at all distances. Only when he becomes presbyopic does he find himself compelled either to lay aside his concave glasses, in reading, or to exchange them, temporarily, for weaker concave, or, possibly, for weak convex glasses.

Comparing Figs. 3571 and 3572, it will be seen that the pencil of parallel rays A A (Fig. 3571) is of notably greater diameter than the pupil, and, conversely, that the pencil A A (Fig. 3572) is of less diameter than the pupil. As the areas of the cross-sections of the two pencils are to each other as the squares of their diameters, it follows that there must be a very considerable gain in the brightness of the retinal image in the case of hypermetropia corrected by convex glasses, and a corresponding loss of illumination in the case of myopia corrected by concave glasses. These two conditions are, in fact, essentially the same as in looking through an opera-glass in the proper direction and in the reversed direction. Hypermetropes, wearing convex glasses, see somewhat better than emmetropes, by moonlight or starlight, and myopes, wearing concave glasses, see less perfectly under the same conditions; in the higher grades of myopia the disability from this cause is sometimes so great as to simulate night-blindness (see Hemeralopia).

Objects viewed through convex glasses appear larger than do the same objects when their images are focussed by the exercise of the accommodation, and, conversely, objects viewed through concave glasses under accommodative tension appear smaller than do the same objects when viewed without exercise of the accommodation. Hence, a presbyope, using convex glasses in reading, sees the print not only clearer than without glasses, but also larger than it appears to an emmetrope under normal exercise of the accommodation. So, also, a hypermetrope, wearing convex glasses, sees all objects larger than when he views them without glasses, and a myope using concave glasses in reading sees the print smaller than when he reads without glasses. In (axial) hypermetropia, however, the actual size of the retinal image is smaller, as in (axial) myopia it is larger, than in emmetropia; and it is a fact now well established that both hypermetropes and myopes wearing neutralizing glasses at the usual distance from the eye see objects of about the same apparent dimensions as does an emmetrope without glasses.

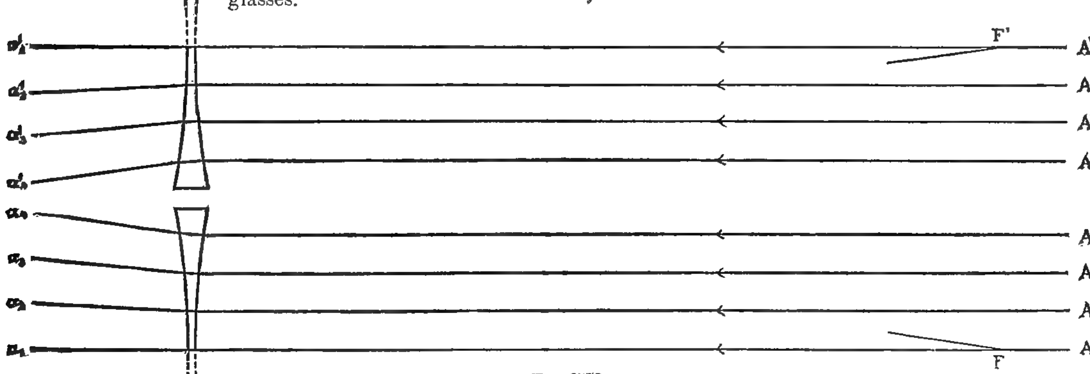

FIG. 3578.

A convex spectacle lens is increased in effective power by increasing its distance from the eye, and, conversely, a concave lens loses in effective power with any increase in its distance. The correct rule of practice is to mount the glasses as near as possible to the eyes, allowing sufficient room for the free play of the eyelashes. A distance of thirteen millimetres from the vertex of the cornea fulfils this condition in most cases, and at the same time allows the correcting lens to be placed almost exactly at the anterior principal focus of the eye, in which position of the glass the retinal image, whether in hypermetropia or in myopia, becomes practically equal in size to the image of the same object when focussed by an emmetropic eye. Whenever a hypermetrope inclines to remove his (convex) glasses to a greater distance from the eye than thirteen millimetres it may be assumed that the glasses are

FIG. 3579. [43]

somewhat too weak fully to correct his hypermetropia, and, conversely, when a myope inclines to wear his (concave) glasses at a distance greater than thirteen millimetres from the eye it may be assumed that the glasses are somewhat too strong. This particular mode of correcting the effect of badly selected glasses in distant vision is but rarely adopted, except in the presence of defective accommodation, as, for instance, by elderly hypermetropes or myopes, and especially by persons who have undergone an operation for cataract. In presbyopia it is a not uncommon practice to slip the (convex) reading glasses far down toward the tip of the nose, in order to make a weak glass do the office of a stronger glass in improving the distinctness of the print, and also in increasing its apparent size; in this position of the glasses it is also easy to look over them at distant objects.

The increase or diminution in the apparent size of objects viewed through a convex or concave lens is not uniform in all parts of the visual field, but is notably greater at its periphery than at its centre. Thus, a large object viewed, centrally, through a spherical convex lens is seen more highly magnified in its peripheral than in its central portions; a square, for example, whose angles are more distant from the centre than is the middle of each side, is seen as if bounded by curved lines with their convexity turned toward the centre of the field.

JAMES W. QUEEN & CO., PHILA.

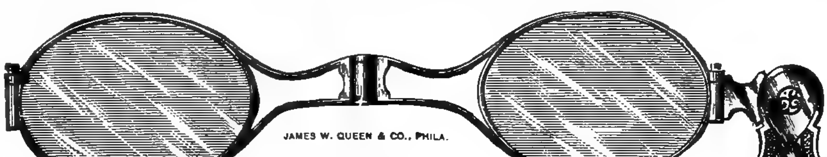
FIG. 3580.

The same square, when viewed through a concave lens, is seen diminished in size, but most diminished in its peripheral portions, so that it appears as if bounded by curved lines with their concavity turned toward the centre. Fig. 3573 shows at *b* and *c* the distortion under which a large square figure *a*—a window, for example—is seen through a convex and a concave lens, respectively; it will be observed that the distortion of the smaller squares increases from the centre toward the periphery of the field.

It has been often remarked that myopes, in selecting concave glasses, are very apt to err by making choice of glasses of somewhat too short focus, which cause objects seen through them to appear very sharply outlined. This phenomenon appears to be a result of the chromatic aberration of the eye, causing the object, when viewed through a concave glass under a full correction for the most highly refrangible (violet) rays of the spectrum, to be seen as if bounded by a very narrow red border, instead of by a broader violet fringe, as when the eye is focussed for the least refrangible (red) rays. If a distant point of light is viewed by an over-corrected myopic eye through a piece of cobalt-blue glass, the light will appear blue, with a narrow red halo; if the eye is under-corrected by its concave glass, the light will appear red, with a broader violet halo.

A convex or concave cylindrical lens, as used for the correction of astigmatism, simply elongates or shortens the retinal image in a direction at right angles to the axis of the lens; thus, the relation of the two diameters of the object appears altered, a circle appearing elongated or shortened to an ellipse, etc. The distortion from this cause in regular astigmatism, when the direction of the two principal meridians happens to be asymmetrical in the two eyes, may give rise to such difference in the two retinal images as to evoke a great variety of stereoscopical illusions from the fusion of the two impressions in binocular vision; illusions of this kind are, however, very soon corrected by experience, as the wearer of the cylindrical glasses becomes accustomed to the new conditions.

Incidental to the action of convex and concave glasses in modifying the exercise of the accommodation is the effect which they exert upon convergence as associated with accommodation. Convex glasses, by relieving the accommodation of a part of its load (in hypermetropia), exert at the same time a positive effect in diminishing the correlated convergence; hence, they rank first among the therapeutic agents at our disposal for arresting the development of convergent strabismus, and even, in many cases, for its cure. Concave glasses, on the other hand, by increasing the demand made upon the accommodation



JAMES W. QUEEN & CO., PHILA.

FIG. 3581.

in near vision (in myopia), evoke also increased action of the recti-interni muscles, with correlated relaxation of the recti-externi, and thus afford relief in many cases of muscular asthenopia and of crossed diplopia, and even of divergent strabismus.

Spectacles, whether convex or concave, may be so mounted as to exert also a direct action upon convergence. This effect may be developed accidentally, as a result of imperfect centration of one or both glasses, and may then be attended with more or less harmful consequences, or it may be produced designedly, and applied with advantage to the treatment of muscular insufficiency.

This action of convex and concave glasses is shown, for three particular cases, in Figs. 3574 to 3576. The large convex lens L (Fig. 3574) receives divergent rays from the point A, situated at a distance equal to its principal focal length, which rays are rendered parallel by the lens. An emmetropic eye at O, behind the centre of the lens, sees an object at A by looking directly at it, in the direction O A; but an eye at D, or at S, in order to see the same object, must look in the direction D Ad, or S As, parallel to O A.

In Fig. 3575 the large convex lens L receives the parallel rays of the pencil A′ A_1, coming from a distant object, and renders them convergent. A hypermetropic eye at O, behind the centre of the lens, sees the object lying in the direction O A, by looking directly at it; but an eye at D, or at S, in order to see the same (very distant) object, must look, not in its true direction, D A′, or S A_1, but in the direction D Ad, or S Aa.

In Fig. 3576 the large concave lens L receives the par-

allel rays of the pencil A′ A_1, coming from a distant object, and renders them divergent. A myopic eye at O, behind the centre of the lens, sees the distant object lying in the direction O A, by looking directly at it; but an eye at D, or at S, in order to see the same (very distant) object, must look, not in its true direction, D A′, or S A_1, but in the direction D A, or S A.

If we take D and S as representing the right and left eye, the effect of the lens, in the three cases under consideration, will be (1) to associate parallelism of the visual axes with full relaxation of the accommodation in looking at a near object (in emmetropia, Fig. 3574); (2) to compel divergence of the visual axes (or else to evoke homonymous diplopia, in looking at a distant object (in hypermetropia, Fig. 3575); or (3) to compel convergence of the visual axes (or else to evoke crossed diplopia) in looking at a distant object (in myopia, Fig. 3576). In all three cases the conditions thus evoked are unnatural, and the second and third involve a divorcement of the allied adjustments of accommodation and convergence. The arrangement shown in Fig. 3574 is that employed in so-called cosmoramas, or peep-shows, to produce the double illusion of increased size and greater distance in looking at a photograph or other picture through a large convex lens. In the arrangement shown in Fig. 3575 single vision with the two eyes is impossible, except in the abnormal condition of divergent strabismus, which, however, is only exceptionally found associated with hypermetropia. In the arrangement shown in Fig. 3576 the excessive convergence incidental to looking through the marginal portions of the concave lens tends to evoke some measure of accommodation also, and thus to impair the distinctness of distant vision when the lens is of such focal length as exactly to correct the myopia.

The proposal to make use of decentrated lenses, as shown in Figs. 3574 and 3576, in uncomplicated presbyopia and myopia,[42] is irrational. In presbyopia complicated with marked falling off in the acuteness of vision, the principle illustrated in Fig. 3574 may be utilized to relieve the recti-interni muscles of undue strain in reading, at exceptionally short range, with convex glasses of very short focal length. The dissecting spectacles of Brücke[32] are constructed on this principle.

The action of decentrated lenses, when the centre of each lens is removed to the temporal instead of to the nasal side of the eye, is shown, for convex and concave lenses respectively, in Figs. 3577 and 3578. In Fig. 3577 the two halves of a convex lens, divided through its centre, are transposed, so that the right eye looks through what was originally the left half of the lens, and the left eye through the right half. The parallel rays A_1, A_2, A_3, A_4, and A'_4, A'_3, A'_2, A'_1, of the two pencils, after traversing the two halves of the lens, become convergent, with foci at F and F′. By varying the distance between the two lenses, the symmetrically refracted rays A_1 A'_1, A_2 A'_2, A_3 A'_3, or A_4 A'_4 may be made to fall opposite the centres of the pupils of the two eyes, which will then be compelled to assume positions varying from parallelism of the visual axes to a considerable degree of convergence.* In the case of the transposed halves of

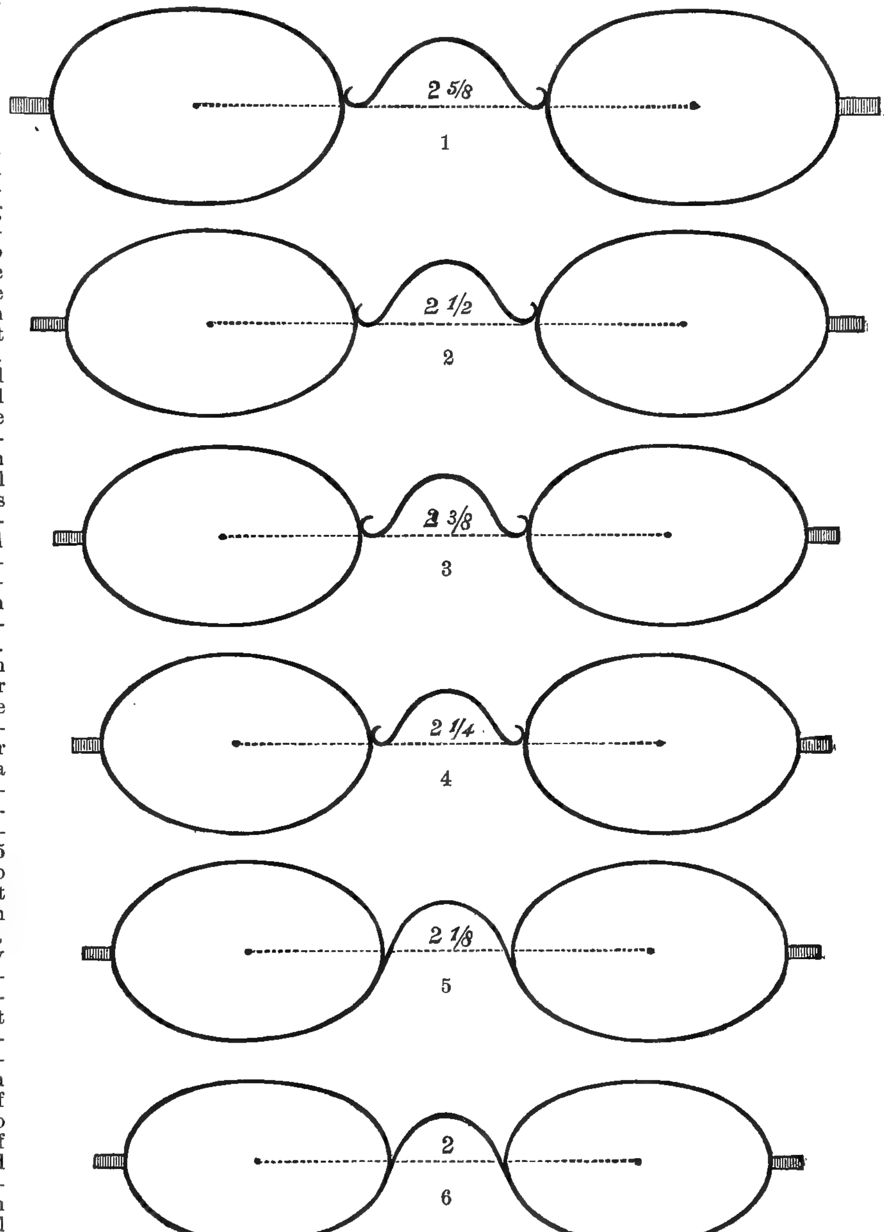


FIG. 3582.[44]

* The arrangement of transposed halves of a convex lens, as shown in Fig. 3577, is that usually adopted, after Brewster,[33] in the construction

a concave lens (Fig. 3578) the conditions are exactly the reverse of those shown in Fig. 3577.

Instead of cutting out two spectacle lenses from a peripheral zone of a very large convex or concave lens, it is found to be quite as convenient, and much less costly, to grind the required convex or concave surface upon one side of a prism; upon the other side of the prism a cylindrical surface may be ground if required for the correction of astigmatism. Such glasses are of not infrequent use in ametropia, when complicated by insufficiency of the recti-interni or of the recti-externi muscles, and are thus available in many cases of muscular asthenopia, and of diplopia of moderate grade even when dependent on paresis of one of the recti muscles; in strabismus, they are seldom of much utility.

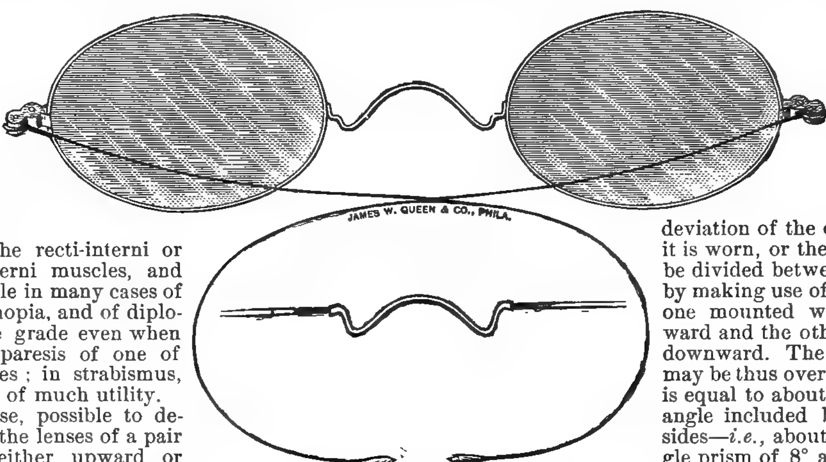

FIG. 3583.

It is, of course, possible to decentrate one of the lenses of a pair of spectacles, either upward or downward, or to decentrate one glass upward and the other downward; this expedient is occasionally utilized in cases of slight upward or downward deviation of one of the visual axes.

The decentration of a spherical lens, whether convex or concave, necessarily gives rise to some distortion of the retinal image, and the greater the decentration the more pronounced will be the distortion. This is shown in Fig. 3573, *b*, and *c*, in which the small squares at the sides and at the angles of the larger square are drawn as they are seen through peripheral portions of a convex or a concave lens. Moreover, the several pencils of rays, after refraction by a decentrated lens, are no longer homocentric, *i.e.*, they no longer converge toward or diverge from a focal point, but pass through two so-called focal lines. In other words, a decentrated spherical lens always gives rise to some degree of astigmatism, which may, in certain cases, be so great as to require correction; this may be effected by using lenses of the plano-convex or plano-concave form, and grinding a cylindrical surface upon the plane side.*

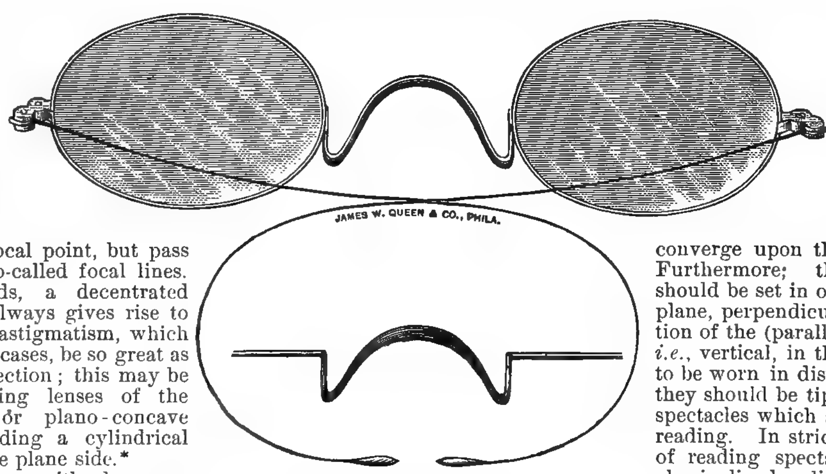

FIG. 3584.

Prismatic glasses with plane surfaces (Fig. 3568) may be mounted with their bases turned toward the nose, in which case they relieve the recti-interni muscles of a part of their work in convergence, and may also restore binocular vision at a distance in cases of crossed diplopia, dependent on very slight divergence of the visual axes. Mounted with their bases turned toward the temples, they are applicable in certain cases of insufficiency of the recti-externi, or of preponderance of the recti-interni, as in the homonymous diplopia which is sometimes observed in low grades of convergent strabismus. A prismatic glass, mounted with the base upward or downward, before one eye only, may be used to neutralize the effect of a slight upward or downward deviation of the eye before which it is worn, or the correction may be divided between the two eyes by making use of two prisms, the one mounted with its base upward and the other with its base downward. The deviation which may be thus overcome by a prism is equal to about one-half of the angle included between its two sides—*i.e.*, about 4° with a single prism of 8° angle, or 8° with a prism of 8° angle worn before each eye. Prisms of more than 8° angle are ordinarily rejected on account of the conspicuous colored fringes due to chromatic dispersion.

The normal effect of any spectacle lens is, as already shown, obtained only when the lens is accurately centred in front of the pupil; another important condition is that the plane in which the lens is set be perpendicular to the direction of the visual axis. The distance between the centres of the two lenses of a pair of spectacles intended to be worn in distant vision should, therefore, be exactly equal to the interpupillary distance, but in the case of reading glasses, the distance between the centres of the two lenses should be somewhat less than the lesser inter-pupillary distance when the visual axes are made to converge upon the printed page. Furthermore, the two lenses should be set in one and the same plane, perpendicular to the direction of the (parallel) visual axes—*i.e.*, vertical, in the case of glasses to be worn in distant vision—but they should be tipped forward in spectacles which are to be used in reading. In strictness, the lenses of reading spectacles should be also inclined a little toward each other, so as to face the point of intersection of the visual axes upon the printed page.

Whenever a (convex or concave) spherical lens is set obliquely to the direction of the visual axis, its refractive power is increased, though in very different degree, in all its meridians, the increase being greatest in the meridian corresponding to the plane of the arc through which the lens is rotated, and least in the meridian of the axis about which the rotation takes place. In the case of a (convex or concave) cylindrical lens, rotated about its axis, the increase in refractive power varies from a maximum, in the meridian at right angles to the axis, to zero, in the meridian of the axis. When rotated about the

of stereoscopes; its effect is to permit the two (slightly different) pictures, mounted upon the stereoscopic slide, to be viewed, at one and the same time, by the two eyes, under moderate convergence of the visual axes, or, as is more commonly the case, to permit two pictures whose corresponding points are more widely separated than are the centres of the two pupils to be viewed by the two eyes with parallel visual axes.

* For a mathematical discussion of these and other examples of the effects of spherical aberration, the reader is referred to special works on optics—*e.g.*, Parkinson's Optics, Chapter IV., "on focal lines of small oblique pencils, and caustics;" also Chapter VII., "on spherical aberration of lenses."

meridian at right angles to its axis, a (convex or concave) cylindrical lens shows also a positive increase in refractive power, though in a lesser degree than when it is

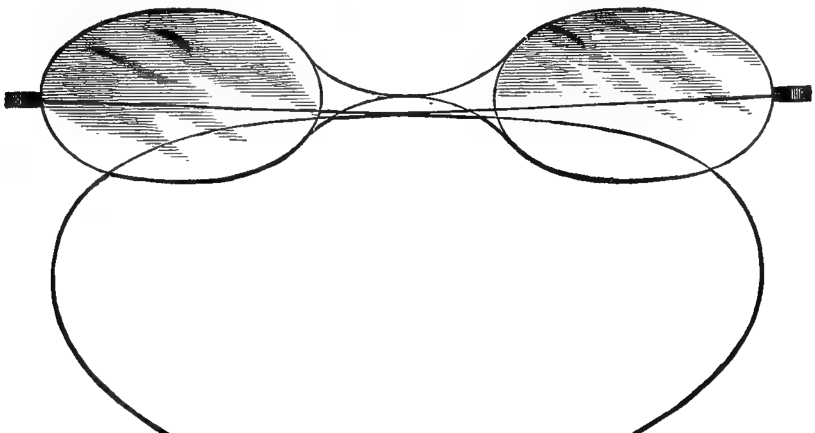

FIG. 3585. [44]

rotated about its axis. It follows that a tipped spherical lens becomes practically equivalent to a (somewhat stronger) spherical lens with a cylindrical lens added to it, and that, in the case of a spherico-cylindrical lens, the special effect of the cylindrical surface may be either increased or diminished, according as the (compound) lens is rotated about one or the other of its principal meridians. A tipped concave spherical lens may be occasionally utilized, in distant vision, in myopia, with astigmatism of relatively low grade, when the ocular meridian of greatest refraction happens to be vertical (or very nearly vertical), and a vertically mounted convex spherical lens may be given, for reading, when the ocular meridian of greatest refraction happens to be (exactly or approximately) horizontal.* Again, in myopia with astigmatism, when the ocular meridian of greatest refraction happens to be approximately horizontal, the wearer of concave spherical glasses may learn the trick of looking obliquely through his glasses, either to the right or to the left, and may thus add materially to his acuteness of vision, though at the cost of acquiring an awkward carriage of the head. So, also, a hypermetrope with some measure of astigmatism, when the ocular meridian of greatest refraction happens to be approximately vertical, may, similarly, get a better correction from his (convex spherical) glasses by looking obliquely through them to one side.

A myope, wearing concave glasses of a power insufficient fully to correct his myopia, is very apt to look obliquely to one side, in order to improve his vision for the vertical lines of a distant object, and he may, at the same time, contract the opening of the eyelids, in order to improve his vision for horizontal lines. In hypermetropia, this habit is but rarely acquired, for the reason that here the accommodation is generally brought into exercise to supplement the effect of the glasses, but in aphakia, owing to the total loss of accommodative power, it is not infrequently observed.

Spectacle lenses are usually mounted in oval rings of metal (rims—*cercles*), or, in the case of eye-glasses, of tortoise-shell, horn, hard rubber, celluloid, etc. The rims used in mounting convex glasses are almost always grooved, so as to grasp the sharp edge of the lens; concave glasses, too, are ground, as a rule, to a sharp edge, and mounted in grooved rims, but it is a not infrequent practice to groove

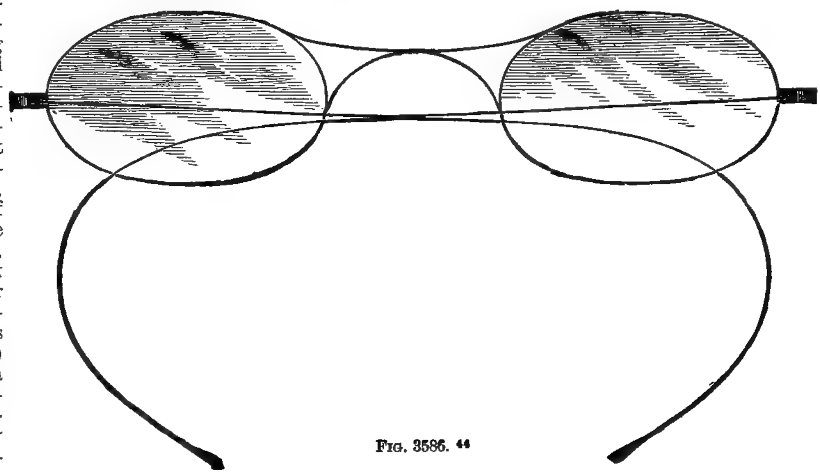

FIG. 3586. [44]

the lens itself, and to sink the rim, which is then made of thin (steel or gold) wire, in the groove. Convex lenses, also, are occasionally mounted with the rims sunken, but at the cost of making the lens needlessly thick and heavy. So-called frameless or rimless glasses have the nose and side pieces attached by means of screws passing through holes drilled in the lenses at their nasal and temporal sides; concave lenses, with their thick margins, lend themselves better to this construction than do convex lenses.

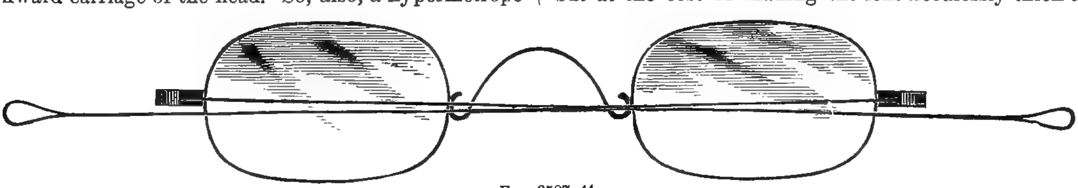

FIG. 3587. [44]

Caprice has sometimes dictated the wearing of a single eye-glass, carried at the end of a riding-whip, a fan, etc., or worn suspended by a cord; in the latter case the glass is held in front of the eye by contracting the orbicularis

* A familiar instance of such a correction, in myopia, is seen in the not infrequent preference given to a tipped (concave spherical) eye-glass over glasses mounted in a vertical position, in a spectacle frame. So, also, after an operation for cataract, a spherico-cylindrical lens, with axis horizontal, may be required to raise distant vision to its maximum, although, for reading, a spherical glass may be preferred, by reason of the augmented refraction, in the vertical meridian, incident to the oblique (downward) direction of the visual axes.

muscle upon its rim in a singularly awkward and inconvenient fashion. Binocular glasses may be divided, ac-

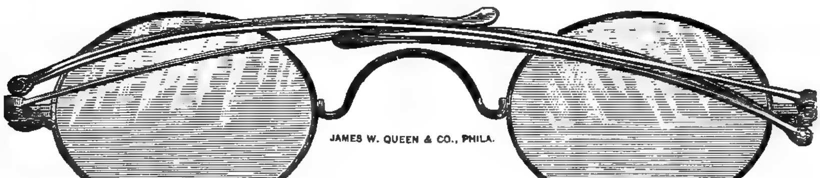

FIG. 3588.

cording to the way in which they are held before the eyes, into three groups—namely, eye-glasses held in the hand (lorgnette—*face à main*; Figs. 3579, 3580, and 3581 [43]), those held in place by means of a spring which pinches the nose (*pince-nez—Nasenzwicker, Nasenklemmer*), and spectacles proper, which are held in place by means of side-pieces passing above and behind the ears (*lunettes à branches*). To these three principal types may be added a fourth, now disused except in the case of protective goggles, in which the glasses are held in place by means of tapes or an elastic band passing around the head above the ears.

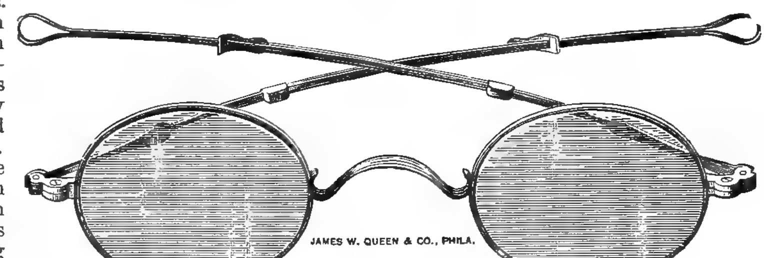

FIG. 3589.

The several parts of a pair of spectacles are (1) the rims (*cercles*), in which the glasses are mounted, (2) the bridge, or nose-piece (*arcade centrale*), by which the rims are connected and supported upon the

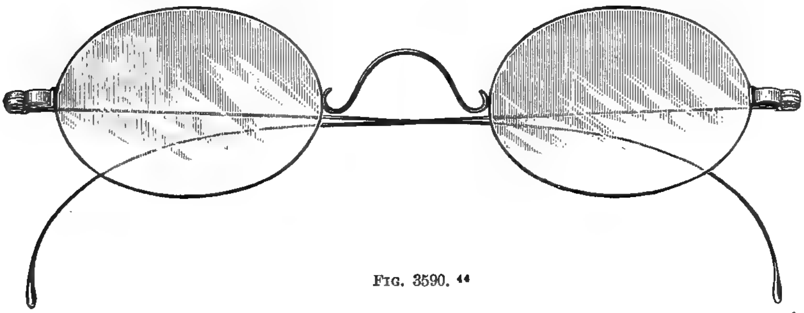

FIG. 3590. [44]

bridge of the nose, and (3) the side-pieces (temples—*branches laterales*), by which the spectacles are held in place upon the head. The size of the rims and the length of the bridge should be so proportioned as to conform both to the interpupillary distance, in order that the wearer may look through the centres of the glasses, and to the width of the face, so that the side-pieces may touch, but not press too tightly against, the sides of the head. In the case of great width of face, larger rims are generally required than when the face is narrow (see Fig. 3582 [44]); any variation from the usual proportion between the interpupillary distance and the width of the face may generally be met by varying the length of the bridge. In order properly to fit the face, it may sometimes be necessary to select a frame in which the distance between the centres of the rims is a little

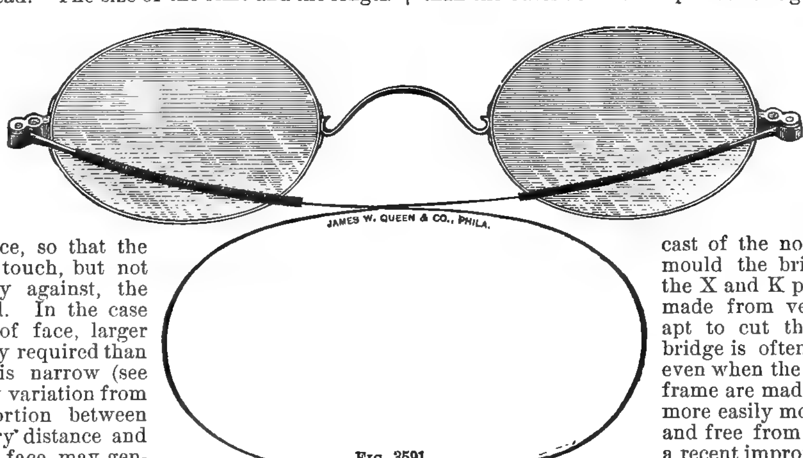

FIG. 3591.

greater or a little less than the interpupillary distance, but in such a case care should be taken, in setting the glasses, to preserve the proper distance between their centres.

The bridge should be shaped to fit the nose, and partially to encircle it; noses, however, differ very greatly in prominence and in thickness, so that no single type of bridge is suited to all cases. The "hoop" bridge (Fig. 3582, 5 and 6) is one of the older forms, and is suited to noses of considerable thickness and prominence; the hoop may lie in the same plane with the glasses, or it may be turned forward at any required angle. The slightly modified form shown in Fig. 3582, 1, 2, 3, and 4 is now more commonly used than the plain hoop, and, like it, may be set at any required angle to the plane of the glasses. These forms are well suited to noses of some prominence, but in other cases they fail to support the glasses at the proper height, or at a sufficient distance from the eyes to avoid contact with the eyelashes. To obviate this serious defect in the hoop bridge two very useful modifications have been recently introduced, namely, the twisted or "snake" bridge (Fig. 3583 [43]), and the "saddle" bridge (Fig. 3584 [43]). The so-called X bridge (Fig. 3585 [44]), and the K bridge (Fig. 3586 [44]), are extensively used in frames of very light weight; they are, however, of less general applicability than the other forms. A perfect bridge should present a rather broad surface of contact with the nose, and special care should be taken to secure an accurate and easy fit; in rare instances it may even be worth while to make a cast of the nose upon which to mould the bridge. Bridges of the X and K patterns, as usually made from very thin wire, are apt to cut the nose. A gold bridge is often to be preferred, even when the other parts of the frame are made of steel, as being more easily moulded to the nose and free from liability to rust; a recent improvement consists in the application to the hoop or saddle bridge of a lining of fine cork. Spectacle-frames of tortoise-shell were once in common use, and are on many accounts to be commended; frames are still made

in limited quantities with the rims and bridge formed from a single piece of shell or of celluloid. Either material may be softened by the application of a gentle heat, so that the bridge may be bent to almost any desired shape.

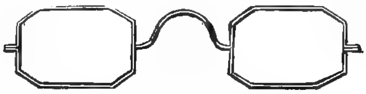

Fig. 3592.[43]

The side-pieces (temples—*branches*) should be slightly bowed to fit the sides of the head; they should be of at least sufficient length to reach a little behind the ears (single temples, Fig. 3587[44]), or they may be made a couple of inches longer by jointing them on a pivot at about the point where they rest upon the ears (turn-pin temples, Fig. 3588[43]), or by the use of a sliding mechanism (sliding temples, Fig. 3589[43]). Best of all are the hooked or "riding" temples (Figs. 3583 to 3586, and 3590[44]), which are made of thin and very elastic wire bent downward in an easy curve behind the ears. By a recent invention, consisting in the introduction of a delicate, spirally wound wire in the side-pieces, near their proximal ends, the flexibility of hooked temples has been materially increased (Fig. 3591[43]).

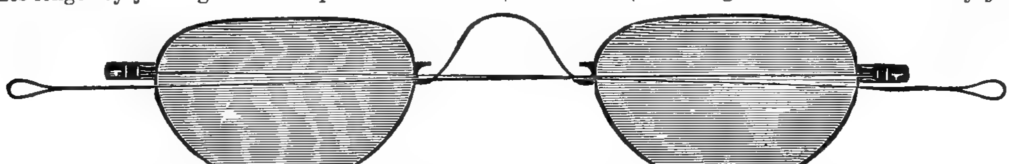

Fig. 3593.[44]

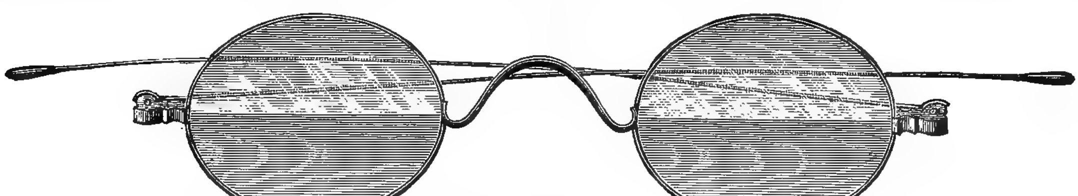

Fig. 3594.[44]

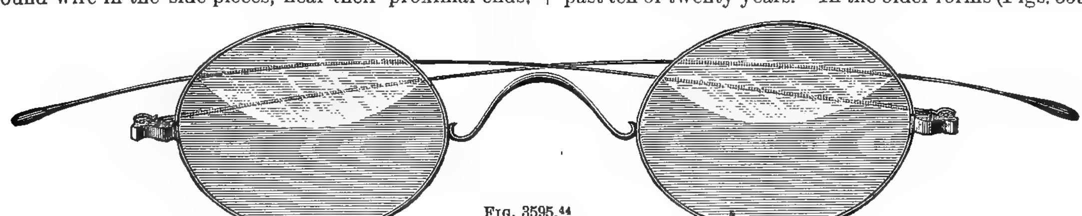

Fig. 3595.[44]

The several parts of a spectacle-frame should be nicely proportioned to each other. In the case of spectacles with single temples the bridge should be of sufficient stiffness to maintain its shape unaffected by the lateral spring of the side-pieces. Only when hooked temples are used is it admissible to make all parts of the frame of very light weight.

Fashion has played its part in prescribing the form of spectacle-glasses; the original shape was doubtless circular, a form still occasionally adopted for spectacles, but more frequently for eye-glasses. The shape now generally preferred is a nearly regular oval, but with considerable variation in the proportion of the two principal diameters. Another and perhaps preferable form is oblong, with rounded angles (Fig. 3587). A parallelogram with the four corners cut off by straight lines (octagon glasses, Fig. 3592[43]) was a favorite shape not many years ago, and, though rather ungraceful, is still occasionally used. Pantoscopic glasses, so called, have the upper part of the rims flattened (Fig. 3593[44]), in order to permit the wearer of reading glasses to see over them in looking at distant objects; the glasses are also set, as a rule, obliquely to the direction of the side-pieces, but perpendicular to the direction of the visual axes in reading. In ametropia, with defective accommodation, it is often convenient to mount two half-lenses in each rim (Fig. 3594[44]), the upper half (convex or concave) of a focal length suited to the correction of the actual hypermetropia or myopia, the lower half, of the focus needed for reading; * a similar effect is obtained, though somewhat less perfectly, by grinding the upper and lower halves of the same lens to different radii of curvature (bi-focal glasses—*verres à double foyer*, Fig. 3595[44]). Another useful arrangement consists in mounting a reading correction in a separate frame, to be hooked upon the front of the spectacles habitually worn in distant vision (Fig. 3596[44]).

Eye-glasses of the *pince-nez* † pattern have been made since an early period in the history of spectacles, but their construction has been greatly improved within the past ten or twenty years. In the older forms (Figs. 3597[44] and 3598[44]) the centres of the glasses stand much too near together, and the glasses themselves are very apt to tip forward in a way that is sometimes very detrimental to the optical effect intended to be obtained from them. In

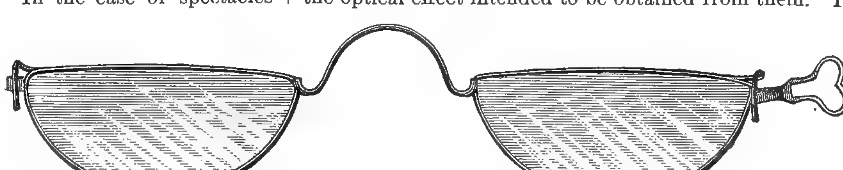

Fig. 3596.[44]

many cases, also, they stand so near to the eyes as to allow insufficient room for the play of the eyelashes, and when-

* Benjamin Franklin is said to have worn such glasses, and they are commonly called by his name.

† In a fresco by Dom°. Ghirlandajo (1449–1494), in the Church of Sta. Trinita at Florence, an elderly bishop is represented as reading through a *pince-nez* set very low upon the nose; the rims of the glasses are circular, and the connecting arc is apparently rigid. This construction and manner of wearing the *pince-nez* explains the objection formerly made to it, as liable to compress the nostrils and impart a nasal quality to the voice. A fac-simile of the portion of the fresco containing this head has been reproduced, in color, in one of the publications of the Arundel Society, London, 1860.

ever the nose is unsymmetrical one glass is pretty sure to stand noticeably higher than the other. In eye-glasses of improved construction these defects are to a considerable extent obviated. Thus most of the modern eye-glasses have some form of projecting nose-clips, which may be set either in the same plane with the glasses, or in a plane behind that of the glasses and inclined to it at any required angle to secure the best possible bearing upon the sides of the nose; some eye-glasses have also a provision for adjusting the clips, upon the two sides, so as to fit noses of almost any shape and thickness, and of very considerable degrees of asymmetry. A cork-lining to the clips greatly increases their adhesiveness, and thus does away with the necessity of strong pressure in order to hold the glasses firmly in position (Figs. 3599 [43], 3600 [43], 3601 [43], and 3603 [43]). The tilting of the glasses, in cases of exceptional prominence of

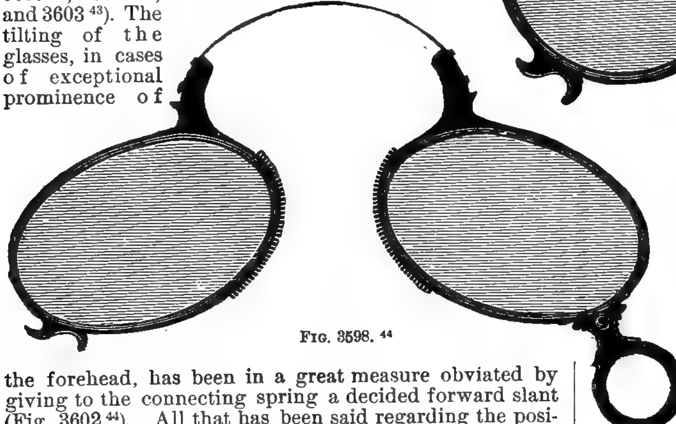

FIG. 3598. [44]

the forehead, has been in a great measure obviated by giving to the connecting spring a decided forward slant (Fig. 3602 [44]). All that has been said regarding the position of the glasses when mounted in spectacle-frames applies equally to eye-glasses, and it is often possible, by taking sufficient pains, to fit up a *pince-nez* which shall prove a very tolerable substitute for a pair of spectacles. For mounting cylindrical and prismatic glasses they are especially unsuitable, by reason of the difficulty which is apt to be experienced in keeping them straight before the two eyes. The especial convenience of eye-glasses lies in the fact that they are easily put on and off; they are not well suited for reading, except for a few minutes at a time, nor for continuous wearing in distant vision. In most cases of asthenopia, and especially in progressive myopia, the wearing of a *pince-nez* should be prohibited.

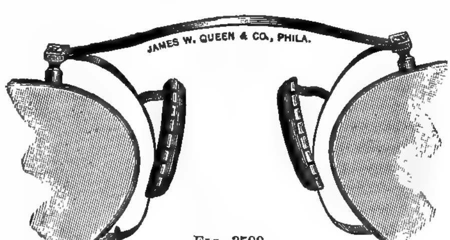

FIG. 3599.

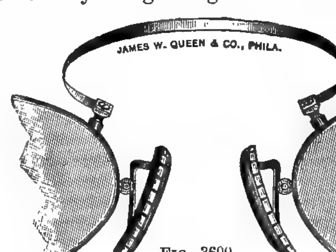

FIG. 3600.

The different methods used in testing eyes for the cor-

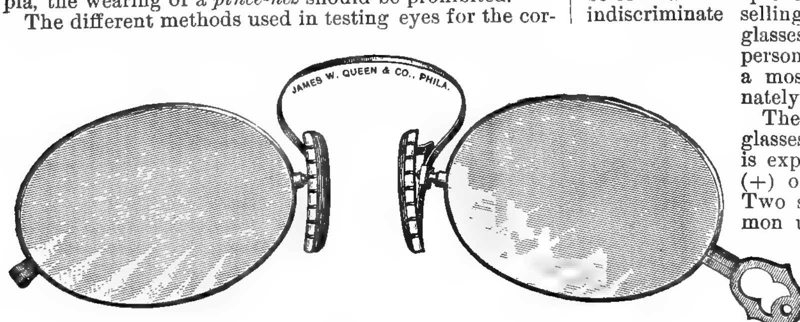

FIG. 3601.

rection of the several refractive and accommodative defects, whether simple or complicated, have been already described under the titles Astigmatism, Hypermetropia, Myopia, Presbyopia, and Optometry. The points to be particularly investigated in all cases are (1) the state of the refraction, (2) the acuteness of vision, and (3) the state of the accommodation. Only after these three determinations have been made, with at

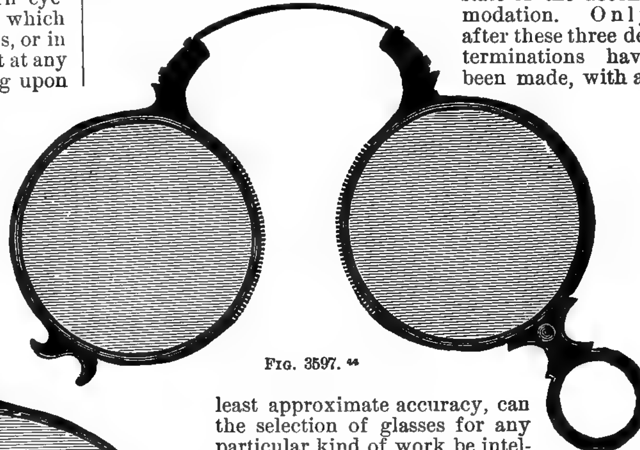

FIG. 3597. [44]

least approximate accuracy, can the selection of glasses for any particular kind of work be intelligently made. In the present state of diffusion of knowledge in the domain of physiological optics these tests can be safely entrusted only to the ophthalmic specialist—physicians and spectacle-dealers being alike incompetent, as a rule, to decide any but the simplest questions. A person who has arrived at the age of forty-five years without having experienced any trouble in the continuous use of his eyes in near and distant work, may not be likely to commit any great error in buying weak convex glasses when he becomes conscious that he is beginning to suffer from the disabilities of presbyopia; but even in such a case an examination of the eyes by a competent observer may bring to light some measure of astigmatism which it may be well worth while to correct, or, possibly, some pathological condition which it may be of vital consequence to detect in its incipiency. The indiscriminate selling of concave spectacles and eye-glasses to young myopes, or to young persons hastily assumed to be myopic, is a most reprehensible, as it is, unfortunately, an almost universal practice.

The power of convex and concave glasses, whether spherical or cylindrical, is expressed by numbers, with the plus (+) or the minus (−) sign prefixed. Two systems of numbering are in common use, the older (inch) system, based on a unit-lens with two curved surfaces of equal radii of 1 Paris inch; the other or new (metric) system, in which a lens of a focal length of 1. metre (dioptric; D) is taken as the unit. In the older system it so happens, through an accidental relation of the Paris to the English inch, that the focal length of a bi-convex or bi-concave lens, of equal radii, in

Spectacles.

English inches is almost exactly equal to the radius of curvature in Paris inches. The two systems may, therefore, be regarded as based respectively upon unit-lenses of 1 English inch and 1. metre focal length. The difference between the two systems consists essentially in the fact that in the case of the smaller unit, of 1. metre focal length, the power of any lens of a power greater than this unit is expressed by a whole number or by a whole number and a decimal fraction, whereas in the case of the larger unit, of 1 English inch focal length, the power of every lens is expressed in the form of a vulgar fraction, with unity for its numerator, and the focal length of the lens, in English inches, for its denominator. Each system has practical advantages of its own, and neither is of such pre-eminent merit as to justify the total rejection of the other. Fortunately, the relation of the metre to the English inch is such as to admit of the use of the two systems interchangeably, by taking the metre-lens (dioptric) as practically equivalent to the lens numbered $\frac{1}{40}$ in the inch system—an assumption which involves an insignificant error, and less than that which arises from the use, at different times and by different makers, of glass whose index of refraction is not always exactly the same. Tables I. and II. give the two series of numbers according to the two systems, as they are generally kept in stock by opticians, and for which grinding tools are ordinarily available.

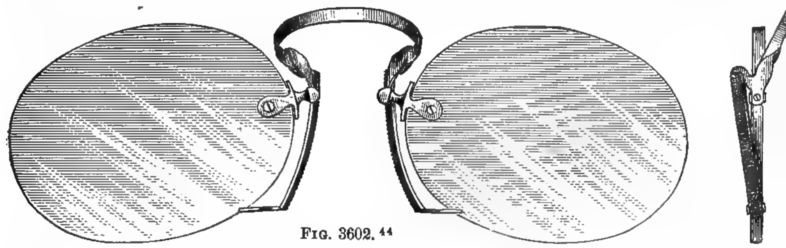

FIG. 3602.[44]

Table I.		Table II.

1–2$\frac{1}{4}$	17.777	....	....
1–2	20.0	....	....

Cylindrical lenses are numbered according to their power (in dioptrics) or focal length (in English inches) in the meridian at right angles to the axis. Lenses of unequal refraction in their two principal meridians are almost always made by grinding a spherical and a cylindrical surface upon the two sides of the same glass, and the formula for such a lens is written, for each surface, exactly as if the lens were made up of a plano-spherical and a plano-cylindrical lens with their plane surfaces in contact. The direction of the axis of a cylindrical lens or surface is defined by giving its inclination (in degrees of arc) to either the horizontal or the vertical plane of the eyeball. If the two surfaces of any lens, where they are cut by the axis of the eye, are not parallel, the deviation from parallelism is expressed by the magnitude of the angle which the two tangent-planes make to each other, as if the two refracting surfaces were ground upon the two surfaces of a prism; the direction of the refracting angle of this prism is defined in the same manner as the direction of the axis of a cylindrical lens.

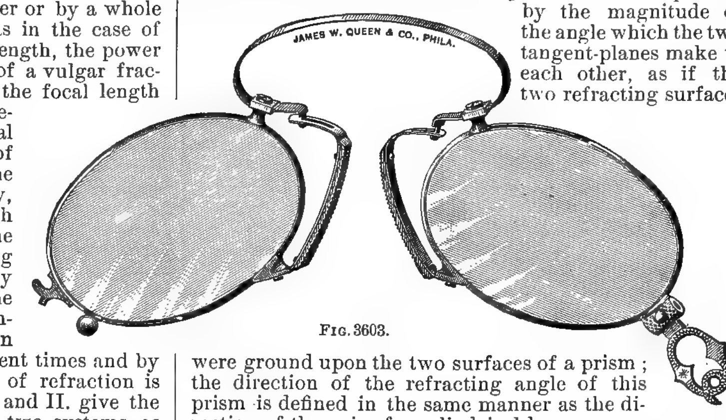

FIG. 3603.

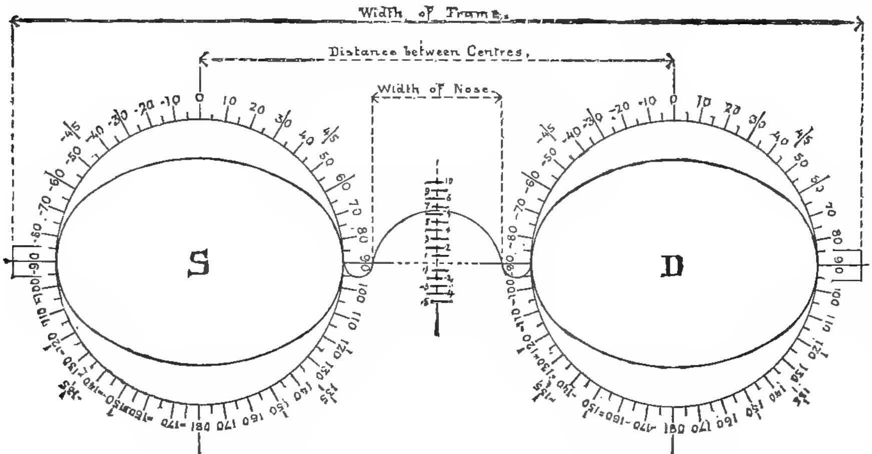
In prescribing spectacles it is convenient and useful to lay off these angles on a printed diagram. Such diagrams have been in common use in this country since 1876, and are furnished, in a variety of forms, by most opticians. A spectacle frame (Fig. 3604) is shown in the position in which the wearer is supposed to look through it, and the angles are marked, in degrees, with the plus (+) sign to the right, and the minus (−) sign to the left of zero, which is taken at the upper end of the vertical meridian. A more usual, but less natural, system of marking the angle of inclination is by beginning with zero on the horizontal line, at the left side, and numbering around the upper half of the circle to 180°. A half-circle is sufficient to designate the direction of the axis of any cylindrical lens, but the whole circle of 360° is required to indicate the different directions in which it may be necessary to turn the refracting edge of a prismatic glass.

The power of any (convex or concave) lens is most easily measured by placing over it an equivalent (concave or convex) lens, of known value, and looking through the two lenses at a straight line, such as a sash-bar of the window; the equivalence of the two lenses is shown by the absence of any enlargement or diminution of the virtual image, as indicated by the immobility of the image of the (vertical) bar when the mutually neutralizing glasses are moved from side to side. In applying this test to a cylindrical lens the axis of the lens must be so turned as to coincide in direction with the line used as a test-object; in the case of a spherico-cylindrical lens the refraction may be measured in the two principal meridians in succession, the lesser of the two measurements representing the spherical, and their difference representing the cylindrical refraction when both surfaces are of the same kind (*i.e.*, convex or concave). The direction of the two principal meridians of a cylindrical or spherico-cylindrical lens is readily determined by holding the lens in a plane perpendicular to the axis of the

eye, and looking, through its centre, at the sash-bar; the lens is then rotated, in its own plane, until the direction of the image coincides exactly with the direction of



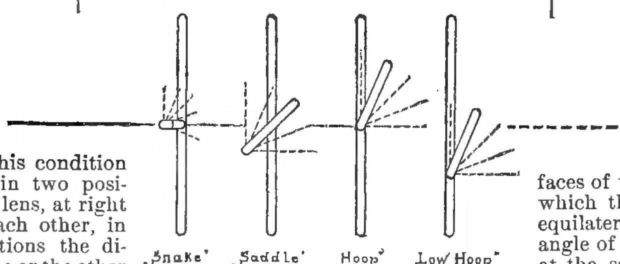


FIG. 3604.

the bar. This condition is fulfilled in two positions of the lens, at right angles to each other, in which positions the direction of one or the other principal meridian coincides with the direction of the bar. The middle point of any spherical or spherico-cylindrical lens is readily found by noting the point at which the crossing of two sash-bars coincides in the image and in the object.

SPECTROSCOPY, MEDICAL. The spectroscope is an instrument for examining the *spectrum*. A *spectrum* is, primarily, the series of colors produced when a ray of white light is transmitted through any transparent body, the surfaces of which are not parallel. The general form which this transparent body takes is that of an equilateral *prism* of glass, the sides forming an angle of sixty degrees. Hollow prisms with sides at the same angle are also used, being filled with transparent liquids.

Sir Isaac Newton first made the observation that when a ray of white light is transmitted through a prism the ray is not only bent out of its course, but is spread into an array of colors, the order of which is nearly invariable, no matter what the source of light or the material of which the prism is composed. Since the facility of differentiating colors varies in different persons, the exact tints of the spectrum so formed are not easy to express, but they are generally assumed to be seven in number, and arranged as follows: violet, indigo, blue, green, yellow, orange, red. If the ray of light be, as in Newton's original experiment, admitted through an opening of appreciable dimensions, the colors will be somewhat confused and will appear unbroken, but when the opening is very narrow a more distinct effect is produced, and, as will be seen below, the spectrum is crossed by numerous dark lines. It is a law of the propagation of light that when a ray passes from one transparent substance to another of different density it undergoes a deflection, known technically as *refraction*. The direction and extent of this refraction depend on the nature of the materials and on the difference of the densities. When the ray passes from a rarer to a denser substance, for instance, from air to water, or from water to glass, the ray is bent (refracted) so as to be more nearly parallel to a line perpendicular to the surface of contact, while if the ray passes in the reverse direction, that is, from a denser to a rarer body, as from glass to water, the refraction is away from the perpendicular. It is upon this principle that the image-forming and magnifying properties of all lenses depend.

The accepted theories in regard to light refer it to very rapid vibration, and the difference between the various colors is supposed to be due to difference in the rate of vibration. White light is supposed to contain all the rates of vibration, and when such a ray undergoes refraction the different vibrations are refracted to different degrees, and hence are separated. If we view a ray through a plate of glass or other transparent body with parallel sides, the refraction produced in one direction on

entering the glass is corrected by the refraction in the opposite direction on emerging, so that, with the exception of a slight displacement of the line of light, no striking optical change is manifest. If, however, the equilateral prism is used, the refraction on emergence is in the same direction as on entering, and the optical action is exaggerated. The separation of the different vibrations that compose a ray of white light is called *dispersion*, and is not coextensive with refraction, that is, bodies of equal refractive power do not necessarily separate the colors to the same extent. This law is a very important one in practical optics, for all lenses are forms with more or less prismatic outlines, and hence produce a dispersive effect. If it were only possible to prevent production of color by neutralizing the refraction, it would be impossible to construct any convenient optical apparatus free from colored images, but by combining different varieties of glass in such forms as to have equal and opposite dispersive powers with difference of refraction, large lenses entirely free from color defects (achromatic) may be constructed.

In the spectroscope the object is to secure as complete and extended a dispersion as possible; that is, to separate the colors thoroughly. For these purposes prisms of dense glass, or hollow prisms filled with carbon disulphide, CS_2, are used.

The simplest method of examining the spectrum is to allow a ray of light to enter a dark room or dark box through a small opening and fall upon a prism. Upon the side of the room opposite the opening will be seen a more or less confused spectrum, in which all the colors will be found diverted from the path which the original ray would pursue if it did not enter the prism, the violet being most diverted and the red the least. Such a method of observation, however, is unsuitable for scientific purposes. The most serious defect in it is that if the ray has an appreciable thickness the vibrations on one part interfere and overlap those of the other, so that the series of colors obtained is really a combination of a number of spectra not coincident with each other. To obtain a pure spectrum the ray must be reduced to an exceedingly fine line of light, in which there will be but few sets of vibrations. This is accomplished by using a very narrow slit, and shutting off all light from the prism except that which passes through this slit. The observation is also much facilitated by viewing the spectrum through a telescope of low magnifying power.

About the beginning of this century Dr. Wollaston, an English chemist, discovered, by using such a slit, that the spectrum of sunlight is not continuous, but is interrupted by numerous fine, dark lines. He did not develop this observation, and it was not until 1814 that Fraunhofer, a German optician, rediscovered these lines and mapped the positions of a considerable number of them. Some of the most prominent he distinguished by letters of the alphabet. They have in consequence generally been known as the Fraunhofer lines. They are all at right angles to the direction of the spectrum, and their distance from each other depends on the dispersive power of the prism. Since each particular line is always seen in the same color, and is more easy to define than the limits of the color itself, these lines are preferred for purposes of comparison.

Various improvements and advances in the construction of apparatus for observing spectra have been made from time to time, until the spectroscope in its usual form consists essentially as follows: A straight tube terminates at one end by a narrow, upright, adjustable slit, and at the other a convex lens, the focal length of which is the distance between it and the slit, so that the rays of light as they pass through the latter are rendered parallel by the lens. In the course of these rays is placed a dense glass prism, or series of prisms, greater dispersion being attained by a combination of prisms. A movable telescope of low magnifying power, arranged so that it can be brought in the course of the rays emerging from the prism, enables one to view conveniently the spectrum formed. Such an arrangement constitutes a *refraction spectroscope*. In the cut there is shown a third tube, illuminated by a candle. This contains a graduated scale, an image of which is projected in the field of view above the spectrum, for the purpose of measurement, as given below.

Another form of the instrument depends on a somewhat different principle, and as it is now in frequent use and possesses advantages over the older form it will be necessary to describe it.

When the surface of a polished flat plate is ruled with a considerable number of fine lines in very close proximity, on viewing the plate obliquely, series of spectra are seen which are due to interferences in the different light waves as they are reflected from the angular surfaces produced by the ruling. This effect is called *diffraction*, and a plate so arranged is called a *diffraction grating*. The superiority of such an instrument rests principally on the fact that in all parts of the spectra the colors are proportionately distributed. In the ordinary spectrum, as seen by the prism, the dispersion is proportionately greater toward the violet end, and consequently this portion is abnormally spread out and the distances between the dark lines are exaggerated.

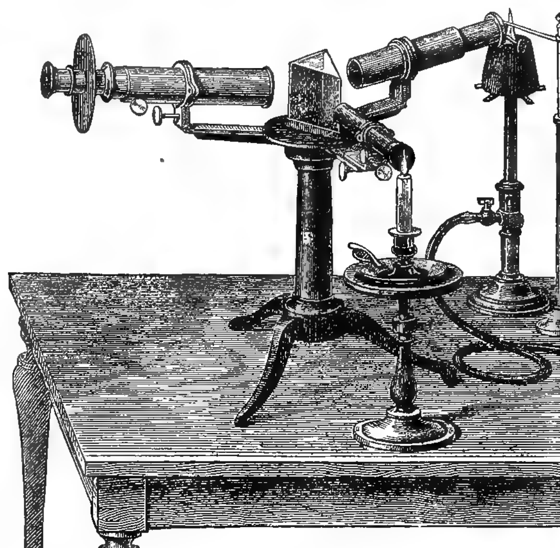

FIG. 3605.

Spectra, by whatever method observed, may be divided into three groups:

1. Continuous spectra: Those in which a more or less continuous sheet of color is seen, usually beginning with violet and ending with red. Such spectra are produced by the light which is emitted from solid objects in a highly heated state.

2. Interrupted, or bright-line spectra: Those in which the colors are seen in the form of narrow lines or bands, separated by proportionately wide, dark spaces. Such spectra are derived from light emitted by gaseous bodies in a highly heated condition.

3. Absorption spectra: Those in which a nearly continuous series of colors is present, but interrupted by dark lines or bands. Such spectra are produced by various conditions, principally, however, by the transmission of white light, or light which would give a continuous spectrum, through substances which have the power of absorbing or annihilating special vibrations. In the applications of the spectroscope to medicine and organic chemistry these absorption spectra are the most important.

It is obvious from the above considerations that we have in the spectroscope, whether of the refraction or diffraction form, a very valuable means of studying structure. In the first place, we can determine with great exactness the character of the source of light, *i.e.*, whether it is composed of gaseous matter intensely heated or of solid particles. Further, taking a source of known

character, we can, by interposing various substances in the path of the light, determine the effect which those substances produce upon the different forms of light vibrations present in the ray, and as particular effects are often peculiar to particular bodies, we have here a means of identification. Thirdly, using a source of heat practically non-luminous, such as the flame of the Bunsen burner, we can detect different substances by the color they impart to this flame, and when several such substances are present the eye alone is unable to separate and distinguish the colors, but by the spectroscope each tint is distinctly indicated

As stated above, it is the absorption spectra that are most important in reference to the medical applications of the spectroscope. Except in the comparatively rare cases of the study of the character of light emitted by luminous organic bodies, living or dead, and in the detection of certain metals present in minute amount in the tissues and secretions, *e.g.*, lithium, the direct study of normal spectra is not much resorted to in biological work.

The arrangement of the spectroscope for observation of absorption spectra is simple. An oil- or gas-flame is adjusted so as to throw a beam of light through the slit of the instrument, by which a continuous spectrum not broken at any point by dark lines is obtained. Sunlight does not answer so well for the purpose, because, owing to certain interfering conditions occurring at the surface of the sun, and also during the passage of the sunlight through our atmosphere, there are numerous absorption bands (Fraunhofer's lines) always present in its spectrum. The material to be examined is placed in a cell with flat sides in the path of the light before it enters the slit. It is scarcely necessary to observe that to secure a satisfactory result the body must be sufficiently transparent to permit some light to pass through, otherwise no comparison as to the effect on different parts of the spectrum can be made. Such a condition is easily obtained by using solutions of the substance in the usual colorless solvents—water, alcohol, ether, glycerine, etc., and diluting until a satisfactory result is obtained. The character of the absorption spectra sometimes differs, according to the solvent used and the presence of free acid or alkali. Working spectroscopes are generally arranged so that two spectra can be compared, one being a standard obtained under known conditions, the other being that of the body to be tested.

To understand the functions of the spectroscope it is necessary to bear in mind that the colors seen are practically images of the slit through which the light passes, and that when the ray contains all the colors, that is, every vibration from violet to red, the prism, in setting out the vibrations according to dispersive-power, gives, of course, a continuous series of images, that is to say, a continuous spectrum. When, however, in the ray of light that enters the slit any vibrations are missing, as in sunlight, or when by some interposed condition certain colors are struck out of the ray, the images which would otherwise be formed by those rays are missing, and hence the spectrum appears interrupted. When the interposed substance strikes out many rays, *e.g.*, deep-colored glasses, the great bulk of the spectrum is missing. The red glasses, for instance, used in photographic dark-rooms strike out all rays but the red. The spectroscope as ordinarily constructed is, unfortunately, subject to serious defects, which can be avoided only by instruments of very expensive form. It has been found that all the forms of glass possess marked absorption powers for certain rays of light. If, instead of employing glass lenses and prisms, we use those made of quartz, and employ as a source of light the electric arc, or burning magnesium wire, a spectrum is obtained which is very much extended at the violet end. This portion of the spectrum exists to a greater or less extent in white light from any source, but is absorbed to such an extent by glass that it is not seen in the ordinary spectroscope. There are also color waves beyond the red, which are only demonstrable by special apparatus. In the usual applications of the spectroscope we cannot, therefore, utilize the so-called ultra-red and ultra-violet rays.

A very important advance has been made recently in practical spectroscopy in the application of photography. A sensitive plate is capable of responding to and recording conditions which the eye is unable to recognize, and we have, therefore, not only a method of extending our knowledge of spectra, but we may obtain permanent records of absolute accuracy, and independent of any general or special defects in vision. This method is yet incompletely developed, but it promises well. The photographic plate is especially capable of receiving impressions from the violet and ultra-violet portions of the spectrum, which are especially those which the eye appreciates with the greatest difficulty, while the yellow and red rays are practically inactive.

Many substances are known which have the power to retard the rate of vibration of light rays, so that they change the color of the light falling on them. Now, the ultra-violet rays, which are inappreciable to the human eye, are caused by extremely rapid vibrations; any substance which will reduce this rate will bring the rays within the range of vision. This property is known as fluorescence. It does not come within the scope of this article to more than refer to it, but it may be mentioned that one of the most recent advances in the preparation of photographic plates is to incorporate into the sensitive material some fluorescent body by which the rays of light are modified and effects produced with colors that would otherwise be inactive. It is not unlikely that we have in this method a line for still further extension of the application of photography to the spectroscope

The only way of acquiring familiarity with spectroscopic appearances is by actual use of the instrument. No drawing, colored or otherwise, can convey perfectly the appearances. Nevertheless, a method of indicating the character and position of the lines is useful, and several plans have been adopted. The use of colored plates is, of course, the most vivid, but too costly for most purposes. The usual methods are either by recording the position of any line, or the centre of a band, by its position on an arbitrary and fixed scale, or by angular position. A form of spectroscope made by Browning, of London, has this latter arrangement. The view telescope moves in a graduated arc, and cross lines in the field enable it to be brought to exact position with any line. By such method or by the scale the lines may be mapped in their relative positions as seen in that particular instrument.

Another method is to indicate the positions of lines by their calculated wave-lengths; that is, the length of one complete movement constituting the ray which produces a line at the given point. Such a method has the advantage of being an absolute indication, and not dependent on any particular instrument. Wave-lengths are determined by mathematical calculation by means of the phenomena observed in diffraction, and the calculation may be easily applied to ordinary cases by plotting off on a chart certain lines of which the wave-lengths are known, and interpolating those of which it is desired to determine the wave-length. These lengths are very minute, and are usually expressed in millionths of a millimetre.

Description of Special Spectra. *Bright-line Spectra.*—Each of the known elements gives a special and distinct spectrum when heated sufficiently to become a luminous gas. It has been pointed out at the beginning of the article that solid substances give continuous spectra, and hence there is no appreciable difference between the spectroscopic appearances of the different elements as long as they remain solid bodies. When the temperature rises sufficiently to convert them into gases, and render them at the same time luminous, the characteristic bright-line spectra are obtained. This temperature can be attained with most elements only by the use of the electric spark. A few bodies, among which are potassium, sodium, lithium, barium, calcium, strontium, and boron, yield at the temperature of the non-luminous gas-flame—Bunsen-burner flame—a limited number of rays which are early observed by the spectroscope as bright lines. Thus sodium imparts to flame a deep yellow color which

consists of two tints, and is seen in the spectroscope as a narrow double line. Potassium gives red and violet lines. By increasing the temperature some of these spectra are modified. When the electric spark is employed the spectra obtained are usually more complex, the bright lines being numerous. The detection of the different elements by this means is not so widely applicable as might at first be supposed, for the method is extremely delicate, and it is difficult to distinguish between the minute traces which often have no significance and the presence of an appreciable amount. Nevertheless, the method has been of great usefulness in special cases in showing the occurrence of some elements in unexpected relations, and the wide distribution of others in minute quantities. Several elements have been discovered by the spectroscope, occurring in such minute quantities that ordinary chemical analysis would have failed to indicate them.

There are a few rare metals which give a limited bright-line spectrum before reaching the temperature at which they became gaseous.

Absorption Spectra.—These are of several kinds. The absorption may affect a considerable part of one or both ends of the spectrum, by which a whole block of color may be cut out, or it may take place in broad bands or in fine lines. The spectrum of the sun and of many of the fixed stars is an example of this latter class. The lines of absorption are numerous, but they are narrow and represent but a small portion of the entire field, which appears to the unassisted eye to be a uniform sheet of color. Band absorption, that is, the cutting out of a considerable number of rays at some point on an otherwise continuous spectrum, is brought about very easily by means of many organic bodies.

Extended absorption, by which a considerable portion of the spectrum is absorbed, is seen in many substances possessing deep color, and the absorption may include all but a single color. Various colored glasses may be used. To test the effect of a graduated increase of color, wedge-shaped glasses may be employed. Hollow wedge-shaped cells are often used for the examination of colored liquids.

The method of observing absorption spectra has been given above. It has been also already pointed out that no description, nor even drawing, can give an adequate idea of the actual appearances of spectra, but for the purpose of completing the article and indicating some of the practical applications of the methods a few absorption spectra will be described.

Line-absorption Spectra.—Some of the rarer elements possess the peculiar property, when in solution, of absorbing special rays of light. Among the best known of these is the metal didymium, which occurs only in some moderately rare minerals. Its compounds have a delicate but distinct rose-red tint, but even when so far diluted as to make the tint not perceptible, they give several absorption-bands about the middle of the spectrum. The vapors of bromine and of nitrogen dioxide, NO_2, which to the eye have much the same color, give each a peculiar series of numerous fine absorption-lines in the central part of the spectrum. The absorption-lines that normally occur in the spectra of the sun and stars are an important clue to the chemical composition and physical condition of those bodies, but a consideration of this topic does not belong here.

Band-absorption.—One of the most familiar and striking instances of this form of absorption is seen in *chlorophyll*, which is the general term under which the green coloring matter of plants is designated. A solution of this substance is easily obtained by macerating leaves with ether or alcohol. The filtered liquid being diluted so as to be fairly transparent has a beautiful green color by transmitted light, and when viewed through the spectroscope transmits all the colors except a band in the extreme red, at which point there appears a well-marked broad dark band. The position of this band is highly characteristic of this substance, and can be detected by careful observation, even when the solution is too dilute to exhibit the color to the eye. In this way the adulteration of animal oils by vegetable oils—for instance, of lard-oil by cotton-seed oil—may often be detected, for cotton-seed oil exhibits the absorption-band of chlorophyll derived from the vegetable tissue.

Valuable use is made of absorption spectra in detecting the nature of various natural and artificial coloring matters. Fuchsine, for instance, not infrequently employed as an artificial coloring matter in wine, gives a broad but not very sharply marked band about the junction of the green and yellow of the spectrum.

It is, however, with reference to the absorption-bands produced by the fluids of the animal body that the clinical applications of the spectroscope are seen. The most important of these are the appearances seen in blood under various conditions. These appearances are due to the hæmoglobin. As ordinarily seen by examining blood much diluted with water, the spectrum is that of oxidized hæmoglobin, *oxyhæmoglobin.* The dilution must be sufficient to allow considerable light to pass, and a modification of the absorption spectrum is obtained by continually adding water until no absorption at all occurs. The same effect may be produced by examining the solution through a wedge-shaped cell, gradually diminishing the thickness of the solution through which the light passes. The effects are briefly as follows: In rather strong solution, all the light is cut off except a portion of the orange and red; when the solution is diluted somewhat, green rays are transmitted, and the dark interval between these and the orange constitutes a broad absorption-band; still further dilution produces a yellowish-green mass of light dividing the dark space into two nearly equal portions, developing, therefore, two well-marked absorption-bands. On still further diluting, the absorption becomes reduced to a single band in the yellow. When to a solution of blood of sufficient density to give the two bands we add some reducing agent, *i.e.*, some body having an affinity for oxygen, the hæmoglobin is *reduced*, and a new spectrum is obtained. For this reduction ammonium sulphide is preferred. The spectrum of reduced hæmoglobin is a single band, broader than, and not exactly coincident with, either of the bands obtained from oxyhæmoglobin, the darkest portion corresponding to the mass of light dividing the two bands in that spectrum. The chemical condition of the blood in the vessels may in this way be tested. Another important result is in determining the effect of various gases and chemical substances in blood, either by direct action or by poisoning animals and quickly subjecting the blood to examination. If we examine blood charged with nitrous oxide (N_2O), we find the spectrum of reduced hæmoglobin, but agitating the blood with air will reproduce the oxyhæmoglobin. When, however, carbon monoxide (CO), carbonic oxide, is introduced into blood, we get a new condition which gives a spectrum resembling, but not identical with, that of oxyhæmoglobin, there being two bands, but their position being slightly nearer the violet.

Furthermore, we cannot so easily restore the original condition by agitating the blood with air, nor will the ordinary reducing agents produce the spectrum of reduced hæmoglobin. Carbon monoxide is known to be one of the most active of the gaseous narcotic poisons, and the above observations show, in part, at least, the peculiar action it has on the essential breathing constituent of the blood. The carbon-monoxide-hæmoglobin—*carboxyhæmoglobin*—spectrum is seen in the blood of persons poisoned by coal-gas or fumes of burning charcoal, and an examination of the blood by the spectroscope in cases of this character may be an important medico-legal point. Another important modification of the hæmoglobin is produced by the action of sulphides, especially by hydrogen sulphide (H_2S), sulphuretted hydrogen. This gas is often present in sewer air, cesspool exhalations, and other foul places, but not invariably, nor in so great quantity as is generally supposed. When its action upon blood is examined we find a spectrum which presents the broad single absorption-band of reduced hæmoglobin (see above), but in addition a band in the red just at the junction with the orange. This band does not disappear on shaking the blood with air, although the two bands of oxyhæmoglobin appear. The body produced by the action of hydrogen sulphide on blood, and to which the properties

above described are due, has been called *sulphæmoglobin*. It has been noticed that this substance cannot be formed by the action of hydrogen sulphide on reduced hæmoglobin, which is the form which exists in the veins; hence, hydrogen sulphide may be introduced into the venous circulation without marked effect, but taken into the arterial system it is very dangerous. The difference between inhalations of this gas, by which it would get directly into arterialized blood, and its introduction into the system through the veins, has been shown strikingly in the recently employed method of treating phthisis by injections of hydrogen sulphide and carbon dioxide. In this case the gas is taken up by the veins of the portal system and excreted before it comes in contact with the arterial blood.

If a solution of blood be exposed to the air for some time it undergoes various changes, accompanied by an alteration in the absorption spectrum. This alteration can be brought about by the action of weak acids, and also of potassium permanganate, on blood. A substance called *methæmoglobin* is formed. Its absorption-bands are three, nearly coincident with those seen when sulphæmoglobin is shaken with air, but one band is more completely within the limits of the red. Methæmoglobin is believed to be a highly oxidized hæmoglobin, but its constitution is in some doubt.

Many other changes in the absorption spectra of blood are known, but while the investigation of them has much to do with physiological chemistry, the matter is too technical for discussion here. It is obvious, from what has been said, that very important medico-legal, toxicological, and even clinical questions can be determined by means of the spectroscopic appearances. The different effects produced on blood by different poisonous gases and vapors, the general symptomatology of what may be the same, offers a means of determining even *post-mortem* the character of the gas, and as an aid in the study of the so-called sewer-gas poisoning the spectroscope will be valuable.

Clinically, the spectroscopic appearances may be utilized for examining the fluids of the body either in their normal or abnormal condition. The spectrum of bile, for instance, may be utilized for the detection of it in the urine, for when the color reaction is too faint to be perceived by the unassisted eye, the spectroscope will show it. Normal urine contains a coloring matter believed to be derived from a constituent of bile, which gives a broad absorption-band on the green. In certain febrile affections another band appears, also in the green, toward the border of the yellow. Blood in urine may also be detected by the spectroscopic tests. If in solution in the urine, the absorption spectrum is seen without difficulty. If the blood be present in the form of methæmoglobin, as is sometimes the case, it will give the three bands peculiar to that body, but it is necessary to distinguish these bands from those produced by a decomposition product of hæmoglobin known as *acid hæmatin*. This distinction can be made by the use of ammonium sulphide, when, if methæmoglobin is present, the band of reduced hæmoglobin, as described above, will appear. If the blood is in the insoluble form no absorption-bands may be shown. In this case the blood is filtered and the filter paper treated with alcohol and ammonia, and then with ammonium sulphide; bands appear which are due to *reduced hæmatin* formed by decomposition.

In the accompanying map are shown some of the important absorption-spectra as seen in a refraction spectroscope of moderate power. Over the plate has been placed indications of the limits of the various colors, but these must be regarded as a mere approximation, as it is not possible to determine precisely at what point one color ceases and another begins. The dotted lines at each end of the plates represent the limits of the visible spectrum in each case, and it will be noticed that there is considerable extinction of color, especially toward the violet end. A represents the spectrum of sunlight, with some of the principal absorption-bands, and the letters which distinguish them. All these bands, as has been remarked above, are absent in the light of ordinary flames and electric lights. The observation of absorption-spectra being made with artificial light does not therefore show any such bands. B shows the absorption-bands of oxyhæmoglobin. The visible spectrum, it will be seen, extends only from green to a short distance on the red. C shows the spectrum of reduced hæmoglobin. The limits of the visible spectrum are extended slightly toward the violet. D is the spectrum of carboxyhæmoglobin, that is, of blood impregnated with carbon monoxide. E is the spectrum of methæmoglobin. F is the

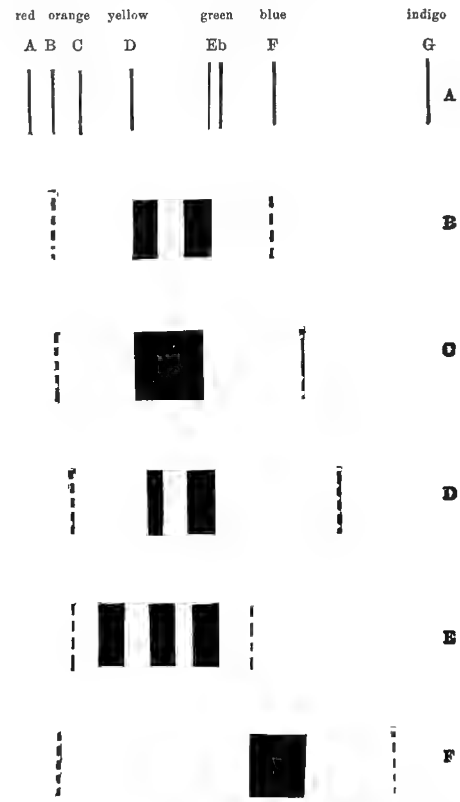

FIG. 3606.

spectrum seen commonly in normal urine. The broad band is at about the junction of the blue and green and is somewhat faint.

Very little practical clinical application, however, is yet made of these spectroscopic appearances. The instruments required are expensive and unfamiliar, and hence unsuited to the general uses of the practitioner. The use of the spectroscope in the detection of various natural and artificial colors, and in the recognition of blood-stains, belongs to special treatises.

Henry Leffmann.

SPERMACETI (*Cetaceum*, U. S. Ph., Br. Ph., Ph. G.; *Blanc de Baleine ou Cétine*, Codex Med., *Sperma-Ceti*). A solid, paraffine-like substance obtained in connection with oil, in cavities or cells in the head of the sperm-whale, *Physeter macrocephalus* Linn., order *Cetacea*.

This enormous mammal, the largest living animal, measuring from forty to sixty, or even eighty feet in length, has the general structure and shape of other whales, but is distinguished by its enormous head, one-third or more as long as the entire body, a single nostril, a very large upper jaw, which is toothless, and a much shorter and smaller lower one, bearing twenty or more pairs of conical simple teeth. Eyes small, near the base of the head; ears inconspicuous. The body tapers backward from the head, bears a small dorsal fin, and a horizontally bifurcated tail.

This whale is gregarious in its habits and is found in the ocean waters of both hemispheres, from the extreme north to the tropics. It is hunted for its oil, which is one of the most valuable of its class.

Spermaceti, or rather the crude fat, is a semi-solid, yellow substance as it is scooped out from its reservoirs, but becomes hard and brittle upon exposure to cold; for purification it is then pressed in bags, when the oil squeezes through, and the solid *cetaceum* is left behind. This can be further purified by melting in water, skimming, and recrystallization. Purified spermaceti is a pearly white, glistening, crystalline, translucent, odorless, and tasteless solid, insoluble in water; soluble in ether, chloroform, and boiling alcohol. Melting-point 111° to 112° F. It is mostly composed of *palmitic* acid combined with *cetyl* (instead of glycerine); there are also small quantities of compounds of *stearic*, *myristic*, and *lauric acids*. It is pretty permanent in the atmosphere, in this respect excelling most fats.

USE.—Spermaceti has no active medicinal qualities. It is sometimes used in sore throats, etc., where its value is mostly as a protective. Its principal employment in medicine is as an ingredient of cerates and ointments, to which it gives consistency, blandness, and permanence. The following are officinal: Cerate of Spermaceti (*Ceratum Cetacei*, U. S. Ph.), spermaceti, ten parts; white wax, thirty-five parts; olive-oil, fifty-five parts; an elegant, white, nearly odorless salve; and Cold Cream (*Unguentum Aquæ Rosæ*, U. S. Ph.), of the following composition:

Expressed oil of almond.......	fifty parts.
Spermaceti....................	ten "
White wax.....................	ten "
Rose-water....................	thirty "

ALLIED ANIMALS.—Several species of whales, besides numerous other *Cetacea*, are hunted for their valuable, and generally very permanent, oils.

ALLIED SUBSTANCES.—The ordinary solid fats and tallows, wax, and paraffine. Ambergris is a peculiar, odorous concretion found in the intestines of the sperm whale. *W. P. Bolles.*

SPERMATOZOA. In this article there is: 1, a brief summary of the structure and development of spermatozoa; 2, a fuller account of the mature spermatozoa; 3, a detailed history of spermatogenesis in mammals; 4, a few historical notes.

1. SUMMARY.—The spermatozoa of mammals are filaments, consisting of a short thicker end called the head, and a very long and delicate thread called the tail. The head varies greatly in shape, according to the species; in man it is broad and thin (Fig. 3609), and is widest at a little distance from the tail. The head contains chromatine, and may be colored by the usual nuclear dyes. The tail consists of three parts: 1, the *middle piece*, next the head, and which is the thickest of the three; it contains an axial thread, and probably always has a *very* fine spiral thread running round it; 2, the *main piece*, and, 3, the *end piece*, which is not more than a line, even as seen with very high magnifying powers. The human spermatozoon is 0.055 mm. long—the head being 0.005 mm., the tail 0.050, and the *middle piece* 0.009.

The development of the mammalian spermatozoa begins with a so-called parent- or mother-cell, which lies near the outer wall of the seminiferous tubule. The mother-cell produces a number of daughter-cells, which also multiply by division; the daughter-cells break down, forming a column of matter (protoplasm), in which lie their nuclei, and at the base of which lies the nucleus of the mother-cell; the nucleus of the mother-cell and the column of matter both ultimately disappear, but exactly how is not determined; the nuclei of the daughter-cells produce each a spermatozoon. The head and tail of the future spermatozoon become visible within the nuclear membrane; the head is formed chiefly by the chromatine of the nucleus; the nuclear membrane finally ruptures, and it, as well as the contents of the nucleus, which have not taken part in the formation of the spermatozoon, are lost; among the lost parts is a special round body of small size, which appears in the nucleus while the spermatozoon is developing; this body may be stained by chloride of gold, but not by hæmatoxyline; its significance is unknown. The long column holding the spermatozoa together has usually been regarded as a cell, and is the supporting-cell *duct*.

2. SPERMATOZOA are the essential fertilizing elements secreted by the male gland. They are minute bodies capable of active locomotion, and present always a form characteristic of the species. In a few instances (certain snails, etc.) there are two distinct forms of spermatozoon for a single species, but usually there is only one form, and that little variable. In a small number of animals the spermatozoa, as in the nematods, are distinctly cell-like, but in the great majority of animals, and so far as I know, in all vertebrates, they are long and thread-like; hence their common German name, *Samenfäden*, first proposed, I think, by Kölliker.

The mammalian spermatozoa are long, slender bodies, varying considerably in configuration (*cf.* Fig. 3607), but all presenting at least the following features in common: One end is thickened and is called the head; it has a strong affinity for nuclear staining fluids; this affinity must be attributed to the chromatine which the head contains, as is shown by the history of its development; the remainder of the spermatozoon is long and slender, and constitutes the tail; the tail consists of, 1, a middle part (Mittelstück), a little thicker than the rest, and situated next to the head; the middle part is traversed by a very fine axial thread, and ends abruptly; and, 2, a hind piece, which, according to some writers, may be subdivided naturally into two segments, the main piece (Hauptstück) and end piece.

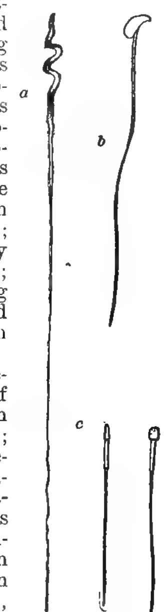

FIG. 3607.—Spermatozoa. *a*, Canary; *b*, common mouse; *c*, bat.

The spermatozoa of the various species differ in size in the proportions of the parts, and often very strikingly in the shape and structure of the head; those of the opossum are especially remarkable for being double: two apparently complete spermatozoa being united to a common plate by their heads (Selenka: "Studien über Entwickelungsgeschichte," Heft iv., p. 106). Twin spermatozoa have also been observed in the rat by Neumann (p. 313, Taf. xvii., Fig. 16, *b*).[38] Compare also Max von Brunn[12] and Brock.[9] The largest known mammalian spermatozoon is perhaps that of a marsupial, phascogale; the spermatozoon of this animal is 0.263 mm. long, the head, however, being only 0.013 mm. (Fürst, p. 354).[20] The spermatozoon of the rat is 0.144 mm. long—the head 0.009, the tail 0.135, and the "middle" piece 0.045 mm.

La Vallette[32] gives a synopsis concerning the forms of vertebrate spermatozoa nearly as follows: *Fish:* The spermatozoa of amphioxus are threads with round heads. In petromyzon the head is rod-like or egg-shaped. The teleosts generally have pin-like spermatozoa; but in the salmonidæ (Owsjannikow) the head is pointed and shaped like a heart pip. The spermatozoa of selachians are much larger, with the head end spindle-shaped and often spirally twisted. *Amphibia:* The head is long, generally pointed, the middle piece short, and the tail is often provided with an undulatory membrane (Retzius[43]). *Reptiles and birds:* The head is usually long, often twisted. *Mammals:* The head is more or less elongated, and generally, in ungulates, the head is flattened and usually more or less egg-shaped in outline, the pointed end toward the tail. Among rodents there is considerable variety of form. In the dog the head is pear-shaped; in the hedge-hog the head is truncated inferiorly and the tail is inserted laterally. No comprehensive summary of

the observed forms of spermatozoa has been made since the publication of Wagner and Leuckart's[51] article in "Todd's Cyclopædia."

The most minutely studied mammalian spermatozoon is that of the rat, thanks especially to the patience of O. S. Jensen, whose posthumous paper[28] furnishes the basis of the ensuing description. The rat's spermatozoon measures 144 μ; its head (Fig. 3608, *B*) is a broad hook, pointed at one end and obliquely truncated at the other; from one corner of the truncated end starts the very long, slender tail, which is divisible into the thicker middle piece (*Mittelstück*, or Jensen's *Verbindungsstück*) and the thinner main piece (*Hauptstück*) (Fig. 3608, *C*), which terminates in a short and still finer thread, called the end piece (*Endstück*). The appearance of the spermatozoon varies according to its degree of development, it not attaining full maturity until it has left the seminiferous tubule. The changes referred to affect principally the head and the middle piece. The head is covered, while the spermatozoon remains in the seminiferous tubules, by a membranous cap (Fig. 3608, *C*), which subsequently disappears. The middle piece has a spiral thread running round its outside (Fig. 3608, *A*). The spiral thread appears soon after the rupture of the nuclear membrane, by which the developing spermatozoon is set free (*cf. infra*). The thread is at first indistinct and makes only a few turns; it rapidly becomes more distinct, and the number of turns increases, until they become so numerous that in a spermatozoon taken from the vas deferens only a series of thick-set cross-lines can be distinguished; these lines have been seen by several observers, and variously interpreted; the spiral may run to the right or to the left. The thread becomes loosened off by the action of glycerine (1 part) and water (4 parts), and is destroyed in one to two hours by 0.6 per cent. salt solution, leaving then the axis uncovered. The thread can be stained by chloride of gold, though the axis cannot. The axis, when the spermatozoa are treated with acetic acid, often breaks up into threads (*cf.* Ballowitz[1]); it shows a lighter line in its centre. These observations lead Jensen to the conclusion that the axis is formed by a wall of fibrillæ surrounding a central core or cavity. The axis does not reach quite to the head, but ends with a little knob, leaving a small, perfectly transparent space between the knob and the head (Fig. 3608, *B*). In some spermatozoa—*e.g.*, horse and ox—though not in those of the rat, there is a minute opening in the head, called the *microporus*, and situated just opposite the knob of the axis. When the spermatozoa are stained with nuclear dyes, most of the head is colored, but the tip of the hook, which contains no chromatine, and is probably formed out of a scrap of the nuclear membrane, remains uncolored; on the concave side of the tip a fine line can be distinguished, due, apparently, to a rod of substance. Sometimes a minute fragment of the nuclear membrane is left adherent to the lower end of the middle piece; for the explanation of this possibility, compare the section below on development.

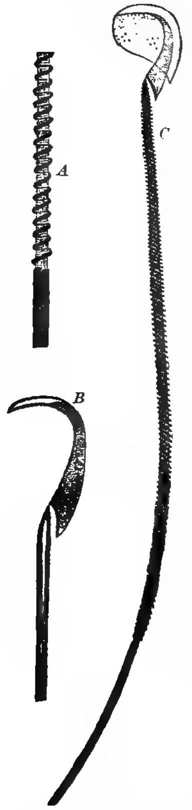

Fig. 3608.—Structure of Rat's Spermatozoon. (After Jensen.) *A*, Young spermatozoon, end of the middle piece and beginning of the main piece, to show the spiral thread—greatly magnified: *B*, head, with part of the axial thread; *C*, immature spermatozoon, anterior half only.

The human spermatozoa are described by Retzius, p. 85,[43] as follows:

The head, seen from the flat side, appears oval (Fig. 3609, *A*), with the front end generally tapering a little, but never pointed; the anterior half or two-thirds has a brighter and more transparent part. Seen on edge (Fig. 3609, *B*), the head has a pointed form, with a posterior, thicker, round, dark part. By adjustment of the focus it can be ascertained that the sides near the point are depressed, somewhat like those of red blood-corpuscles. Retzius could nowise succeed in demonstrating a special tip (Spiess) corresponding to that in the salamander. The following piece (Schweigger-Seidel's *Mittelstück*) is directly united with the head by a transverse joint; there is no neck in Eimer's sense; the middle piece is cylindrical and relatively small, about as long, or a little longer, than the head; its surface is often granular or rough, and there cling to it a few shreds of protoplasm, as has been described by several investigators; the spiral thread could not be distinguished. The *main piece* of the tail is about half as thick as the Mittelstück, gradually tapers, and ends abruptly at the beginning of the still finer and very short *end piece*. There is, according to Retzius, no membrane such as has been described by Gibbes,[22] whose account has received Krause's[30, 31] confirmation. It seems to me probable that there is a spiral thread, which may be loosened by maceration, as is the case with the rat, and that such altered spermatozoa were seen by Gibbes, and led him to assume the existence of an undulatory membrane in the human spermatozoa.

Fig. 3609.—Human Spermatozoa. (After Retzius.) *A*, Complete spermatozoon; *B*, head seen from the side; *C*, extremity of the tail. All highly magnified.

3. Spermatogenesis.—The seminiferous tubules are cylindrical, *i.e.*, in cross-sections they appear round; a large part of the tubule is filled with spermatozoa in various stages of development. The outer boundary is marked by a distinct line corresponding to the tunica propria, a layer of endothelial cells, with flat oval nuclei (Neumann,[38] p. 306). Next to the tunica comes a layer which, as far as known, presents pretty much the same appearances, whatever may be the stage of development of the spermatozoa within. This layer contains two kinds of cells: *First*, the large Sertoli's cells, as they may be called after their discoverer.* These cells are identical with Merkel's Stutzzellen, La Vallette's spermatogonien, Swaen and Masquelin's cellules folliculaires. *Second*, smaller granular cells.

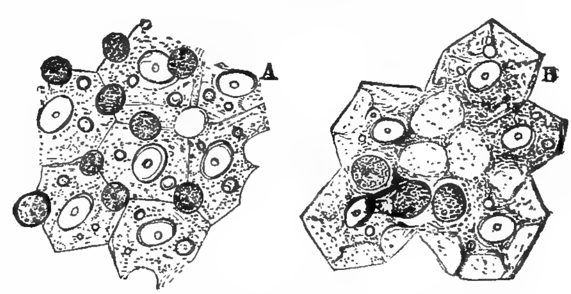

Fig. 3610.—Peripheral Layer of the Seminiferous Tubule of a Rat. Two views from a teased preparation. (After Neumann.)

Examined in surface views (Fig. 3610) (compare also Figs. 5, 6, and 41 of Furst's paper[20]), the *large cells* are seen to be mostly hexagonal in outline, to touch one another, and to pass below, *i.e.*, outside, the small cells; they have large, clear, oval nuclei, with sharp outlines, and usually a single, well-marked nucleolus. The nuclei lie quite near the tunica propria, but in man lie farther inward, and are in this case not so near the tunica

* First described by Sertoli in H. Morgagni (cf. Henle's Jahresbericht for 1864, p 120). Compare Sertoli, Arch. Sci. mediche, ii., 107 (1877).

as are the small cells. Around the nucleus there lie a few highly refractile granules, which may be stained by osmic acid, and are probably fat. The small cells lie in depressions or cups of the large cells (Fig. 3610, *B*), and when the small cells are knocked out—as sometimes happens in teasing—the partitions between the cups appear more distinctly and create a network figure, which has misled von Ebner and others into describing a real network as constituting the layer. The large cells also have long columnar prolongations, as can be best seen in transverse sections of the tubules (compare Fig. 3616); the prolongations are united with bundles of developing spermatoblasts. The *small cells* are very different; they lie over the outlines of the large cells, and between their centripetal prolongations (compare Fig. 3616); they are granular, have comparatively little protoplasm, and nuclei more or less nearly spherical in shape. The nuclei vary considerably in appearance, as these cells multiply by indirect division; usually they contain a chromatine network or a coiled chromatine cord; sometimes the network is concentrated at one side of the nucleus, leaving the other side comparatively clear. At certain periods the nuclei are found in various stages of karyokinesis. The cells resulting from the division of the small cells form the packing between the inward columns of the large cells, hence in cross-sections we get alternating columns (Fig. 3616). The descendants of the small cells produce the *spermatoblasts*, and the spermatoblasts are converted into the spermatozoa. The small cells are then the parents of the spermatozoa, and may be called the parent-cells; a great variety of names have been employed to designate them, such as mother-cells, spore-cells, germinative cells, Samenstammzellen, etc.

Formation of the Spermatoblasts.—The parent-cells divide and produce probably two daughter-cells, although the number has never been accurately ascertained. According to Biondi,[5] the nucleus of the parent-cell remains and becomes like the nucleus of the large cells (Sertoli's or supporting cells). The daughter-cells divide, and their descendants also divide, until there is produced a column of cells (Fig. 3611), which stretches in a radial line from the mother-cell toward the centre of the tubule, and is packed in between the columnar centripetal prolongations of Sertoli cells (*cf.* Figs. 3611 and 3616). Probably, then, although investigators are not agreed in regard to this point, the mother-cells divide in such a way that the cells resulting from the division are unlike—one of them preserving the character of the mother-cell, and the other differing from it in having a relatively larger nucleus and a finer chromatine network; the appearance of the nuclei varies, of course, according as they are in the resting or divisional (kinetic) phase.* The cell most like the original one, and which we may call still the mother-cell, lies at the outer edge of the tubule, while the other, or first daughter-cell, lies toward the centre (Fig. 3611). The mother- or parent-cell, as already stated, produces at least a second, and perhaps more daughter-cells, so that the column grows centripetally. The column also grows by multiplication of the daughter-cells, but the cells thus formed lie in the innermost part of the column; they are smaller (Fig. 3611) than the first generation of daughter-cells; they have relatively large nuclei, with the chromatine gathered into two or three spots—nucleoli. We thus have a column of cells in which we can distinguish three zones: 1, The outer zone of the mother-cell; 2, the middle zone of the daughter-cells; 3, the inner zone of the second generation of daughter-cells. These zones remain more or less marked for a considerable period, for, as the cells of the inner zone change into spermatoblasts, those of the middle zone change into second daughter-cells, and as the inner spermatoblasts change into spermatozoa, the cells of the second zone change into spermatoblasts; the innermost zone long continues one stage ahead. The tri-zonal arrangement is very conspicuous in cross-sections.

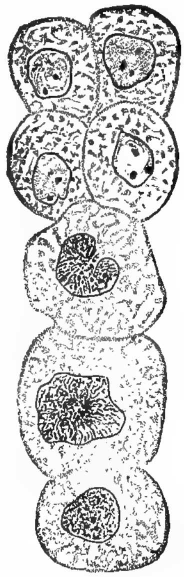

Fig. 3611.—Column of Spermatocytes from the Rat. × 600. (After Biondi.)

* For figures of the karyokinetic division of the daughter-cells, see Fürst, Figs. 10–13.[20]

The division of the daughter-cells presents many peculiarities, and does not conform exactly to Flemming's well-known scheme of phases for indirect division. Attention was first directed to these peculiarities by Carnoy, in an important memoir.[13] Flemming[19] has since confirmed these discoveries, in large part, by observations on the salamander, and gives a plate of diagrams which is instructive as a facile means of comparison.

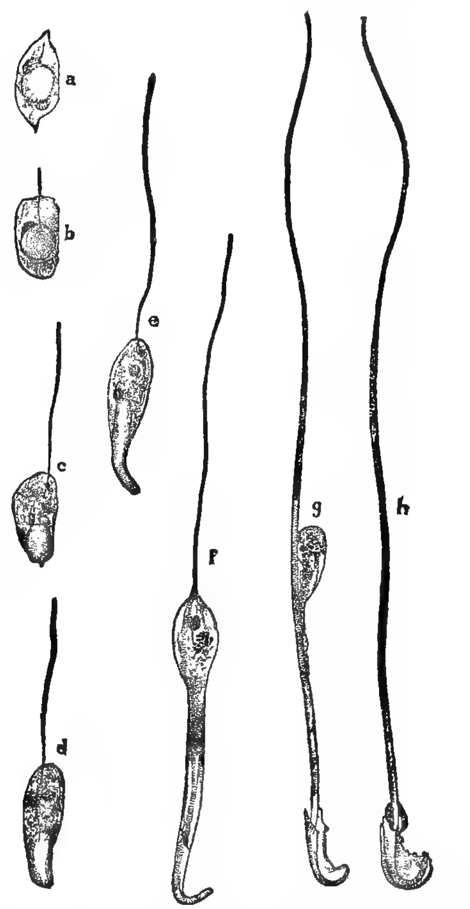

Fig. 3612.—Developing Spermatoblasts of the Rat. *a, b, c, d, e, f, g, h*, Successive stages. × about 750 diameters. (After H. H. Brown.)

The spermatoblasts arise from the nuclei of the second daughter-cells (spermatocytes), and not as Brown[10] and many others have, I think, erroneously believed, each out of a whole cell. Biondi[5] seems to me right in his statement that the bodies of the cells break down, or at any rate lose their boundaries, thus creating a granular protoplasmatic column in which the nuclei lie. The mother-cell participates in these changes, hence its nucleus comes to lie at the base of the column. This nucleus has meanwhile altered its character, and become large, clear, and nucleolated. Now, these columns are the same as the large Sertoli's, or supporting cells above described. By no means all writers agree with this account of the origin of Sertoli's cells, but all other explanations that I

have found appear to me vague and confused, and the history of the changes here advocated is clear, and accounts for the well-established grouping of the spermatoblasts in the substance of Sertoli's column; this essential phase is explained satisfactorily by no other theory.

The nuclei congregate at the inner end of the column, and there change their character and become recognizable spermatoblasts (Figs. 3612 and 3616).

Development of the Spermatoblasts into Spermatozoa.—The nuclei change into spermatozoa as follows: The chromatine is at first unequally distributed throughout the nucleus; it then in great part accumulates at the end of the nucleus toward the outer wall of the tubule; particles of the chromatine are said to remain in other regions of the nucleus, and finally to gather together to form the small accessory corpuscle mentioned below. The main mass of the chromatine is concerned in the formation of the head of the spermatozoon; it is at first quite round (Fig. 3612, *a* and *b*), but soon begins to alter its shape, gradually assuming the form of the spermatozoon head (Fig. 3612, *c, d, e, f*). The tail appears very early as a delicate filament, lying entirely within the nucleus (Fig. 3612, *a*), but shortly after is found to project beyond the nuclear membrane *b*, and lengthens rapidly, *e, f, g*. The nuclear membrane is very distinct; it elongates into an oval bag, *b, c*, one end of which lies close against the chromatine, while the other surrounds part of the tail and is wide; the lengthening continues, *e, f, g*, with accompanying changes of form, best indicated by the figures; the part of the tail within the nuclear membrane becomes the middle piece (Fig. 3613), but the spiral thread is not developed until later. The accessory body may be readily seen in the rat; unlike the chromatine of the head it can be stained by chloride of gold, hence if it is formed of chromatine at all, the chromatine must have undergone alteration. Finally, the nuclear membrane ruptures (Fig. 3614), a portion of the membrane remains upon the head, and the caudal bag sometimes endures longer (Fig. 3612, *g*), but at last also disappears, except that in certain cases a trace of it remains visible as a fine cross-line at the end of the middle piece. Fürst and others think that the axis of the tail is formed from the chromatine, and that the sheath of the axis arises from the achromatic substance of the nucleus (caryoplasma). After the rupture of the nuclear membrane, the young spermatozoa still develop a little further. The spermatozoa are ultimately liberated, and, falling into the lumen of the tubule, pass off.

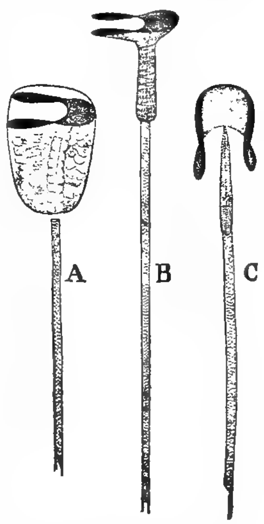

FIG. 3613.—Developing Spermatozoa of a Marsupial, Metachirus Quica. A, B, C, different stages. (After Fürst.)

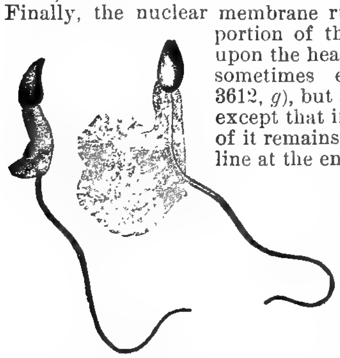

FIG. 3614.—Human Spermatoblasts, to Illustrate the Rupture of the Membrane. (After Wiedersperg.)

From their mode of development, it is evident that the spermatozoa necessarily lie in bundles, each bundle being held together by a Sertoli's column (Fig. 3615); at first they lie at the inner end of the column, at a considerable distance from the basal nucleus (Fig. 3615), but as the nuclei (spermatoblasts) lengthen, the heads push their way toward the base of the column (Fig. 3616). Now, as the development of the daughter-cells (spermatocytes) is continually progressing between Sertoli's columns, we obtain in sections the long-known remarkable appearances shown in Fig. 3616, of bundles of spermatozoa alternating with columns of proliferating cells.

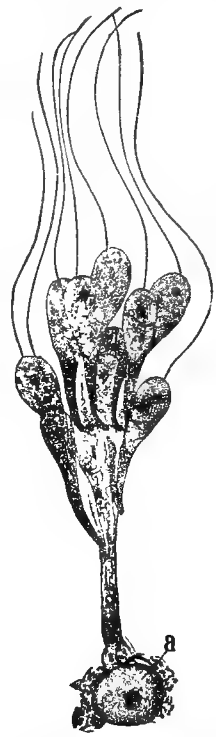

FIG. 3615.—Sertoli's Column, with a Basal Nucleated Nucleus and a Cluster of Developing Spermatoblasts. (After H. H. Brown.)

4. HISTORICAL. — The seminal animalcules were, it is stated, first discovered by Ludwig Hamm, then a student at Leyden, in August, 1677. Loewenhoeck claimed the merit of having made the discovery in November of the same year, and in 1678 Hartsoeker published an account of them, professing to have seen them as early as 1674. They were long considered to be probably parasites, and it was not until Prevost and Dumas's researches that it was definitely ascertained that the "animalcules" were the essential fertilizing element. Thus Richard Owen, in his article on "Entozoa" (1836), in "Todd's Cyclopædia," includes the spermatozoa under that head, although he writes—"it is still undetermined whether they are to be regarded as analogous to the moving filaments of the pollen of plants or as independent organisms" (vol. ii., p. 412). But just after he adds: "Although no distinct organs of generation have been detected, there is reason to suspect that the *spermatozoa* are oviparous; they are also stated to propagate by spontaneous fission, the separation taking place between the disk of the body and the caudal appendage; each of which develop the part required to form a perfect whole."
